Pumas of the Santa Ana Mountains are genetically depauperate, isolated, and display signs of a recent and significant bottleneck. In general, coastal California puma populations have less genetic diversity and less gene flow from other populations than those farther inland [9] (Table 1). This study showed that two coastal populations (Santa Ana Mountains and Santa Monica Mountains) had particularly low genetic variation and gene flow from other regions. Lack of gene flow is likely due in part to natural barriers to puma movement: geography and habitat (Pacific Ocean to the west; less hospitable desert habitat bounding certain regions, etc.). However, our data suggest that anthropogenic developments on the landscape are playing a large role in genetic decay in the Santa Ana Mountains puma population. As large solitary carnivores with sizable habitat requirements, pumas are extremely sensitive to habitat loss and fragmentation [48,49].

The genetic bottleneck in the Santa Ana Mountains pumas is estimated at less than about 80 years, depending on definitions of effective population size ( $N_e$ ) and puma generation time. Luikhart and Cornuet [37] state that the bottleneck signatures decay after "4 times  $N_e$  [here estimated to be 5.1] generations". Logan and Sweaner [50] estimated generation time for their New Mexico population of pumas to be 29 months (2.4 years) for females. If an allowance of 2.4–4.0 years is made for generation times (unknown) in the Santa Ana Mountains population, the maximum estimated time since a bottleneck would be about 40–80 years. This was a period of tremendous urban development and multi-lane highway construction in southern California, particularly I-15 [51]. It is likely that the potential for connectivity between the Santa Ana Mountains and the Peninsular Range-East region will continue to be eroded by ongoing increases in traffic volumes on I-15, and

conversion of unconserved lands along the I-15 corridor by development and agriculture [8,48,52].

An isolated population of pumas in the Santa Monica Mountains to the north of the Santa Ana Mountains also exhibit low values relative to other western North American populations (see Table 2 in [53]). Santa Monica pumas are isolated by urbanization of a megacity and busy wide freeways (Ventura county, including greater Los Angeles region [53]). Multiple instances of intraspecific predation, multiple consanguineous matings (father to daughter, etc.), and lack of successful dispersal highlight a suite of anthropogenic processes also occurring in the Santa Ana Mountains. Our collective findings of kinked tails *and* very low genetic diversity in Santa Ana pumas F95 and M96 may portend manifestations of genetic inbreeding depression similar to those seen in Florida panthers [54,55]; however recognizing that kinked tails can have non-genetic etiologies.

Our analyses suggest that the Santa Ana Mountains puma population is highly challenged in terms of genetic connectivity and genetic diversity, a result hinted at in Ernest et al. [9] and now confirmed to be an ongoing negative process for this population. This compounds the demographic challenges of low survival rates and scant evidence of physical connectivity to the Peninsular Ranges east of I-15 (unpublished data). Beier [6] documented these same challenges during the 1990's, and data from the ongoing UCD study suggest the trends have accelerated. Substantial habitat loss and fragmentation has occurred and is continuing to occur; Burdett et al. [10] estimated that by 2030, approximately 17% of puma habitat that was still available in 1970 in southern California will have been lost to development, and fragmentation will have rendered the remainder more hazardous for pumas to utilize. Riley et al [53] document a natural "genetic rescue" event: the 2009 immigration and subsequent breeding success of a single male to the Santa Monica Mountains. This introduction of new genetic material into the population was paramount to raising the critically low level of genetic diversity, as also exemplified by the human-mediated genetic augmentation of Florida Panthers with Texas puma stock [56].

## Abstract

Anticoagulant rodenticide (AR) poisoning has emerged as a significant concern for conservation and management of non-target wildlife. The purpose for these toxicants is to suppress pest populations in agricultural or urban settings. The potential of direct and indirect exposures and illicit use of ARs on public and community forest lands have recently raised concern for fishers (*Martes pennanti*), a candidate for listing under the federal Endangered Species Act in the Pacific states. In an investigation of threats to fisher population persistence in the two isolated California populations, we investigate the magnitude of this previously undocumented threat to fishers, we tested 58 carcasses for the presence and quantification of ARs, conducted spatial analysis of exposed fishers in an effort to identify potential point sources of AR, and identified fishers that died directly due to AR poisoning. We found 46 of 58 (79%) fishers exposed to an AR with 96% of those individuals having been exposed to one or more second-generation AR compounds. No spatial clustering of AR exposure was detected and the spatial distribution of exposure suggests that AR contamination is widespread within the fisher's range in California, which encompasses mostly public forest and park lands. Additionally, we diagnosed four fisher deaths, including a lactating female, that were directly attributed to AR toxicosis and documented the first neonatal or milk transfer of an AR to an altricial fisher kit. These ARs, which some are acutely toxic, pose both a direct mortality or fitness risk to fishers, and a significant indirect risk to these isolated populations. Future research should be directed towards investigating risks to prey populations fishers are dependent on, exposure in other rare forest carnivores, and potential AR point sources such as illegal marijuana cultivation in the range of fishers on California public lands.

## Introduction

Anticoagulant rodenticide (AR) exposure and poisoning has emerged as a conservation concern for non-target wildlife [1,2,3]. These toxicants are used to eradicate or suppress rodent pest populations in agricultural or urban settings to minimize economic losses [1,4]. Generally, the mechanism of AR function is to bind and inhibit enzyme complexes responsible for the recycling of vitamin K<sub>1</sub>, thus creating a series of deleterious clotting and coagulation impairments [4,5]. The ARs are grouped into two classes: first-generation compounds, which require several doses to cause intoxication, and second-generation ARs, which are more acutely toxic often requiring only a single dose to cause intoxication and persist in tissues and in the environment [1,4,6,7]. Rodents have started to develop resistance to both first-generation and second-generation ARs, prompting increas-

ingly greater reliance on more acutely toxic compounds and increased distribution by AR users [1,7,8].

Primary exposure by ingestion of bait or secondary exposure through consumption of exposed prey has been documented in numerous species of endangered and common non-target wildlife [1,3,9,10,11,12,13]. Wildlife are thought to be at greatest risk of exposure to ARs in agricultural, urban or peri-urban settings, where large quantities of these compounds are often used [12,14,15]. However, little is known about the risks to wildlife in settings with little or no anthropogenic influences.

Fishers (*Martes pennanti*), a large mustelid and the largest member in the genus *Martes*, were once widely distributed throughout west coast of North America, but have experienced significant population declines, including extirpation from some regions and contractions of historic ranges [16,17,18]. Populations of fishers inhabiting California, Oregon and Washington have been

**Figure 1. Fisher (*Martes pennanti*) current range in California and project areas.** Current range (shaded areas) of the two isolated California populations of fishers (*Martes pennanti*). Areas of fisher projects that generated data for exposure and mortality to anticoagulant rodenticides are outlined within the two isolated populations.  
doi:10.1371/journal.pone.0040163.g001

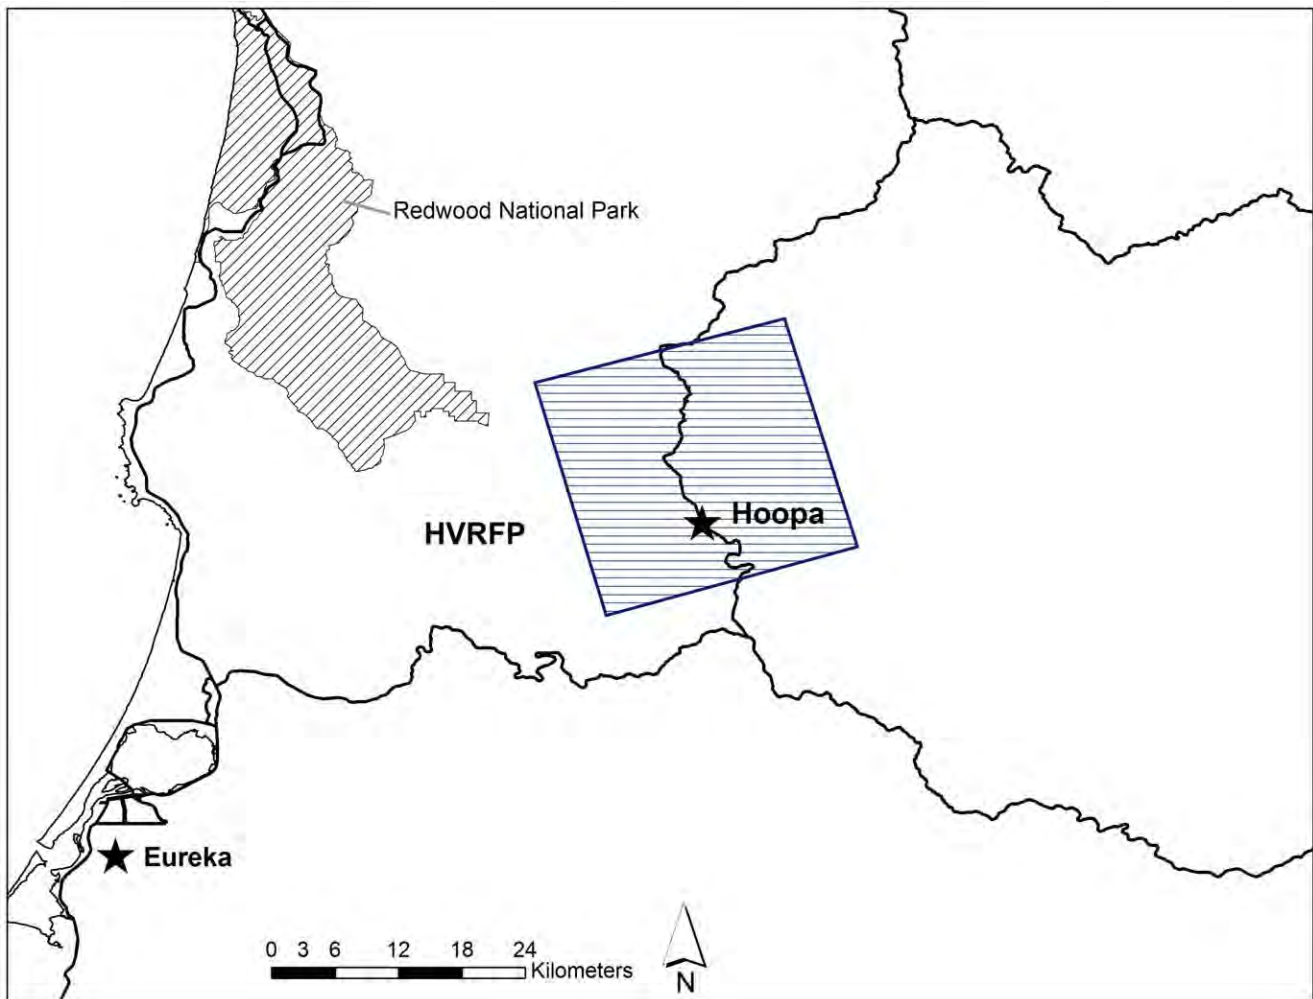

designated as a Distinct Population Segment (DPS) and declared a candidate species for listing under the federal Endangered Species Act [17,19]. The west coast DPS encompasses areas where fishers were extirpated from Washington and central and northern Oregon, a reintroduced population in the Cascade mountains of southern Oregon, and two extant and isolated populations, one spanning southern Oregon and northern California and another in the southern Sierra Nevada mountains of California [17,19]. The population status of fishers in the southern Oregon/northern California is unknown; however population estimates for the isolated fisher population in the southern Sierra Nevada range from 150–300 fishers, with 120–250 in the adult age class [17,20,21]. Because fishers in the DPS occur in and are dependent on mid to late-seral stage coniferous and hardwood forests and are not associated with agricultural or urban settings, toxicants have not been previously considered a likely threat to fisher populations [17,22,23].

We assessed the magnitude of AR exposure and poisoning among fisher carcasses submitted for necropsy from 2006 to 2011 as part of a collaborative effort studying threats to population persistence of fishers in California. Additionally, spatial analysis of telemetry data from sampled fishers was conducted in an effort to identify potential sources of AR in the environment. We hypothesized that due to fishers being a forest-dependent carnivore, exposure to ARs will be rare.

## Methods

### Ethics Statement

All procedures involving animals were reviewed and approved by the University of California, Davis, Animal Care and Use Committee (Protocol No. 16551).

**Figure 2. Enlarged map of fisher (*Martes pennanti*) project area for the northern California population at the Hoopa Valley Reservation Fisher project (HVRFP).**

doi:10.1371/journal.pone.0040163.g002

### Study Area

Fishers were captured in box traps modified with a plywood cubby box (model 207, Tomahawk Live Trap Company, Tomahawk, Wisconsin, USA), sampled, and fitted with a VHF radio-collar and monitored via telemetry. Fisher carcasses were submitted from the two isolated California populations by three fisher monitoring projects (Figure 1). Carcasses from the northern California population were submitted by the Hoopa Valley Reservation Fisher Project (HVRFP), conducted in northwestern California within tribal, private and public lands, and non-monitored fishers on public and private lands throughout the northern Sierra Nevada/southern Cascade Mountain borderlands of north central California (Figure 2). Carcasses from the southern Sierra Nevada California population were submitted by the Sierra Nevada Adaptive Management Project (SNAMP) and the USDA Forest Service Kings River Fisher Project (KRFP); both projects were conducted on the Sierra National Forest in the northern and central portions of this population's extent (Figure 3).

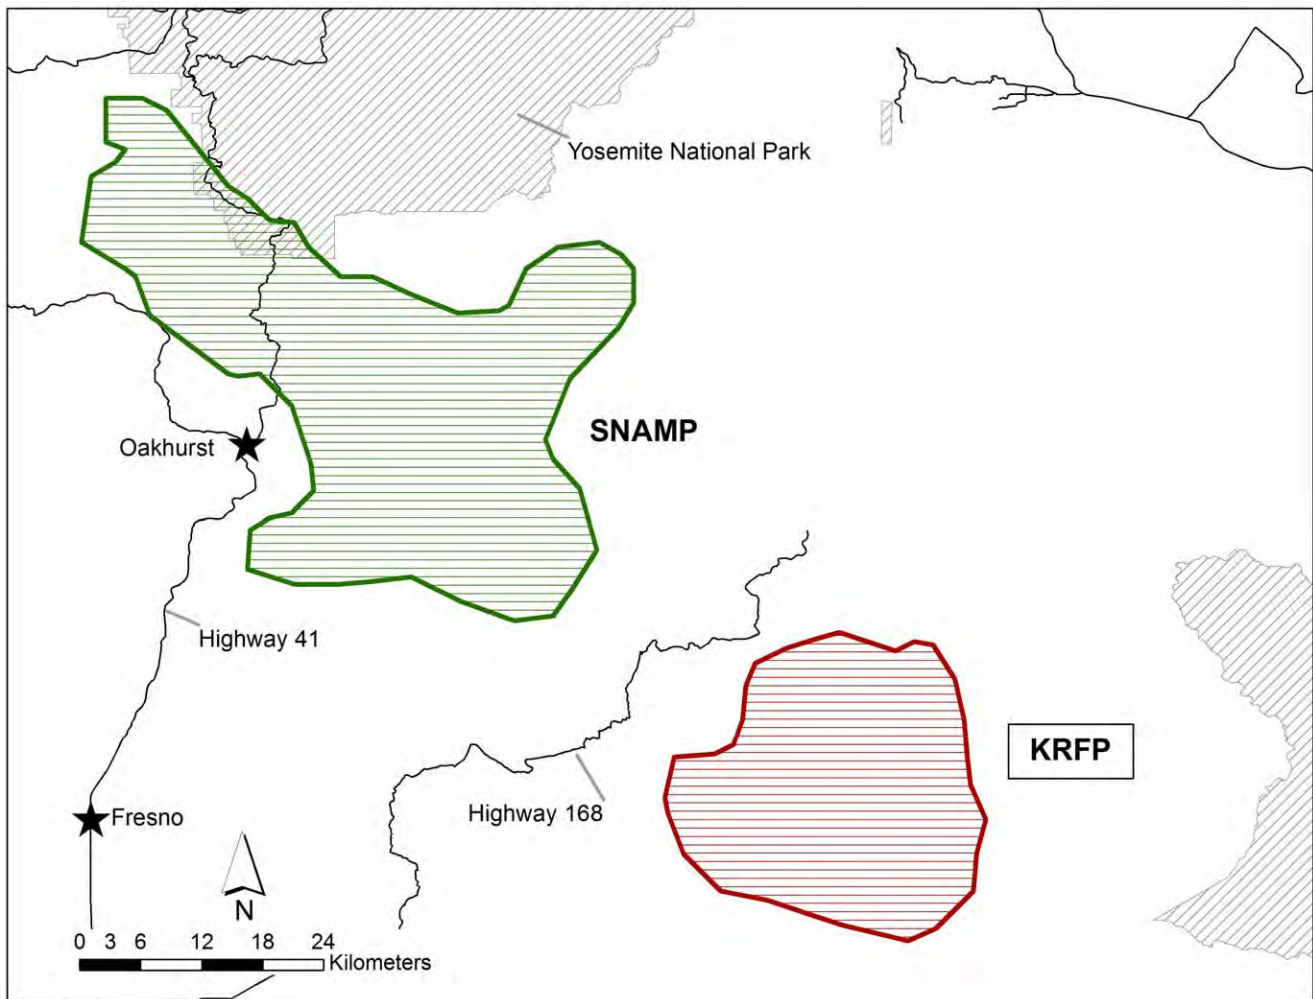

### Sample Collection

Deceased fishers were collected by project personnel whenever a fisher was determined to be inactive for >24 hours, a mortality signal from the VHF collar was detected or when unmarked fisher

carcasses were opportunistically observed at the project sites or adjacent areas. Fisher carcasses were stored in a  $-20^{\circ}\text{C}$  freezer until a complete necropsy to determine causes of mortality was performed by a board-certified pathologist specializing in wildlife at the California Animal Health and Food Safety Laboratory System (CAHFS) or the University of California Davis Veterinary Medical Teaching Hospital in Davis, CA, USA. Liver samples were collected during necropsy and submitted for screening and quantification of seven ARs at CAHFS by liquid chromatography-tandem mass spectrometry for screening presence of ARs and high-performance liquid chromatography to quantitate positive samples. The AR compounds tested for included first-generation ARs, warfarin (WAF), diphacinone (DIP), chlorophacinone (CHL), and coumachlor (COM); and second-generation ARs, brodifacoum (BRD), bromodiolone (BRM), and difethialone (DIF). The reporting limits were 0.01 ppm for BRD, 0.05 for WAF, BRM, and COM, and 0.25 ppm for DIP, CHL, and DIF. Detectable compound concentrations that were below quantitate limits were labeled as "trace" concentrations. All results were reported on a tissue wet weight basis and reviewed by a board-certified toxicologist [12,24].

Age classification was determined by tooth wear, sagittal crest or testicular/teat development, field and laboratory observation, and

**Figure 3. Enlarged map of fisher (*Martes pennanti*) project areas for the southern Sierra Nevada population: the Sierra Nevada Adaptive Management Project (SNAMP) and Kings River Fisher Project (KRFP).**

doi:10.1371/journal.pone.0040163.g003

monitoring of individual animals [17,18,25]. Fishers were classified as kits when fully or semi-altricial and dependent on milk for nourishment (roughly  $\leq 10$  weeks), juveniles if weaned and  $< 12$  months of age, sub-adults when between 13–24 months of age, and adults  $\geq 24$  months of age [17,18,25].

### Statistical Analysis

Prevalence of AR exposure among fishers was calculated for the total sample, each sex and each age class. We compared the AR exposure prevalence between sexes within and between the two California populations using two-tailed heterogeneity chi-square tests of association [26]. The effects of sex and population on the number of anticoagulant rodenticides found per individual were analyzed with a two-way ANOVA [27]. All tests were conducted using the program NCSS (Number Cruncher Statistical Software, Kaysville, UT, USA) with an alpha level  $p = 0.05$ .

### Spatial Analysis

For monitored fishers, telemetry locations were used to generate 95% minimum convex polygon (MCP) home-range centroids to represent a centralized point within the core area of movement within each individual fisher home-range within each project area [28]. For each fisher, three centroids representing three sampling

timeframes were calculated using ArcView 9.1 home range extensions (ESRI Inc., Redlands CA., USA) [29]. The first centroid incorporated all fisher locations from initial capture until death, irrespective of the monitoring time; the second centroid incorporated fisher locations collected six months prior to death; and the third centroid incorporated only the fisher locations collected three months prior to death. These two latter centroids containing locations collected over a shorter time period prior to death were calculated because some ARs have relatively short half-lives and any spatial clustering in these MCP centroids might suggest the locale of recent sources of AR exposure. Only fishers with  $\geq 3$  months of monitoring were used for spatial analysis, individuals that had less than or were opportunistically collected were excluded.

Centroids were analyzed by spatial scan statistics to determine whether exposure to ARs, exposure to different generation classes (1<sup>st</sup> and 2<sup>nd</sup>) of ARs, or exposure to individual compounds of ARs were distributed uniformly or spatially clustered in each of the two California populations [30]. SaTScan version 9.1.1 (M. Kulldorff, Harvard Medical School, Boston, MA, USA) was used to evaluate two separate models. First, a Bernoulli model utilizing count data was used to determine if spatial clustering occurred in exposed and non-exposed fishers, or in first or second-generation class AR

**Table 1.** Exposure and mortality due to anticoagulant rodenticides (AR) fishers (*Martes pennanti*) within the two isolated populations, northern California and southern Sierra Nevada.

Fisher population	Number of fishers tested (F:M)	Number of AR exposed fishers (F:M)	Number of AR mortalities	$\bar{x}$ , SD and range in all, female (F) and male (M) exposed fishers	Chi-square	Probability Level	DF
Northern California	18 (11:7)	13 (72%) (8:5)	2	1.38 (SD = 0.84; range 1–3) (F) 1.13 (SD = 0.35; range 1–3) (M) 1.8 (SD = 0.84; range 1–3)	0.004	0.952	1
Sierra Nevada	40 (18:22)	33 (83%) (16:17)	2	1.70 (SD = 0.88; range 1–4) (F) 1.47 (SD = 0.87; range 1–4) (M) 2.00 (SD = 0.85; range 1–4)	0.925	0.336	1
All California	58 (31:27)	46 (79%) (26:20)	4	1.61 (SD = 0.83; range 1–4) (F) 1.33 (SD = 0.73; range 1–4) (M) 2.00 (SD = 0.82; range 1–4)	0.844	0.358	1
Heterogeneity chi-square					0.085	0.77	1

Mean number ( $\bar{x}$ ) of AR compounds detected per individual, range of numbers of AR per individual and standard deviation (SD) are given for all, female (F) and male (M) fishers for each population. Chi-square and heterogeneity Chi-square test analyzing exposure between the sexes both within and between the populations. doi:10.1371/journal.pone.0040163.t001

exposure. The second model, a multinomial model using categorical data, was used to assign each fisher to a group based on the number of AR compounds detected and to examine possible clustering of individuals with high numbers of AR compounds [31]. SatScan uses these models to scan the geographic area encompassing the MCP centroids to detect spatial clusters encompassing not more than 50% of the centroids [32]. The elliptical scanning window option was chosen for both models because it utilizes both circular and elliptical shapes to allow for a better fit to linear geographic features (i.e. drainages or ridgelines) that occur within the fisher's habitat [32,33]. All statistical values from the models were generated by Monte Carlo simulations of 999 iterations and clusters evaluated for significance with  $\alpha = 0.05$ .

## Results

### Population-level Exposure to AR

Forty-six of the 58 fisher carcasses tested (79%) were exposed to one or more compound of AR (Table 1). Frequency of exposure ( $p > 0.05$ ) and the number of ARs per fisher ( $p > 0.05$ ) were similar between populations and sexes (Table S1). The number of AR compounds detected per individual ranged from 1–4 (Table 1). Exposure to at least one AR among age classes ranged with one of 4 pre-weaned kits (25%), 4 of 4 (100%) juveniles, 12 of 17 (70%) sub-adults, and 29 of 33 (88%) adults. Both first and second generation ARs were detected, with BRD being most common and detected in 44 of the 46 (96%) exposed fishers, followed by BRM (16 of 46; 35%), DIP (8 of 46; 17%), CHL (four of 46; 9%), DIF (one of 46; 2%), and WAF (one of 46; 2%). Quantifiable levels of BRD ( $\bar{x} = 0.22$  ppm; range trace –3.4 ppm) and BRM ( $\bar{x} = 0.12$  ppm; range trace –0.54 ppm) were detected while only trace levels of other ARs were detected (Figure 4). No samples had detectable levels of COM and no indicator dye or AR bait was detected in either stomach or the GI contents of any fisher.

### Northern California Fishers

Thirteen of 18 (72%) fishers from the northern California population were exposed to an AR compound (Table 1). Brodifacoum was detected in 12 (92%), BRM in two (15%), DIP in two (15%), CHL in one (8%), and WAF in one (8%) of the 13 exposed individuals.

### Sierra Nevada Fishers

Thirty-three of 40 (83%) fishers from the southern Sierra Nevada were exposed to an AR compound (Table 1). Brodifacoum was detected in 32 (97%), BRM in 14 (42%), DIP in six (18%), CHL in three (9%), and DIF in one (3%) of the 33 exposed individuals.

### Spatial Distribution of AR Exposure

Complete centroids were generated for 42 monitored fishers, 12 fishers from the northwestern California population (all 12 from HVRFP) and 30 from the southern Sierra Nevada population (19 from SNAMP, 11 from KRFP). Of these fishers, 3-month MCP centroids were generated for 39 fishers, and 6-month centroids for 27 (Table S2). Spatial analysis for 6-month centroids from the KRFP could not be conducted because all fishers in the data set were AR exposed. Sixteen fishers were excluded from the analysis due to lack of monitoring data. No spatial clustering of AR exposure was detected for any of the temporal periods, specific AR compounds, generation class of AR, or distribution of numbers of ARs per fisher in any of the study areas (Table S2; Figure 5, Figure 6).

**Figure 4. Quantification levels of anticoagulant rodenticides detected in California fishers.** Anticoagulant rodenticides (AR) brodifacoum (BRD), bromodiolone (BRM), difethialone (DIF), chlorophacinone (CHL), diphacinone (DIP), warfarin (WAF) and coumachlor (COM) parts per million (PPM) levels detected in positive fishers (*Martes pennanti*) in California. Blue diamonds represent AR quantification levels (ppm). Red diamonds represent levels in fishers that died due to AR ingestion. doi:10.1371/journal.pone.0040163.g004

### AR-Mortalities

Cause-specific mortality factors for all 58 fishers sampled ranged widely and included predation, infectious and non-infectious disease processes and vehicular strikes (M.W. Gabriel unpublished data). The cause of death for four of these fishers was attributed to lethal toxicosis, indicated by AR exposure with simultaneous coagulopathy and bleeding into tissues or cavities and ruling out any concurrent processes that might cause hemorrhaging [34]. Two of the four fishers killed by ARs were from the southern Sierra Nevada population, and two were from northern California (Table 1) and the case details are described below.

#### Southern Sierra Nevada

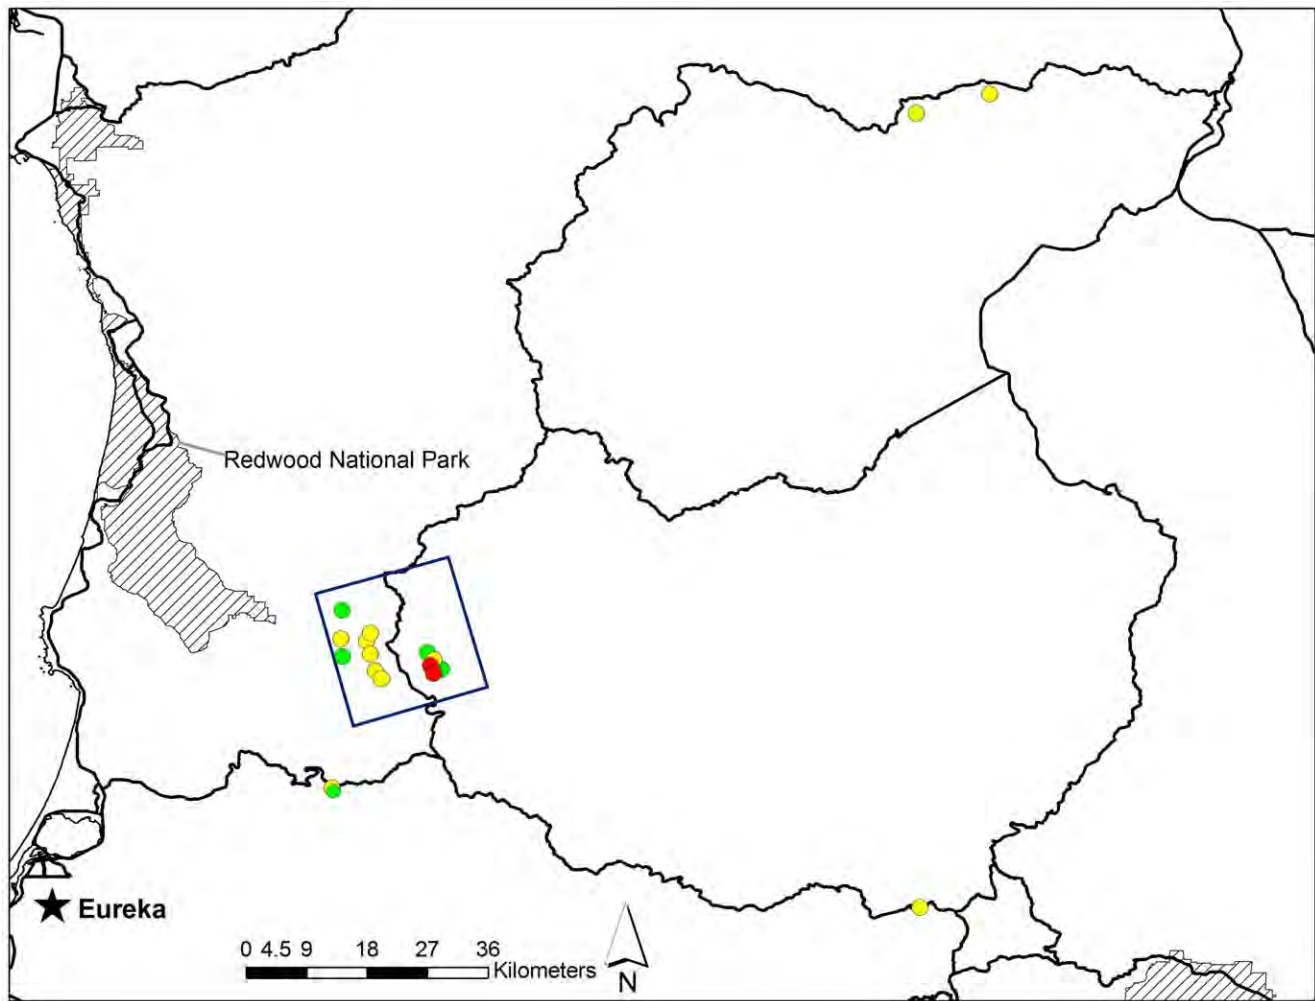

An adult male fisher was recovered on 15 April 2009, in the southern Sierra Nevada at the SNAMP project area. The fisher showed no signs of predation or scavenging (Figure 7). Gross necropsy determined that the fisher was in good nutritional (3.45 kg) and fair postmortem condition. Frank blood was observed in both the thoracic and abdominal cavities (150 ml and 100 ml respectively), and in the pericardial sac (7 ml) (Figure 8). The stomach and lower gastrointestinal tract contained some blood but no prey or formed feces, and no mucosal changes were noted. There were no other findings on gross examination. Histopathologically, no significant changes were observed in any tissues. Brodifacoum and BRM were detected and quantified in the liver sample at 0.38 ppm and 0.11 ppm, respectively, and CHL at trace levels (Figure 4).

The second fisher mortality was a lactating adult female recovered on 2 May 2010 in the center of a paved rural highway in the SNAMP project area approximately 3.7 km from Yosemite

National Park. Vehicular strike was initially suspected as the cause of mortality due to the location of the carcass but lacerations, abrasions and visual evidence of trauma were not seen on gross examination of the intact carcass. The post-mortem state of the carcass was good and the nutritional state was poor (2.54 kg). Shallow subcutaneous hemorrhage was noted over the hindquarters and spinal column with no associated fractures, punctures or abrasions. There was approximately 20 ml of frank blood within the thoracic cavity. There was no evidence of pneumothorax, vessel ruptures, or visceral tearing. No blood or visceral damage was seen in the abdominal cavity. Stomach contents contained various rodent parts with formed feces in the descending colon. Histopathologically, no significant changes were observed in any tissues. Brodifacoum and BRM were detected and quantified at 0.60 ppm and 0.17 ppm, while one first generation AR, DIP was detected at a trace level within the liver tissue (Figure 4). No evidence was present to suggest that this fisher died due to vehicular trauma, despite its location on the highway.

#### Northern California

A sub-adult male fisher was recovered on 4 May 2010 at the base of several riparian shrubs near a watercourse in northwestern California at the HVRFP. Severe ectoparasitism on the carcass was noted in the field with ticks in both replete and non-replete stages. Predation was not suspected due to absence of external wounds. The gross necropsy determined that this fisher (2.65 kg) was in poor nutritional condition with no subcutaneous or visceral fat. Frank blood was present in the right external ear canal, nasal and oral cavities, within the lumen of the trachea and within the periorbital tissue with no associated skull fractures or punctures.

**Figure 5. Exposure to and mortality from anticoagulant rodenticides (AR) in fishers (*Martes pennanti*) from the isolated northern California population.** Green circles represent negative fishers, yellow circles represent exposed fishers, while red circles are fishers that died due to AR toxicosis.

doi:10.1371/journal.pone.0040163.g005

The stomach was devoid of prey. The colon only contained semi-formed feces. Ectoparasitism was severe with approximately 48 female and 10 male American dog ticks (*Dermacentor variabilis*) and 8 female and 2 male western black-legged ticks (*Ixodes pacificus*) removed from various regions of the fisher. The liver sample from this fisher had quantifiable levels of BRD at 0.04 ppm as well as a trace level of CHL (Figure 4).

The second northern California fisher AR death, was an adult male recovered on 26 May 2010 at the HVRFP. Field observations included no evidence of predation or scavenging. The nutritional state as well as the postmortem condition were poor. Gross necropsy determined that the fisher (2.89 kg) had no body fat present in any of the tissues. Frank blood was present in both thoracic and abdominal cavities. The stomach contained red and black fluid but no prey. Ectoparasitism was severe with 204 female and 27 male adult American dog ticks in both replete and non-replete stages on areas of the muzzle, chest, tops of fore-and hind-limbs as well as inguinal sections. Severe nematodiasis was seen in skeletal muscle throughout the body (trichinosis). Pulmonary nematodiasis (lungworm) was also noted in the marginal portions of the lungs. Histopathologically, no notable disease processes were seen but severe parasitism was noted. The

liver sample for this fisher had quantifiable levels of BRD at 0.61 ppm and trace levels of BRM (Figure 4).

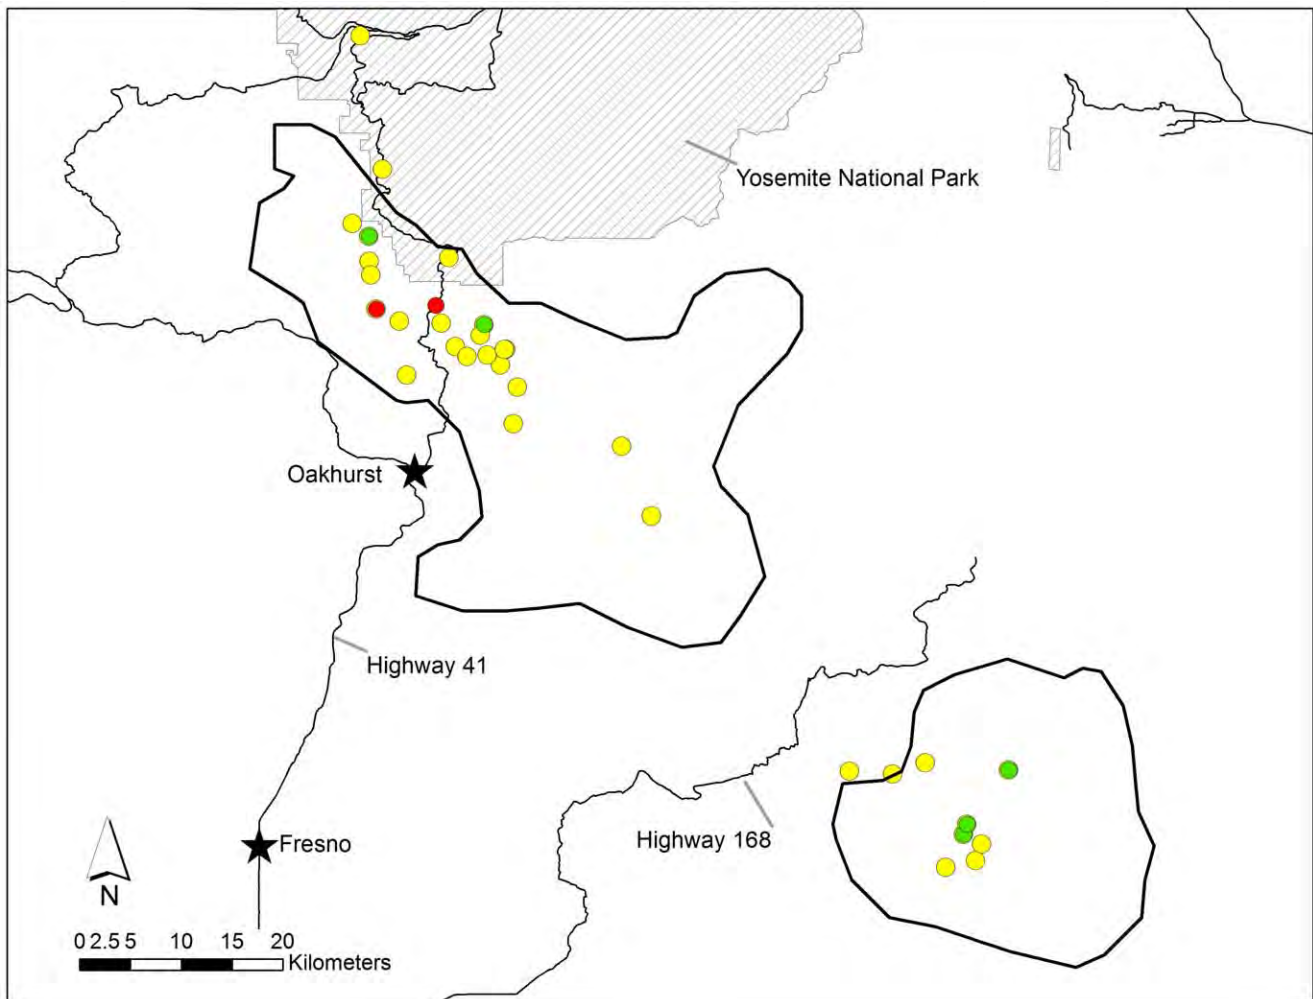

#### Neonatal Transfer of AR

Necropsies and AR testing was performed on four kits who were all still dependent on mother's milk when they died following maternal abandonment from their mothers death. One kit, a female fisher (0.32 kg) from KRFP tested positive for AR exposure. This kit was approximately six weeks of age and was recovered within a monitored maternal den tree shortly after maternal abandonment. Cause of death was determined to be acute starvation and dehydration. The liver tissue contained trace level of BRD but there was no associated hemorrhaging in any tissues, body cavities or lumina, suggesting that this finding was not clinically significant.

#### Discussion

Our findings demonstrate that anticoagulant rodenticides, which were not previously investigated in fishers or other remote forest carnivores, are a cause of mortality and may represent a conservation threat to these isolated California populations. This is

**Figure 6. Exposure to and mortality from anticoagulant rodenticides (AR) in fishers (*Martes pennanti*) from the isolated southern Sierra Nevada population.** Green circles represent negative fishers, yellow circles represent exposed fishers, while red circles are fishers that died due to AR toxicosis.

doi:10.1371/journal.pone.0040163.g006

the first documentation of exposure to ARs and of direct mortality from ARs in fishers anywhere in their geographic range. Earlier studies suggest ARs posed little or no additive mortality effects on non-target populations [7,35,36]. The shortfall of many of these studies was the utilization of common cosmopolitan species so they did not take in consideration that AR mortality may be additive in otherwise compromised populations. The spatially ubiquitous exposure observed within all post-weaning age classes and across the project areas in their contemporary range in California is of significant concern especially considering the recent work of Spencer et al. (2010), who demonstrated that even a small increase in human-caused mortality of 10–20% in the isolated Southern Sierra Nevada fisher population would be enough to prevent population expansion if other restrictive habitat elements were removed.

The high rate of exposure to second generation AR compounds (96% of exposed fishers) in these populations is surprising and cause for concern. This generation of ARs are not only more acutely toxic, but have long retention (>150 days half-life) through biphasic elimination in mammal tissues [1,37]. Second-generation ARs are more toxic because death can occur from a single primary ingestion by a rodent [1,5,37,38].

However, rodents can receive a lethal dose of second-generation ARs in one feeding bout and it can take up to 7 days before clinical signs manifest [1,39]. Therefore, prey that have consumed a “super-lethal” dose of AR can pose a substantial risk to predators for several days prior to death [39]. In one study, a group of Norway rats (*Rattus norvegicus*) was given a choice between BRD bait and untreated food and another group had access only to the BRD bait [1]. Both groups consumed 10 and 20 median lethal doses ( $LD_{50}$ ) on the first day and 40 to 80  $LD_{50}$  doses by day 6.5, respectively [1]. If sources for these toxicants are maintained for even short periods, exposed rodents, the main prey source for fishers in these populations [17] can pose significant threats to their predators.

Many manufactures use “flavorizers” since the AR compound may be bitter and unpalatable to rodent pests [1,39]. Emulsions used to increase palatability include sucrose, bacon, cheese, peanut butter, and apple flavors (Sure-Gro Inc., Brantford, Ontario, Canada and J.T. Eaton, Twinsburg, Ohio, USA), and thus could be palatable to generalist carnivores like fishers. Although we did not visually detect AR bait in the stomach or GI tracts of any fishers that died, primary poisoning cannot be completely ruled out.

**Figure 7. Condition of the undisturbed mortality site in which a fisher (*Martes pennanti*) mortality due to anticoagulant rodenticide from the southern Sierra Nevada population was found.**

doi:10.1371/journal.pone.0040163.g007

#### Sub-lethal AR Exposure

In addition to the risk from lethal toxicosis, sub-lethal AR exposure may compromise fishers through a reduction in the function of normal clotting [5,37,40,41]. The occurrence of AR-exposed wildlife dying from minor wounds that otherwise might have easily resolved themselves if ARs were not present suggests contributory lethal effects [1]. Several cases describe raptors receiving minor defensive lacerations or trauma from

prey that lead to the raptor's death by exsanguination or hemorrhaging [1,42]. Fishers actively pursue a wide array of terrestrial and arboreal prey [17,18]. Hence, it is conceivable that a fisher could receive similar wounds or trauma from prey, or during the pursuit of prey. Consequently, if clotting mechanisms were compromised due to ARs, benign injuries could lead to serious complications [1,42,43,44]. The leading causes of mortality within the USFWS DPS is intraguild

**Figure 8. Thoracic cavity hemorrhaging containing 150 ml of frank blood due to coagulopathy after lethal exposure to anticoagulant rodenticides in a fisher (*Martes pennanti*) from the southern Sierra Nevada population.**  
doi:10.1371/journal.pone.0040163.g008

predation (G.M.Wengert, unpublished data). It is possible that some of these cases, AR exposure could have compromised clotting mechanisms at the predation attempt and this deserves further study.

High levels of tick infestations were noted in two of the AR mortalities when compared to other sympatric species within the same project area [45]. In addition, locations of these replete ticks were in infrequent regions in other captures, most likely due to a lack of regular grooming. Whether ARs played a role by allowing more ticks to obtain a blood meal due to immobilization due to compromised clotting factors is unknown.

Furthermore, sublethal AR exposure may decrease an animal's resilience to environmental stressors. In a study on rabbits and rats subjected to stressors such as severe decreases in ambient temperature (i.e. frostbite), approximately 10% of test animals died; however when animals were exposed to low non-lethal doses of anticoagulants and subjected to the same stressors, mortality rates increased to 40–70% [46]. It is unknown if stressors or injuries from environmental, physiological or even pathogenic factors could predispose fishers to elevated mortality rates when coupled with AR exposure.

#### Neonatal Transfer of AR

The documentation of neonatal or lactational transfer of AR to a dependent fisher kit was unexpected, and the effects of AR exposure to a kit during fetal development or shortly after birth are unstudied. AR exposure in pregnant or whelping domestic

canids varied, causing no clinical signs in some cases [47] but death due to coagulopathy immediately after delivery in other cases [48]. The female fisher who gave birth to this kit did not exhibit clinical signs at pre- or postpartum captures and monitoring of her maternal den site verified that one kit survived from that litter (Rebecca Green, United States Forest Service, personal communication). Nevertheless, clinical signs including hemorrhaging, inappetence and lethargy have been seen in domestic canid puppies of AR-exposed mothers [47,48]. Mild to severe manifestations such as low birth weight, stillbirth or eventually neonatal death has been documented in several cases [47,48,49]. In one human study where pregnant women received low doses of warfarin due to severe risk of thromboembolic events, 33% of them had stillbirths, 28% had abortions, and 11% of the neonates died shortly after birth [50]. The range for congenital anomalies and miscarriages in pregnant females for prescribed doses of warfarin varied from 15 to 56% and long-term neurological symptoms have been reported in children that were exposed in-utero [51]. The fetotoxic effects of AR in pregnant fishers and their fetuses are unknown. In addition, because fishers exhibit delayed implantation of the blastocyst, whether ARs may cause pregnant females to abort or reabsorb the fetus merits further research [52,53,54]. The transfer of first generation ARs from mother to offspring in milk is not well-understood and there are no data on lactational transfer of second-generation ARs [49].

**Figure 9. One of several nine-pound buckets of anticoagulant rodenticide removed from an illegal northern California marijuana operation within the northwestern California fisher (*Martes pennanti*) project boundary.**  
doi:10.1371/journal.pone.0040163.g009

### Quantification Levels

The quantity (ppm) of AR we observed in fisher liver tissues varied and overlapped extensively in both sublethal and lethal cases with no clear indication of a numeric threshold that might indicate an amount leading to morbidity or mortality. This lack of predictive ability has been shown in numerous wildlife cases [1,12,55]. For example, Brodifacoum, the most prominent AR compound detected in fishers in this study ranged considerably in lethal cases among individual mustelid species, with 0.32–1.72 ppm in stoats (*Mustela ermine*) [55,56,57], 0.7 ppm in least weasels (*Mustela nivalis*) [56], 1.47–1.97 in ferrets (*Mustela furo*) [57] and 9.2 ppm in American mink (*Mustela vison*) [3,36]. In addition, there are stark differences for acute LD<sub>50</sub> doses among genera, where minute amounts of brodifacoum bait caused death in domestic canids but domestic felids required doses 5 to 40 times higher [38]. The same variability seen in both mustelids and other carnivores suggests that predicting clinical thresholds for fishers would be pre-mature [1,58]. Furthermore, AR exposed fishers had an average of 1.6 AR types within their systems, and possible interaction effects from a combination of 2 or more AR compounds within a fisher and other species are entirely unknown [1,37].

### Potential Sources of AR

Spatial analyses did not reveal any obvious point sources of AR exposure. Instead, these analyses suggested that exposure is widespread across the landscape. Previous studies expected that exposure to AR compounds would be clustered near areas of human activity or inhabitations and that exposure would not be common outside of these areas [1,12,14,24]. Incongruously, data from this study refuted this hypothesis thus making the finding even more significant. Furthermore, these exposures occurred within a species that is not closely affiliated with urban, peri-urban or agricultural settings in which second-generation ARs typically are [1,12,14,24]. Federal and state regulations for anticoagulant rodenticide usage are specific for both generations. Before the June 2011 Environmental Protection Agency (EPA) regulations [39], second generation class ARs could be purchased at local retailers, with recommendations for placement in weather- and tamper-resistant bait containers no more than 50 feet from any building [39]. However, since June 2011, second generation ARs have not been available to consumers at retail, but only at agricultural stores (farm, tractor or feed stores) with additional form and weight restrictions [39]. These newly passed regulations are aimed at further restriction of irresponsible and illegal use of ARs [39]. However, we would have expected that with either pre- or post-

**Figure 10. Multiple packets of anticoagulant rodenticides found surrounding an illegal marijuana grow site within the southern Sierra Nevada fisher (*Martes pennanti*) project.**  
doi:10.1371/journal.pone.0040163.g010

June 2011 regulations, second generation AR exposed fishers would have overlapped with urban, peri-urban, or agricultural environments. This pattern is acknowledged in several studies, such as Riley et al. (2007) where bobcat (*Lynx rufus*) and mountain lion (*Felis concolor*) total quantification levels of AR exposure were associated with human-developed areas. Numerous studies have documented that secondary poisoning cases are closely associated with recent agricultural or urban pest eradication efforts [1,13,14,24].

The majority of habitat that fishers in California and fishers throughout the DPS currently and historically occupied is not within or near agricultural or urban settings [17]. Several fishers that were exposed had been monitored their entire lives and inhabited public or community lands where human structures are rare or non-existent (M. Higley, R. Sweitzer, C. Thompson unpublished data). Therefore, exposure from first or second-generation AR use at or within 50 feet of residential or agricultural structures and settings were considered unlikely due to fisher habitat requirements and general lack of association with humans. This suggests that wide-spread non-regulated use of second

generation second generation ARs is occurring within the range of fishers in California, especially on public lands.

A likely source of AR exposure to fishers is the emerging spread of illegal marijuana cultivation within California public and private lands [59,60]. In 2008 in California alone, over 3.6 million outdoor marijuana plants were removed from federal and state public lands, including state and national parks, with thousands of pounds of both pesticides and insecticides found at grow sites [59,60,61]. In 2011, a three week eradication operation of marijuana cultivation removed over 630,000 plants and 23,316 kg of trash including 68 kg of pesticides within the Mendocino National Forest in the northern California fisher populations range [17,62]. Anticoagulant rodenticides and pesticides are typically dispersed around young marijuana plants to deter herbivory, [60,62,63] but significant amounts of AR compounds are also placed along plastic irrigation lines used to draw water from in order to deter rodent chewing [60,62,63] (M.W. Gabriel, personal observation). A recent example in which over 2,000 marijuana plants were removed less than 12 km from one of the project areas revealed that plants on the peripheral

**Figure 11. Anticoagulant rodenticide bait pellets (bright green) with plant fertilizer freely dispersed around 2,000 plants from northern California marijuana grow site within the northwestern California fisher (*Martes pennanti*) project boundary.**  
doi:10.1371/journal.pone.0040163.g011

edges as well as nearby irrigation had large amounts of second generation AR placed (Figure 9, Figure 10, Figure 11). Finally, just within a single eradication effort, multiple kilometers (>40 km) of irrigation line within National Parks and Forests in California were removed [60,62]. Placement of ARs at the grow sites and along irrigation lines which jut out great distances from the grow site itself may explain why there are no defined clusters of AR exposure.

It is noteworthy that the AR fisher mortalities we documented occurred in different areas of their California range but within a relatively short seasonal period between mid-April to mid-May. We cannot specify the exact explanation or source contributing to all AR mortalities that occurred within this short temporal period. This period is when females are providing for offspring as well as males searching for mates; however, preliminary spatial data for fishers in California document that females have more confined home-ranges during this period, while males have slightly larger home-ranges (S. Matthews, R. Sweitzer, unpublished data).

Additionally, several books available to the general public identify the optimal time for planting marijuana outdoors is during mid to late spring, and seedlings are especially vulnerable to rodent pests [64,65,66]. Of additional concern is that April to May is the

denning period for female fishers and a time when fisher kits are entirely dependent on their mothers [17,18]. The documentation of a lactating female mortality attributed to AR toxicosis during this period suggests that most likely kits would be abandoned and die from female mortalities during this time.

In conclusion, this study has demonstrated that fishers in the western DPS, which are of conservation concern and a candidate for protection under the Endangered Species Act, are not only being exposed to ARs, but ARs are a direct cause of mortality and indirect mortality (i.e. kit abandonment) in both of California's isolated populations. Consequently, these toxicants may not only pose a mortality risk to fishers but could also pose significant indirect risks by depleting rodent prey populations upon which fishers depend. The lack of spatial clustering of exposed individuals suggests that AR contamination is widespread within this species' range and illegal or irresponsible use of ARs continues despite recent regulatory changes regarding their use. Because we do not know the long-term ecological ramifications of these toxicants left on site long after marijuana grows are dismantled, heightened efforts should be focused on the removal of these toxicants at these and adjacent areas at the time of dismantling. Further regulation restricting the use of ARs to only pest management professionals

as well as continued public outreach through state wide Integrated Pest Management programs may be warranted. In addition, promotion of compounds that do not possess the propensity for secondary poisoning (i.e. zinc phosphide) should be considered in non-professional use settings. Furthermore, ARs in these habitats may pose equally grave risks to other rare and isolated California carnivores such as the Sierra Nevada red fox (*Vulpes vulpes nector*), American marten (*Martes americana*), wolverine (*Gulo gulo*), gray wolf (*Canis lupus*) or raptors such as northern spotted owls (*Strix occidentalis caurina*), California spotted owls (*S.o. occidentalis*) and great gray owls (*Strix nebulosa*). Future research should be directed to investigating potential risks to prey populations as well as other sympatric species that may allow a better understanding of the potential AR sources contributing to these exposure and mortality rates from anticoagulant rodenticides.

## Supporting Information

**Table S1 A two-way ANOVA analyzing the effects of California fisher (*Martes pennanti*) populations and sex on the number of anticoagulant rodenticides found per individual.**

(DOCX)

**Table S2 Results of spatial scan statistics to detect clusters of anticoagulant rodenticide (AR) exposed fishers within each California fisher project.** Number of individual fisher minimum convex polygon (MCP) centroids used for each temporal period, specific AR types, generation class of

AR and distribution of numbers of ARs per fisher (number of AR positive fishers per test in parentheses) are shown. (DOCX)

## Acknowledgments

We would like to acknowledge the contributions of two anonymous reviewers as well as the following people and organizations. University of California at Davis (UCD) Veterinary Medical Teaching Hospital and pathologists Megan Jones and Patricia Gaffney and the (UCD) graduate group of Comparative Pathology, Drs. Jonna Mazet and Richard Brown, the biologists at all the projects sites including Kerry Rennie, Rebecca Green, Tessa Smith, Jim Garner, and countless others. Logistical support was provided by Integral Ecology Research Center, California Animal Health and Food Safety Laboratory System, Hoopa Valley Tribal Forestry, U.C. Berkeley, United States Forest Service, National Park Service, United States Fish and Wildlife Service and the Bureau of Indian Affairs. Most of all we would like to thank the late Dr. Linda Munson for initially taking the fisher health project under her wing. Her mentorship and contributions to wildlife conservation will be remembered and appreciated.

## Abstract

We examined visiting patterns of pollinators of *Betonica officinalis* L. (Lamiaceae) in experimentally fragmented calcareous grasslands and corresponding control plots at two study sites (Movelier and Nenzlingen) in the north-western Swiss Jura mountains. Fragments (1.5 × 1.5 m) were isolated by a 5-m wide strip of frequently mown vegetation while the control plots were situated in the adjacent undisturbed vegetation. The most common pollinator, the bumblebee *Bombus veteranus* (Apidae), visited fragments 53.7% less frequently than control plots. Furthermore, a change in foraging behaviour of *Bombus veteranus* was observed. In fragments the bumblebees visited more inflorescences, flew longer total visiting distances and the visiting time per patch tended to be higher than in control plots. The distribution of angles between arrival and departure direction (turning angles) differed from a uniform distribution in fragments but not in control plots. The increased directionality of bumblebee flight might be due to a decrease in floral rewards. Our results show that small-scale habitat fragmentation can affect plant pollination at two levels both relevant for plant fitness. First, lower visitation rates indicate a limitation of pollinators which might result in reduced seed set of the pollinated plant. Second, changes in pollinator behaviour might reduce pollen dispersal among flowers, increase inbreeding and hence reduce genetic variability in populations of this bumblebee pollinated plant. © 2002 Elsevier Science Ltd. ## 1. Introduction

Nutrient-poor, calcareous grasslands are among the habitats with the highest species richness in western Europe (Zoller, 1954; Ellenberg, 1982; Willems, 1982). However, industrialisation and changes in agricultural land use since the 1950s caused a dramatic decline of this once common type of grassland, and the remaining remnants are often small, fragmented and isolated (e.g. Willems, 1982; Zoller et al., 1986; Fischer and Stöcklin, 1997). Fragmentation of these natural habitats has especially negative biological consequences for ecosystem functions (Saunders et al., 1991; Kearns et al., 1998), such as plant–pollinator interactions, the subject of the present study.

The ecological importance of pollinators in their communities is crucial (Kearns et al., 1998). The entire structure of biotic communities will be dramatically changed when keystone plant species lose their pollinators. A

cascade of changes including a decline in biodiversity may follow (Allen-Wardell et al., 1998; Kearns et al., 1998). Habitat fragmentation can affect pollinator behaviour, population size of animals and plants, and even pollinator morphology (Phillips, 1997; Berwaerts et al., 1998; Thomas et al., 1998; VanDyck and Matthysen, 1999). These changes might in turn influence community structure, population dynamics, trophic levels and genetic diversity in natural ecosystems. Plants experience lower fitness if pollinators are missing or reduced in numbers (e.g. Jennersten, 1988; Pavlik et al., 1993; Fischer and Matthies, 1997; Robertson et al., 1999). Furthermore, habitat fragmentation can change the spatial distribution of plants, which in turn changes foraging patterns of pollinators (Cresswell, 1997). If the distance between plants to be pollinated is too large, pollination is limited (Schmitt, 1983; Klinkhamer et al., 1989) and plant fitness may be reduced due to inbreeding and/or outbreeding depression caused by increased genetic drift (Waser and Price, 1983; Van Teuren et al., 1991; Holsinger, 1993; Percy and Cronk, 1997; Gigord et al., 1999). Thus, a change in pollinator behaviour might strongly affect plant reproductive success and plant fitness.

There is empirical evidence that habitat fragmentation can influence pollinator populations directly or indirectly, and may cause declines of pollinators (Allen-Wardell et al., 1998). However, little attention has been given to the effect of fragmentation on pollinator behaviour. The aim of this study was to investigate under natural conditions the influence of experimental small-scale fragmentation on the pollinator behaviour of *Bombus veteranus* (Apidae), the most common pollinator of *Betonica officinalis* L. (Lamiaceae), a typical perennial forb in calcareous grasslands of the Swiss Jura mountains.

## 2. Methods

### 2.1. Fragmentation experiment and sampling

The study was carried out from 22 July to 7 August 1998 in the experimental habitat fragmentation study site of the University of Basel in the Swiss Jura mountains (Baur and Erhardt, 1995; Baur et al., 1996). The original design, established in spring 1993, consists of three field sites with a total of 12 blocks (Fig. 1) on nutrient-poor, dry calcareous grasslands belonging to the Teucro-Mesobrometum type (Ellenberg, 1988). In the present study the medium-sized fragments (1.5×1.5 m) and control plots of equal size from six blocks at two sites were used (three blocks at Movelier and three blocks at Nenzlingen). These field sites are situated near Nenzlingen (10 km south of Basel) and near Movelier (5 km north of Delémont).

In each block, fragments were separated by a 5-m wide strip of frequently mown vegetation (6–12 times per year). Corresponding control plots of equal size were mirror-symmetrically arranged and surrounded by undisturbed vegetation (Fig. 1). Because the original control plots varied largely in occurrence of *Betonica officinalis*, we placed control plots in the undisturbed vegetation so as to contain approximately the same number of *Betonica officinalis* inflorescences as in the fragments. Thus, in the surroundings of the control plots numerous other *Betonica officinalis* inflorescences were present, whereas those in the fragments were separated by at least 5 m from other *Betonica officinalis* inflorescences.

In each patch (fragment or control plot) all *Betonica officinalis* inflorescences and open flowers were counted. The positions of all flowering *Betonica officinalis* inflorescences were mapped in 36 cells measuring 25×25 cm. Pollinators were observed in each patch for 20 min on three separate days. We recorded the visitation pattern of every flower visitor entering the plot during the survey. We measured for each insect the visiting distances between successively visited inflorescences, the total flying distance in the patch and the turning angles. Flower visitors that were already in the patch at the beginning

Fig. 1. Experimental layout for one of 12 experimental blocks of 29×32 m established in spring 1993. Each unit contained one large (4.5×4.5 m), one medium (1.5×1.5 m) and two small fragments (0.5×0.5 m), all of them separated by a 5-m wide strip of mown vegetation (white area), as well as the corresponding control plots, which were mirror-symmetrically arranged and surrounded by undisturbed vegetation (grey area).

of the survey were not considered. Additionally, the duration of the visit in the plot of each flower visitor was assessed using a DAT-recorder. Observations were performed between 10:00 and 16:00 in sunny and warm weather. To avoid any time effect the order of surveys in fragments and their control plots were randomised on each observation day. Fragments and control plots of each site were surveyed on three different days (Nenzlingen on 22 and 30 July and on 8 August 1998, Movelier on 24 July and on 6 and 7 August 1998).

The distance between nesting sites of *Bombus veteranus*, the most frequent visitor, and the experimental patches could potentially have affected our observations. However, the fact that bumblebees can forage several hundred metres away from their nesting sites (Osborne et al., 1999), and the design of our experiment (random distribution of fragments and control plots) suggest that positions of nesting sites do not affect the results of the present study.

### 2.2. Data analyses

To compare the number of visits between fragments and control plots a chi-square goodness of fit test with a hypothesised ratio of 1:1 was used for each site (Zar, 1999). We used pooled data from the three survey days for each fragment and control plot.

To prevent spatial pseudoreplication, data from visiting patterns were averaged per fragment or control plot, respectively, for each survey day. To prevent temporal pseudoreplication we used the average of the three survey days per site, thus, resulting in 12 independent replications (six fragments and six control plots). Three-way analyses of variance (ANOVA, type III model, using JMP 3.1, SAS, 1995) with the fixed factors site and treatment and the random factor block nested by site were used to examine effects on the following parameters (patches refer to fragments or control plots):

Percent of visited inflorescences

$$= \frac{\text{Mean of visited inflorescences per bumblebee}}{\text{Total number of inflorescences in patch}}$$

Visiting time per patch related to inflorescence number (= “Visiting time per patch”)

$$= \frac{\text{Mean time spent in patch per bumblebee}}{\text{Total number of inflorescences in patch}}$$

Ratio of mean visiting distances

$$= \frac{\text{Mean distance flown between two successively visited inflorescences}}{\text{Mean nearest neighbour distance between inflorescences}}$$

Ratio of total visiting distances

$$= \frac{\text{Total distances between visited inflorescences in patch per bumblebee}}{\text{Total nearest neighbour distances between inflorescences in patch}}$$

As a measure of the pollinators’ flight directionality, turning angles between the arrival and departure directions were assessed from visiting patterns of single bumblebees. For data analysis angles were assigned to 18 classes each of 20°. The distributions of angles recorded in fragments and those from the control plots were compared with a uniform distribution using chi-square goodness of fit test (Zar, 1999). Furthermore, a 2×18 contingency table (G-test) was used to compare the distribution of angles in fragments with those in control plots (Zar, 1999).

### 3. Results

The number of inflorescences per patch as well as the number of open flowers were not affected by the

experimental fragmentation but differed between sites (Table 1). Furthermore, the number of open flowers per inflorescence did not differ between sites ( $F_{1,4}=0.44$ , n.s.) or treatments ( $F_{1,5}=0.17$ , n.s.).

In total, the visiting pattern of 314 flower visitors was recorded. Among them, 218 belonged to the most common species, *Bombus veteranus*. The remaining flower visitors were other Hymenoptera (34), *Zygaena* spp. (42), other Lepidoptera (12) and Diptera (eight). Individuals of *Bombus veteranus* visited the fragments less frequently (69 individuals) than the control plots (149 individuals; Fig. 2) which means 53.7% fewer visits in the fragments.

Fragmentation significantly influenced the behaviour of the pollinator *Bombus veteranus* (Fig. 3). The percentage of visited inflorescences and the ratio of total visiting distances was significantly higher in fragments than in control plots (Fig. 3A,D). Thus, flying longer distances and especially visiting more inflorescences within a fragment indicate more near-neighbour pollination, which may result in increased inbreeding in pollinated plants in the fragments. Furthermore, the “visiting time per patch” tended to be longer in fragments than in control plots (Fig. 3B), while the ratio of mean visiting distances did not differ between fragments and control plots (Fig. 3C). A significant site effect on

Fig. 2. Percentage of visits of *Bombus veteranus* in fragments (open bars) and corresponding control plots (black bars) at the two different sites, separated per day (D1, D2, D3 = first, second and third observation day, respectively). The numbers above the bar indicate the total number of observed bumblebees at this day. The difference between fragments and control plots was significant for both sites (Movelier:  $\chi^2=4.48$ , d.f. = 1,  $P=0.034$ ; Nenzlingen:  $\chi^2=28.00$ , d.f. = 1,  $P<0.001$ ).

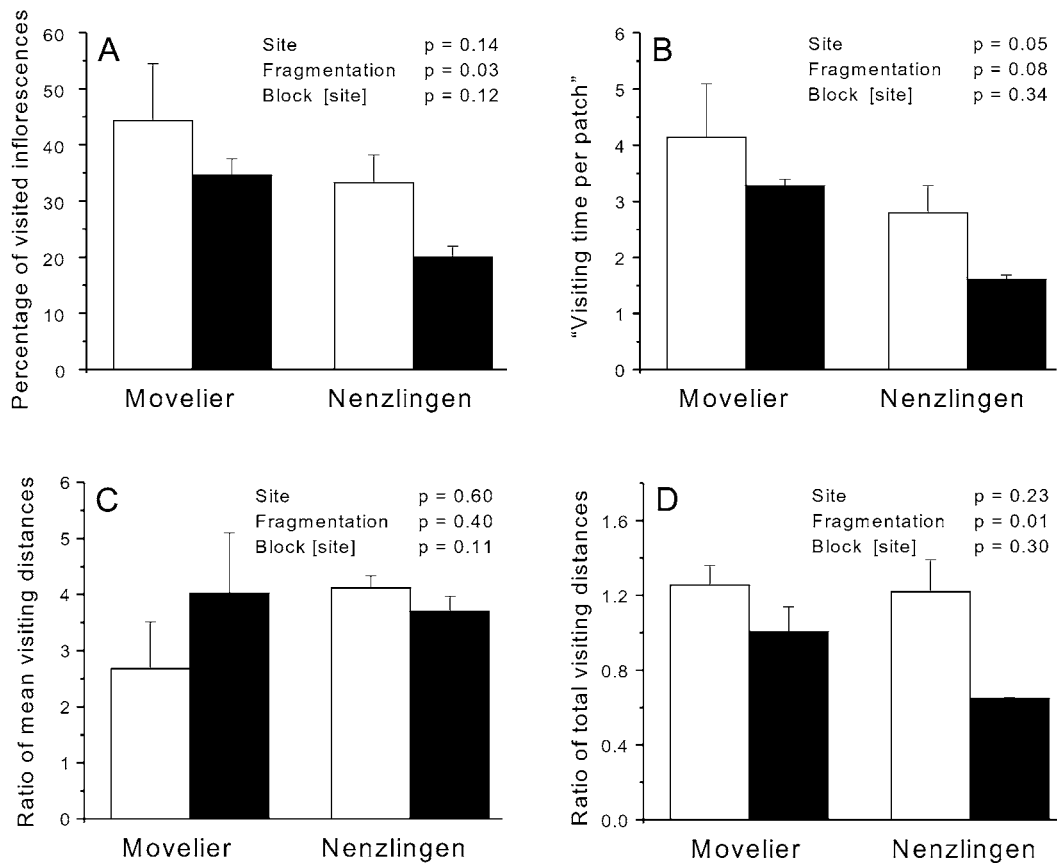

Fig. 3. Effect of habitat fragmentation on the behaviour of the pollinator *Bombus veteranus* visiting *Betonica officinalis* (mean $\pm$ 1 S.E.; open bars = fragments, black bar = control plots) at the sites Movelier and Nenzlingen. (A) percentage of visited inflorescences, (B) visiting time per patch related to inflorescence number ("visiting time per patch"), (C) ratio of mean visiting distances, and (D) ratio of total visiting distances.

the behaviour of *Bombus veteranus* was only found in "visiting time per patch" (Fig. 3B).

The distribution of turning angles of foraging *Bombus veteranus* differed significantly from a uniform distribution in fragments (Fig. 4,  $\chi^2 = 48.28$ , d.f. = 17,  $P < 0.001$ ), but not in the control plots (Fig. 4,

$\chi^2 = 23.79$ , d.f. = 17,  $P = 0.12$ ). There is thus a stronger tendency towards directionality in fragments than in control plots. However, a direct comparison of the distributions of turning angles in fragments and control plots revealed no significant difference ( $G = 14.14$ , d.f. = 17,  $P = 0.66$ ).

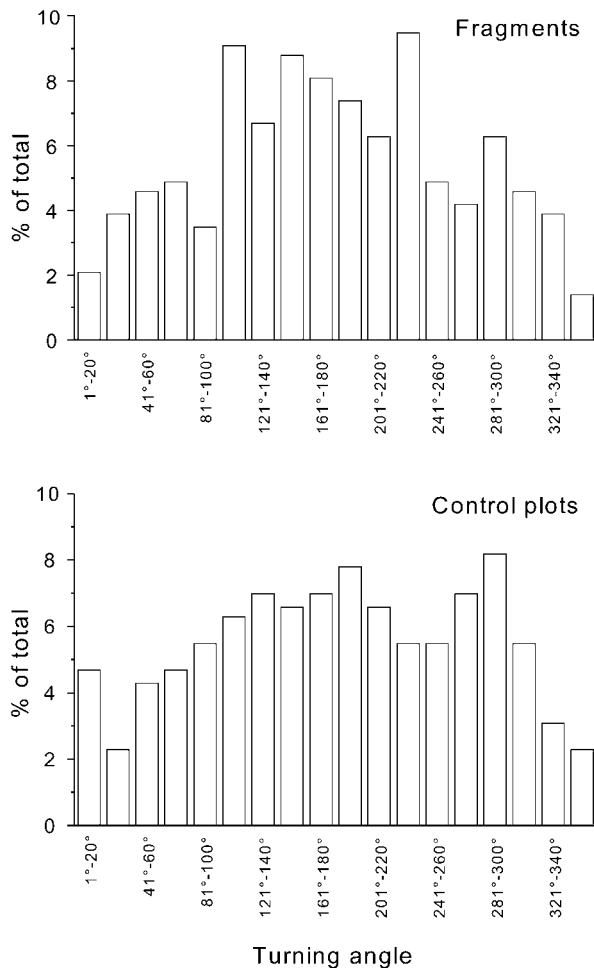

Fig. 4. Distribution of turning angles for *Bombus veteranus* visiting *Betonica officinalis* inflorescences in fragments ( $n=285$ ) and control plots ( $n=256$ ).

#### 4. Discussion

The present study shows that the behaviour of the most common pollinator of *Betonica officinalis*, the bumblebee *Bombus veteranus*, was altered by small-scale fragmentation of calcareous grasslands. Bumblebees visited more inflorescences, flew longer total distances and tended to stay longer in fragments than in control plots (Fig. 3A,B,D). Thus, *Bombus veteranus* preferred to stay within the fragment rather than flying a long distance to reach the next inflorescence outside the fragment. Rasmussen and Brodsgaard (1992) examined visiting patterns of *Bombus lapidarius* in *Lotus corniculatus* patches, which were of different sizes and interspersed with dry areas dominated by mosses, lichens and short grass. Most flights of *Bombus lapidarius* were restricted to single patches (97.4%), although the animals had no difficulty to cross the distance of 10–40 m between patches. Since long distance flying is energetically expensive, the higher visitation rate within patches can be explained by the attempt of pollinators to

optimise net energetic gain during foraging (Zimmerman, 1982; Price, 1997). In the present study, fragments were 53.7% less frequently visited than control plots. As a consequence, nectar rewards of inflorescences in fragments might be higher and pollinators might probe more thoroughly because movement decisions are based on the amounts of nectar encountered in flowers (Heinrich, 1979; Cresswell, 1990). However, measurements of nectar samples of *Betonica officinalis* did not support this assumption. The nectar quantity was smaller in fragments than in control plots, whereas the nectar concentration was higher in fragments than in control plots (H.-P. Rusterholz, unpublished data). These differences could be a result of lower soil moisture in fragments than in control plots resulting from frequent mowing of the surroundings (H.-P. Rusterholz, personal communication). In spite of this, bumblebees visiting fragments could have a more economic net energetic gain if they properly probe all available inflorescences in fragments.

The bumblebees' attempt to achieve the highest net energetic gain is confirmed by the observed difference in "visiting time per patch" between the two study sites (Fig. 3B). At Movelier, where there were fewer inflorescences per patch, bumblebees spent more time in a particular patch relatively to the total number of inflorescences, i.e. they visited more intensively all available inflorescences. This finding is supported by other studies in which bumblebees probed fewer flowers per plant and bypassed more plants with increased plant aggregation (e.g. Zimmerman, 1982; Cresswell, 1997). Furthermore, the directionality of foraging movement of bumblebees decreases with increasing plant aggregation (Cresswell, 1997). Additionally, edge plants in isolated patches provoke more reversals of flight than plants in the centre of patches (Rasmussen and Brodsgaard, 1992). Therefore, we assumed that foraging pollinators show less distinct directionality in their flights in fragments, while in the control plots pollinators would rather pass through the patch and, consequently show a directionality in their flight. Directionality in foraging flight decreases revisitation and results in decreased self-pollination, which in turn may affect the genetic structure of the plant population (Cartar and Real, 1997). In the present study bumblebees tended to fly more directly in fragments than in control plots (Fig. 4). A possible explanation could be an adjusted behaviour pattern of foraging strategy. The directionality of flights between inflorescences is random when rewards are high but approaches 180° when rewards are intermediate or poor (Heinrich, 1979; Richards, 1997). Thus, the lower nectar volume of flowers in fragments mentioned earlier might explain the observed tendency towards directionality in fragments.

Most relevant for plant fitness are the lower visitation rates in fragments and the tendency of bumblebees to

remain in isolated patches. Pollinator limitation may reduce seed set while the frequent neighbour visits may reduce the exchange of pollen between distant plants. Thus, gene flow is reduced between fragments which may decrease the probability of outcrossing. Indeed, genetic investigations conducted in the same fragmentation experiment revealed that offspring of *Betonica officinalis* had a lower genetic diversity and an increased self-fertilisation rate in fragments (H.P. Rusterholz, personal communication). These findings illustrate general processes in fragmented landscapes, which in turn might lead to an Allee effect followed by the extinction of small plant populations (Allee et al., 1949; Courchamp et al., 1999).

We showed that experimental small-scale fragmentation reduced flower visitation and changed the behaviour of a common pollinator. Other pollinator species might be affected in a similar way. The reproductive success of pollinated plants might be reduced in fragments due to higher geitonogamy and increased rate of inbreeding. However, any extrapolation of the findings to large-scale fragmentation should be made with caution.

Migration is essential for maintaining genetic diversity among populations, and pumas (*Puma concolor*) provide an excellent model for studying the genetic impacts of migrants on populations isolated by increasing human development. In densely populated southern California, USA, puma populations on the east and west side of interstate highway 15 (I-15) have become fragmented into a small inbred population on the west side (Santa Ana Mountains) and a relatively larger, more diverse population on the east side (Eastern Peninsular Range). From 146 sampled pumas, genetic analyses indicate seven pumas crossed I-15 over the last 15 years, including four males from west to east, and three males from east to west. However, only a single migrant (named M86) was detected to have produced offspring and contribute to gene flow across the I-15 barrier. Prior to the M86 migration, the Santa Ana population exhibited inbreeding and had significantly lower genetic diversity than the Eastern Peninsular Range population. After M86 emigrated, he sired 11 offspring with Santa Ana females, decreasing inbreeding measures and raising heterozygosity to levels similar to pumas in the Eastern Peninsular Range. The emigration of M86 also introduced new alleles into the Santa Ana population, although allelic richness still remained significantly lower than the Eastern Peninsular Range population. Our results clearly show the benefit of a single migrant to the genetics of a small, isolated population. However, ongoing development and habitat loss on both sides of I-15 will increasingly strengthen the barrier to successful migration. Further monitoring, and potential human intervention, including minimizing development effects on connectivity, adding or improving freeway crossing structures, or animal translocation, may be needed to ensure adequate gene flow and long-term persistence of the Santa Ana puma population.

# 1. Introduction

Without the benefits of immigration, genetic drift and breeding among closely related individuals can lead to an accumulation of deleterious alleles and inbreeding depression, reducing population fitness and increasing extinction risk [1–3]. Immigration benefits populations primarily by increasing heterozygosity and allelic richness, both of which are critical for population persistence [4,5]. Heterozygosity is of immediate importance to individual and population fitness [6,7], whereas allelic richness is directly related to the adaptive potential and long-term viability of populations [8,9]. In small populations, heterozygosity is lost at a slower rate and regained more quickly than allelic richness [2,10,11]. Although a single migrant per generation may be sufficient for maintaining genetic diversity among populations [12–14], populations are becoming increasingly fragmented by human development [15,16], and the desirable one-migrant-per-generation minimum is not always met [12,17–19].

In the United States, fragmented puma (*Puma concolor*) populations are becoming models for the study of genetics in small, isolated populations [20–24]. Complete geographical isolation of the Florida panther (*P. concolor coryi*) resulting in severe inbreeding is the extreme example [25]. Translocations of pumas from Texas to Florida have successfully alleviated inbreeding depression but, without additional immigration (natural or artificial), long-term population viability is uncertain [22,26]. Puma populations along the highly urbanized west coast of the United States are also becoming isolated, primarily by expanding human development [27–31]. Demographic and genetic concerns, along with threat of disease, have brought the long-term viability of these urban puma populations into question, and genetic restoration may be required [21,23,24,32–34].

Within southern California, our research team has been monitoring puma populations in the Santa Ana Mountains and Eastern Peninsular Range since the early 2000s [34]. Pumas in the Santa Ana Mountains are exhibiting signs of inbreeding, and are isolated from the more genetically diverse Eastern Peninsular Range population by an 8–10 lane freeway (Interstate 15 [21,34]), which is one of two major freeways that run north–south between two of the most urban regions in the United States (the greater Los Angeles area: approx. 18.7 million; San Diego County: approx. 3.3 million [35]). In *P. concolor*, young males (approx. 18 months of age) are the primary dispersers [28,36] and are responsible for significant gene flow among populations [37]. Our team previously documented that a single male crossed I-15 from the Eastern Peninsular Range and successfully produced offspring in the Santa Ana Mountains [21,34]. However, the impact of that individual, and potentially others, on the genetic diversity of the inbred Santa Ana population has not been studied.

To assess the effects that migration can have on small, isolated populations, we studied the impact of inter-population movements on inbreeding, heterozygosity and allelic richness between the Santa Ana and Eastern Peninsular Range puma populations [21,34]. We used morphological data from field captures to estimate ages of individual pumas. Assignment and pedigree models were used to determine population and familial structure, and the identification of family units allowed us to more accurately identify migrants and whether they reproduced. We then estimated inbreeding, heterozygosity and allelic richness in the two populations before and after migration events. Our results demonstrate the extent to which a single migrant can benefit the genetics of a small, isolated population.

## 2. Material and methods

### 2.1. Capture methods and age determination

We captured, marked and monitored radio-collared pumas from 2001 to 2016 in the Santa Ana Mountains and Eastern Peninsular Range. Capture methods are detailed in Vickers *et al.* [34]. We examined movements of radio-collared pumas from 2001 to 2016 to help identify potential migrants among ranges. Permission to carry out fieldwork and necessary permits were obtained from the California Department of Fish and Wildlife (CDFW), California Department of Parks and Recreation, The Nature Conservancy, United States (US) Fish and Wildlife Service, US Forest Service, US Bureau of Land Management, US Navy/Marine Corps, Orange County Parks Department, San Diego County Parks Department, Riverside County Parks Department, San Diego State University, University of California–Riverside, Audubon Starr Ranch, Vista Irrigation District, Rancho Mission Viejo/San Juan Company, Sweetwater Authority, California Department of Transportation, the City of San Diego Water Department and Parks Department, and the Irvine Ranch Conservancy as described in Vickers *et al.* [34].

## 2.2. Genetic sampling and microsatellite DNA data collection

We analysed genetic samples from 146 pumas among the Santa Ana Mountains, San Gabriel Mountains, San Bernardino Mountains and the Eastern Peninsular Range. Genetic sampling is detailed in Ernest *et al.* [21]. Briefly, we obtained blood or tissue samples for analysis of nuclear DNA from pumas captured for telemetry studies, and from those found dead or killed by state authorities for livestock depredation or public safety, some preceding year 2001. Forty-four microsatellites (electronic supplementary material, table S1), which met the assumptions of Hardy–Weinberg proportions and linkage equilibria were used for genotyping individuals. Each sample was genotyped at least twice and genotypes were determined by two independent observers. Negative and positive controls were included in each PCR. Specific extraction, PCR and sequencing methods are detailed in Ernest *et al.* [21].

## 2.3. Population assignment

We used spatially explicit Bayesian population assignment programs GENELAND v. 4.0 [38] and TESS v. 2.3 [39] and followed all developer recommendations. In GENELAND, the number of populations ( $K$ ) is a parameter optimized by the model. First, we ran 15 spatial models from 1 to 10  $K$ . We then ran five spatial models holding  $K$  at the modal  $K$  of the initial runs. We selected the model with the greatest log posterior probability and ran an admixture model. Each run included an uncertainty on coordinate of 0.01 decimal degrees (approx. 11 km), 100 000 iterations, a thinning interval of 100 and a 25% burn-in period.

In TESS,  $K$  must be tested over a range of possible values. First, we ran 10 non-admixture models for each  $K$  from 2 to 10. For model comparisons, TESS computes a deviance information criterion (DIC). We ran 10 spatially conditional auto-regressive admixture models for each  $K$  to the DIC plateau of non-admixture models. All models included pairwise great circle geographical distances, 100 000 iterations, and a 25% burn-in period. We retained 20% of the models which contained the lowest DIC scores and used CLUMPP v. 1.1.2 [40] to perform model-averaging.

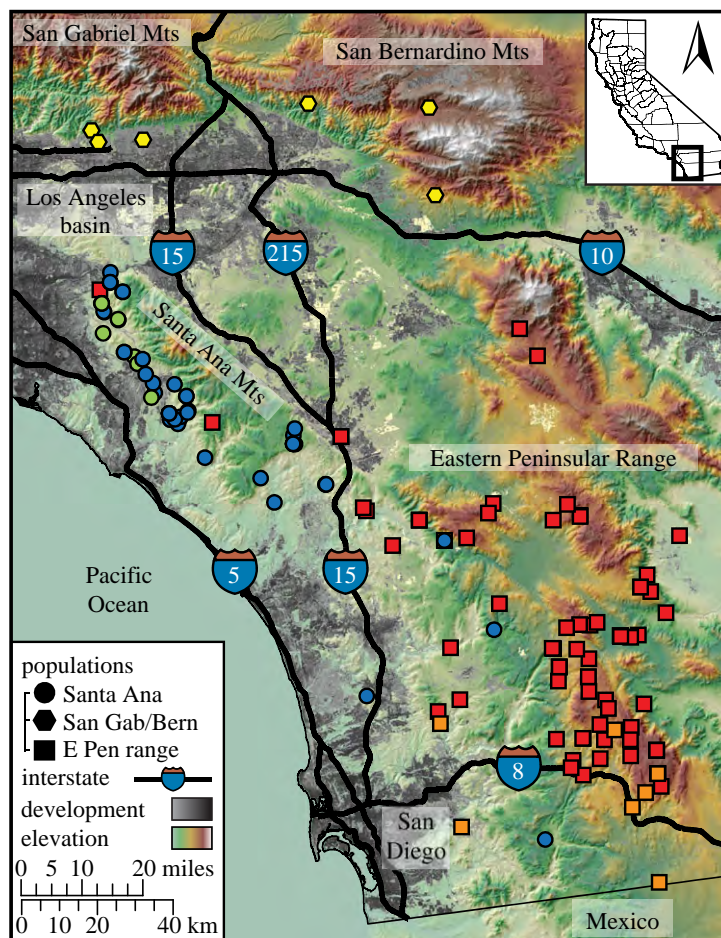

## 2.4. Pedigree reconstruction

We used program CERVUS v. 3.0.7 [41] to construct pedigrees. We ran additional sibship analyses with program COLONY v. 2.0.6.2 [42,43]. In both programs, 1% genotyping error was allowed. Parent–offspring relationships were determined based on age estimates from the morphological data taken during captures.

## 2.5. Measures of genetic diversity and population divergence

To assess inbreeding, we calculated internal relatedness using package R<sub>hh</sub> 1.0.2 in program R v. 3.3.0 [44,45]. Internal relatedness measures a relative outbred–inbred continuum, where negative values are suggestive of outbred individuals and positive scores are suggestive of inbreeding [45]. We calculated unbiased expected heterozygosity ( $\hat{H}_E$ ) in GenAlEx 6.502 [46,47]. Unlike observed heterozygosity and measures of allelic richness,  $\hat{H}_E$  is a robust genetic diversity estimator for small sample sizes [46,48]. To measure the number of alleles, we calculated allelic richness using sample-size correcting rarefaction methods in FSTAT 2.9.3.2 [49,50]. Population divergence ( $F_{ST}$ ) was also calculated in GenAlEx; significance testing was based on 999 permutations [47].

Internal relatedness, heterozygosity and allelic richness data met the assumptions of linear models. Population differences in internal relatedness were calculated using analyses of variance (ANOVAs). To assess the validity of internal relatedness as a measure of inbreeding, we used a  $T$ -test to determine if the internal relatedness of offspring was higher than the average internal relatedness of their consanguineous parents. Temporal and population differences in heterozygosity and allelic richness were tested using a repeated-measures (RM) ANOVA with locus treated as the repeated measure. We used Tukey's honest significant differences *post hoc* tests. Statistics were computed in program R using base software for linear models (ANOVAs,  $T$ -tests) and packages lme4 1.1–12 [51] and lsmeans 2.23–5 [52] for mixed models (RM-ANOVAs). For temporal analyses, samples collected from 2000 to 2016 were divided into five time periods (2000–2003, 2004–2006, 2007–2009, 2010–2012, 2013–2016). If an individual puma was estimated to have been alive at any point during that time period, it was included in the analysis.

**Figure 1.** Pumas sampled ( $N = 146$ ) in the Los Angeles–San Diego region of California, USA (inset map) were subdivided into three populations separated by major interstate highways (I-15, I-10). Circles, hexagons and squares indicate pumas, respectively, belonging to the Santa Ana, San Gabriel/Bernardino and Eastern Peninsular Range populations identified in GENELAND (figure 2a). Colours correspond to highest subpopulation admixture proportions identified in TESS (figure 2b).

## 3. Results

### 3.1. Population assignments and migrations

Based on our Bayesian population assignment analyses, we identified three geographically structured populations (Santa Ana, SA; San Gabriel/Bernardino, SGB; Eastern Peninsular Range, EP) with additional substructure within SA and EP (figures 1 and 2). Given the low sample size of SGB pumas ( $N = 6$ ), temporal measures of internal relatedness, heterozygosity and allelic richness could not be calculated and further analyses were restricted to SA and EP. Pedigree analyses indicated the additional substructure within SA was composed of a male migrant (named M86; M/F for male/female, followed by capture number) and his 11 offspring (figure 2b,c). Substructure within EP primarily corresponded to a female puma (F20) and her offspring, but several substructure-assigned individuals were not first-order relatives (i.e. parent–offspring, full-sib) of F20 (figure 2b,c).

With our pedigree analyses, we identified frequent mating within, but not among, populations. There was only one observed instance of mating among populations, which occurred when M86 migrated from EP into the Santa Ana Mountains in 2010 and mated with F61, F89, F133 and mated with his offspring F92 (figure 2). Notably, F92 had the lowest internal relatedness of all pumas sampled in the Santa Ana Mountains ( $-0.14$ ). Additional detections of inbreeding in EP included M39 mating with his daughter F47 to produce F49, with whom he also mated. M71 also mated with his mother, F20.

**Figure 2.** Population assignments (a,b) and pedigree analyses (c) of pumas ( $N = 146$ ) in the Los Angeles–San Diego region of California. Program GENELAND (a) identified three populations including the Santa Ana (blue), San Gabriel/Bernardino (yellow) and Eastern Peninsular Range (red) mountains. Program TESS (b) identified additional substructure within the Santa Ana population (green) and within the Eastern Peninsular Range (orange). Pumas were numbered in the order they were captured and M or F refers to whether that individual was a male or female, respectively (upper x-axis). Migrants from the Eastern Peninsular Range to the Santa Ana Mountains ( $N = 3$ ) are indicated on the left; migrants from the Santa Ana Mountains to the Eastern Peninsular Range ( $N = 4$ ) are indicated on the right. Familial relationships (c) were estimated using the pedigree-reconstruction program CERVUS, and confirmed with program COLONY. Within the pedigree, individual squares (males) and circles (females) are filled based on maximum admixture proportion in TESS (b). Coloured borders indicate the location where immigrant pumas were sampled. Individuals with unknown lineages (i.e. singletons) are pooled in open boxes. Instances of inbreeding are indicated with double lines.

**Figure 3.** Internal relatedness (i.e. relative outbred–inbred continuum) of Santa Ana and Eastern Peninsular Range pumas. Wide background boxplots represent populations identified in GENELAND (figure 2*a*). Colours of foreground boxes correspond to TESS subpopulations (figure 2*b*). Green corresponds to M86 and his offspring. Orange primarily corresponds to F20 and her offspring. Min, max, inter-quartiles and median are presented.

Internal relatedness was significantly ( $T_{137} = 5.4$ ,  $p < 0.001$ ) higher in SA (mean  $\pm$  s.e.:  $0.13 \pm 0.02$ ) than EP ( $0.00 \pm 0.01$ ; figure 3). Inbred offspring had significantly higher internal relatedness relative to the average internal relatedness of their consanguineous parents ( $+\Delta 0.18 \pm 0.05$ ;  $T_{10} = 3.79$ ,  $p = 0.003$ ).

### 3.2. Migration effects on population genetics

Our genetic analyses detected a total of seven migrants across I-15, all of which were males (figure 2). The three migrants originating from EP had negative internal relatedness (M86:  $-0.07$ , M119:  $-0.07$ , M151:  $-0.18$ ), indicative of outbreeding. All but one of four migrants from SA had positive internal relatedness (M56:  $0.29$ , M109:  $-0.09$ , M120:  $0.38$ , M145:  $0.17$ ). M86 was the only migrant known to reproduce, with a total of 11 offspring identified (figure 2*c*). M86 and his offspring had significantly lower internal relatedness compared with other SA pumas (ANOVA  $F_{3,135} = 16.87$ ,  $p < 0.001$ ; Tukey's HSD  $p = 0.007$ ; figure 3). All other subpopulation pairwise comparisons were not significant (Tukey's HSD  $p > 0.8$ ), indicating M86 decreased internal relatedness of his SA-offspring to comparable levels of EP pumas (figure 3).

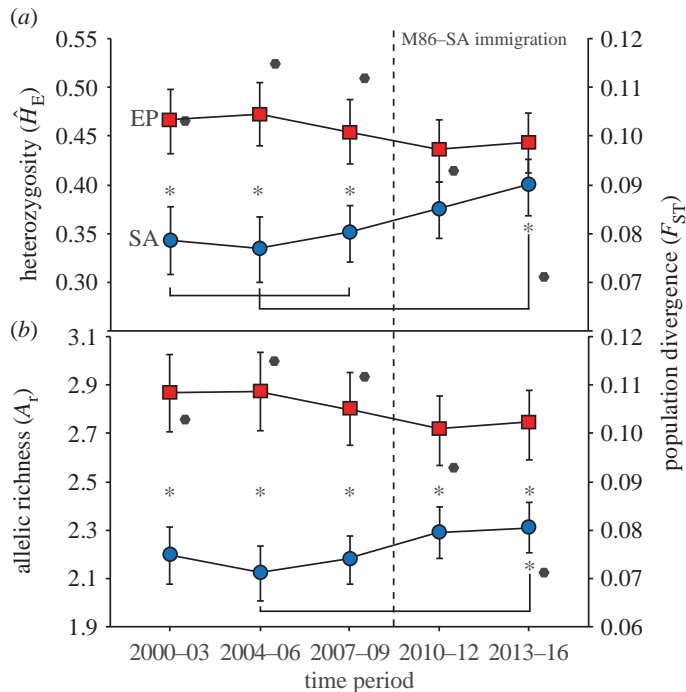

Prior to the M86 migration into the Santa Ana Mountains, SA had significantly lower heterozygosity ( $\hat{H}_E$ ) and allelic richness ( $A_r$ ) than EP in all time periods (RM-ANOVA: Tukey HSD  $p < 0.0001$ ). After the M86 migration,  $\hat{H}_E$  increased in SA and was no longer significantly different from EP ( $p = 0.24$ ,  $p = 0.67$ ; respectively). Although  $A_r$  in SA significantly increased after the M86 immigration, SA had significantly lower  $A_r$  than EP in all time periods ( $p < 0.001$ ). SA–EP population divergence ( $F_{ST}$ ) decreased after the M86 immigration; however, populations remained significantly diverged at all time periods (999 permutation tests,  $p < 0.001$ ; figure 4).

## 4. Discussion

### 4.1. Single-migrant genetic restoration

Our results demonstrate that a single migrant can have immediate positive effects on the genetics of a small, isolated and inbred puma population. Within the urbanized Los Angeles–San Diego region of California, the Santa Ana Mountains (SA) population is inbred and genetically depauperate compared to the Eastern Peninsular Range (EP) population [21]. Our analyses show that prior to the successful immigration and reproduction by a single male (M86), the SA population had significantly higher internal relatedness, significantly lower heterozygosity and significantly lower allelic richness than the EP population. After the immigration of M86, we observed significant improvements in all genetic measurements. M86 produced 11 offspring with four SA females. Even though one of M86's matings was with his daughter, he and all his offspring had significantly lower internal relatedness (i.e. they were less inbred) than other SA pumas and they exhibited internal relatedness values comparable with EP pumas. Heterozygosity and allelic richness both significantly increased in the SA population after the M86 immigration. Heterozygosity increased to the point that it was no longer significantly different from

**Figure 4.** Temporal patterns of (a) unbiased expected heterozygosity, (b) allelic richness, and population divergence ( $F_{ST}$ : black hexagons; right y-axis) for the Eastern Peninsular Range (EP) and Santa Ana (SA) puma populations before (left of vertical dashed line) and after (right of the vertical dashed line) the migration of M86 into SA from EP. Unbiased expected heterozygosity is a robust genetic diversity estimator for small sample sizes; allelic richness was sample-size corrected. All pairwise  $F_{ST}$  estimates were significantly different from zero. Squares/circles are offset from hexagons for easier visualization. Pumas estimated to be alive at any point within time periods were included in time period estimates. Means and s.e.s are presented. Sample sizes include 27 (number of males & females: 13 & 14, respectively), 25 (11 & 14), 26 (16 & 10), 28 (22 & 6), and 33 (26 & 7) for EP; 10 (1 & 9), 9 (5 & 4), 29 (16 & 13), 38 (21 & 17) and 24 (13 & 11) for SA.

the EP population. Allelic richness increased more modestly, remaining significantly lower than the EP population in all time points.

It is possible that the emigration of M86 has resulted in genetic rescue (i.e. alleviation of inbreeding depression). However, genetic rescue is difficult to confirm given the natural variation in individual survival/reproduction rates, population dynamics, and environmental conditions which affect individuals and populations [53]. Pumas in the Santa Ana Mountains have low annual survival rates (mean 0.56; [34]), and five of the seven pumas that have crossed I-15 are known to be deceased. Pumas in the region can legally be shot for depredation events (such as when lions are suspected of killing domestic animals or endangered species), are hit by cars, are killed illegally, die of other causes or have limited food resources [34]. Additionally, young immigrant males have the additional challenge of establishing territories, avoiding fights with conspecifics, finding food and mating in a previously unknown landscape [34]. Thus, the migration of two or more EP population pumas per generation is probably needed for successful reproduction at least once per generation and for maintaining genetic diversity in the SA population.

The significant increase in heterozygosity and allelic richness caused by the emigration of M86 suggests that little or no gene flow occurred between the SA and EP populations in the period immediately prior to this study. Although low sample sizes through 2000–2006 in SA could have biased genetic diversity estimates, the low sample size estimates (i.e. 2000–2003 and 2004–2006) were consistent with each other and with the more-intensively sampled time period prior to M86 (i.e. 2007–2009). Additionally, our estimates of genetic diversity are robust to differences in sample size. Given the high mortality rates in the SA, it is remarkable that M86 produced a large number of offspring ( $N = 11$ ) prior to his death. However, his contribution to gene flow was foreshortened because he was killed by a vehicle strike, and over half of his offspring are either deceased or in captivity. Another migrant from EP to SA (M151) was apparently killed prior to successfully siring offspring in the SA. This puma had the lowest internal relatedness of any migrant pumas we sampled, but he was unable to enhance genetic

diversity in the SA because he was legally shot on a depredation permit after repeatedly preying on domestic animals. Further monitoring of the only remaining migrant (M119) in the Santa Ana Mountains, as well as M86's surviving offspring, will be important for tracking population viability, and assessing the long-term impacts of migration.

In a region north of the Santa Ana Mountains and west of Los Angeles, pumas in the Santa Monica Mountains exist in very low numbers (approx. 10 total pumas at any one time) and are also isolated by a major roadway [23,27]. Over 10 years, a single male migrant was detected to have crossed the road into the Santa Monica Mountains and was the only detected breeding male. Although that male enhanced genetic diversity after producing eight detected offspring, the genetic structure of pumas in the area were completely changed because of low census size. By contrast, M86 increased genetic diversity of SA despite the Santa Ana Mountains supporting multiple breeding males and approximately 20–30 adult pumas at any one time [54]. Pumas in the Santa Ana Mountains are thought to represent a genetically distinct population [21,34]. Thus, our observations differ from the Santa Monica Mountains, which may represent family- or group-level dynamics. The only reported puma population with a lower heterozygosity than the SA population was in Florida, where pumas nearly went extinct from inbreeding depression, but were genetically rescued by translocating pumas from the state of Texas [22,26]. Given that the SA population has similar estimates of genetic diversity to just a few established pumas in the Santa Monica Mountains [23], our results indicate genetics may be an issue for SA population viability in the near future [24]. The SA population and pumas in the Santa Monica Mountain region are genetically distinct and exhibit no gene flow [21], further illustrating how urbanization and road fragmentation can completely separate populations that are geographically close (less than 70 km in this case). This may indicate a widespread issue for pumas throughout the rapidly urbanizing state of California.

## 4.2. Importance of genetic diversity in small populations

The loss of rare alleles and accumulation of deleterious alleles can occur in small populations through genetic drift and inbreeding [2,55,56]. We used internal relatedness, an individual index ranging from outbred to inbred, to estimate degree of inbreeding [45]. In other mammalian systems, high internal relatedness (indicative of inbreeding) correlates with high incidence of disease [57], low reproductive success [45,58] and low survival [59]. Inbreeding depression is well documented in the Florida puma population and associated physical abnormalities included kinked tails [22,60]. Anecdotal evidence of two SA pumas with the highest internal relatedness values also exhibited kinked tails [21], suggesting inbreeding depression may also be present in the SA population. In this study, internal relatedness increased in offspring produced from consanguineous (i.e. highly related) mate-pairs, validating its use as a measure of inbreeding [45]. However, the observed decrease in internal relatedness does not confirm that genetic rescue has occurred [61], and further studies are needed to explicitly assess the extent of inbreeding depression in the SA population [62].

Heterozygosity is a classic measure of genetic diversity and has been correlated to disease resistance [63,64], resistance to toxicants [65], increased fecundity [66,67] and puma survival [68,69]. We observed a significant increase in heterozygosity after the immigration of M86, to the point that heterozygosity of SA pumas was no longer significantly different from that of EP pumas. Whereas heterozygosity is thought to be of immediate importance to individual and population fitness [2], allelic richness is thought to be more important for the adaptive potential of populations because alleles are the raw material on which evolution occurs [2,9,70]. We observed a significant increase in allelic richness after the immigration of M86 into the SA population. However, allelic richness remained significantly lower than that of the EP population. Larger populations have a greater capacity for unique alleles simply because they have more individuals to harbour them [2,70]. Thus, we do not expect the SA population, which has a smaller effective population size and less habitat [21,34], to ever exhibit the same allelic richness as the EP population.

## 4.3. Implications and conclusion

We identified three puma populations in this region, including the SA, SGB and EP populations. Although population assignment models GENELAND [38,71] and TESS [39,72] showed similar patterns, TESS identified genealogical substructure not identified by GENELAND. We determined the additional substructure in the SA population originated from an immigrant male (M86) and his 11 offspring. However, the additional substructure in the EP population appears to be a family-unit admixed from

a currently unsampled population, perhaps from Mexico or Arizona. The SGB population, and the within-population family groups in SA and EP, were not previously identified [21], probably due to limited sampling. Future researchers should consider the behaviour of certain Bayesian clustering algorithms when analysing population genetic structure of populations containing related individuals [73,74]. Without pedigree or relatedness data, family-unit genetic clusters could mistakenly be classified as populations [75].

We identified a total of seven migrants, all males. Four moved east and three moved west across I-15. With the exception of M56 who was GPS-collared when he crossed I-15 in 2010, it is not known exactly when these migrants crossed the I-15 barrier. If they migrated at their dispersal ages, which is most likely, then based on their estimated ages when sampled their crossings would have all occurred between 2008 and 2014. TESS underestimated the number of migrants by including M86 into a SA subpopulation, whereas GENELAND overestimated the number of migrants by incorrectly assigning an inbred offspring (M124) of M86 to the EP population. The addition of our pedigree analysis allowed us to more accurately identify migrants and family groups, and showed that only one of three migrants into the SA population successfully established a territory and mated. Interstates, including I-15, have been reported to be major barriers to puma movement [21,28,34,76], and we suspect I-10 is also a barrier to puma gene flow. However, additional samples and further monitoring in the San Gabriel and San Bernardino Mountains are needed to assess the impact of I-10 on puma movements and population genetics.

Despite the increases in heterozygosity and allelic richness in the SA population, and despite being only separated by a single interstate highway, the SA and EP populations remain significantly diverged (i.e. significant pairwise  $F_{ST}$ ), and SA pumas still face threats from disease, human development, and stochastic demographic, genetic and environmental events [24,33,34,77]. As observed in other systems where a single or a few migrants genetically restored a population [14,23,53,78,79], genetic diversity will decrease and inbreeding will increase, without continuous gene flow [22,26,62,80–82]. Our results clearly show the benefit of a single migrant to the genetics of a small, isolated population. However, if one successfully breeding migrant per generation is required for long-term persistence [12,13], multiple migrants (usually dispersing males) must cross I-15 east to west in each generation to presume one is successful at breeding. Thus, future monitoring, and potential human intervention in the form of improved or new I-15 crossing structures, limitations on new development, or puma translocations, may be needed to ensure adequate gene flow and population viability.

The ability of pumas to cross I-15 is very limited, and will only decrease. Several pumas have been killed on I-15 in the past 30 years, but road mortalities are only one aspect of barrier effects. Other barrier effects include the combination of noise, light, human presence, adjacent development and other anthropogenic factors. It is essential that the ability of pumas to cross over or under I-15 not be reduced further, and mitigation measures to reduce road barrier effects should be pursued. As of this writing, large residential developments are proposed to be constructed within the two primary puma travel corridors between the Eastern Peninsular and Santa Ana Ranges, and immediately adjacent to the existing crossing structures [73–86]. Construction of these developments is likely to further degrade the ability of pumas, especially dispersing males who are essential for gene flow, to move between the Eastern Peninsular and Santa Ana Mountain Ranges. The critical importance of successful migration and reproduction to the long-term persistence of the SA population should be considered in the planning and approval process for any development near these key crossing points. The construction of new I-15 crossing structures between the Eastern Peninsular and Santa Ana Mountain Ranges has been under study and discussion by multiple regional governmental entities and various researchers and stakeholders for more than two decades. However, no engineering studies have been done, costs are expected to be substantial and funding sources have not been identified.

These results, in combination with the challenges of preserving and improving the state of genetic connectivity for pumas in this region, emphasize that despite M86's success in improving some genetic parameters of the SA population, the population remains at risk of further genetic decline. The political and conservation barriers are large, and positive change will depend on a great deal of political-will, and both public and private investments. In the case of the Florida panther and the Santa Monica Mountains pumas, large amounts of funding were mobilized once these subpopulations were threatened with extirpation. The SA population, and possibly other puma populations in California in the future, may also need human intervention to persist.

**Ethics.** All animal capture and handling protocols were approved on university, state and national levels. We operated under Protocol 10950/PHS, Animal Welfare Assurance number A3433-01, with capture and sampling procedures

approved in Protocol number 17233 by the Animal Care and Use Committee at the University of California, Davis, and Memoranda of Understanding and Scientific Collecting Permits from the California Department of Fish and Wildlife (CDFW). Permission and permits to carry out fieldwork is detailed in Material and methods section.

Data accessibility. Data analysed in this paper are accessible through Dryad: (<http://dx.doi.org/10.5061/dryad.1kh2n>) [87].

Authors' contributions. K.D.G., T.W.V., W.M.B., H.B.E.: designed the study; T.W.V., W.M.B., H.B.E.: collected data; K.D.G., H.B.E.: analysed data; K.D.G., H.B.E.: wrote manuscript; K.D.G., T.W.V., W.M.B., H.B.E.: reviewed draft manuscripts and approved final manuscript.

Competing interests. We declare we have no competing interests.

Funding. Primary funding for the genetic analysis was provided by the San Diego County Association of Governments Environmental Mitigation Program (T.W.V., H.B.E., K.D.G.; <http://www.sandag.org>). Sample and other data collection was funded by: California Department of Fish and Wildlife (T.W.V., W.M.B., H.B.E.; <https://www.dfg.ca.gov/>), California State Parks (W.M.B.; <http://www.parks.ca.gov/>), the Nature Conservancy (T.W.V., W.M.B., H.B.E.; <http://www.nature.org/>); The McBeth Foundation (W.M.B., T.W.V.; <http://mcbethfoundation.com/>); the Anza Borrego Foundation (W.M.B.; <http://theabf.org/>), Natural Communities Coalition of Orange County (T.W.V.; <https://oconervation.org/>); the National Science Foundation (W.M.B., T.W.V., H.B.E.; <http://www.nsf.gov/>), the Foothill/Eastern Transportation Corridor Agency (T.W.V., W.M.B.; <https://www.thetollroads.com/>), the San Diego Foundation (T.W.V.; <http://www.sdfoundation.org/>), Felidae Conservation Fund (W.M.B., T.W.V.; <http://www.felidaefund.org/>), the Mountain Lion Foundation (T.W.V.; <http://www.mountainlion.org/>), the Santa Rosa Plateau Foundation (T.W.V.; <http://www.srpf.org/>), the Institute for Wildlife Studies (T.W.V.; <http://www.iws.org>) and private donors.

Acknowledgements. We especially acknowledge and thank P. McMinn for her contribution to lifespan databases used in pedigree construction. Samples, data and expertise were provided by multiple people and agencies, including California Department of Fish and Wildlife (R. Botta, J. Colby, K. Brennan), California State Parks, The Nature Conservancy, UC Davis Wildlife Health Center, UC Davis Veterinary Genetics Laboratory and the US Geological Survey. We thank the following for their technical assistance: T. Drazenovich, L. Dalbeck, T. Gilliland, J. George, C. Torres, J. Sanchez and M. Plancarte. GIS data management was provided by B. Cohen. Fieldwork assistance was provided by J. Bauer, C. Bell, J. Bourdon, P. Bryant, D. Dawn, M. Ehlbroch, P.J. Falatek, D. Krucki, K. Logan, B. Martin, B. Millsap, M. Puzzo, D. Sforza, L. Sweanor, C. Wiley, E. York and numerous volunteers. Thanks to E. Boydsen, K. Crooks, R. Fisher and L. Lyren for assistance coordinating field projects and sample acquisition. We also appreciate the cooperation provided by the University of California South Coast Research and Extension Center, the California Department of Transportation and all of the land owners and managers who allowed field activities on their properties.

## Abstract

Fragmentation of wildlife populations is increasing on a global scale and understanding current population genetic structure, genetic diversity, and genetic connectivity is key to informing wildlife management and conservation. We genotyped 992 pumas (*Puma concolor*) at 42 previously developed microsatellite loci and identified 10 genetic populations throughout the states of California and Nevada, USA. Although some genetic populations had large effective population sizes, others were small and inbred. Genetic diversity was extremely variable (heterozygosity,  $uHe = 0.33–0.53$ ), with some populations nearly as low as an endangered subspecies, the Florida Panther (*P. c. coryi*,  $uHe = 0.24$ ). Specifically, pumas in the Sierra Nevada were genetically diverse and formed the largest genetic source population in the region. In contrast, coastal and southern populations surrounded by urbanization had low genetic diversity, fragmented gene flow, and tended to be genetic sinks. The strong population genetic structuring of pumas across California ( $F_{ST} = 0.05–0.39$ ) is vastly different than other genetic studies in less-urbanized states, including our analysis in Nevada, where pumas had few barriers to gene flow and weak population differentiation. Our results have far-reaching conservation and management implications for pumas and indicate large-scale fragmentation in one of North America's most biodiverse and rapidly-urbanizing regions.

## Introduction

Fragmentation of wildlife habitat and resultant impacts to populations are increasing worldwide and urbanization is one of the primary contributors (Crooks et al. 2017; Fahrig 2003; Haddad et al. 2015; Newbold et al. 2016). Unlike

natural barriers that have impacts over a geological timescale (Albert et al. 2016), urbanization can have more immediate effects on gene flow among populations (Balkenhol and Waits 2009; Karlson et al. 2014). Gene flow is critically important to individual fitness and to the evolutionary potential of populations because successful migrants can diversify gene combinations (i.e., increase heterozygosity) and introduce new genetic material (i.e., increase allelic richness) (Caballero and García-Dorado 2013; Chapman et al. 2009; Frankham 2015). Without receiving gene flow, small populations are especially subject to inbreeding, genetic drift, and increased extinction risk (Carlson et al. 2014; Wootton and Pfister 2015).

Population fragmentation is increasingly evident for species located in the urbanized western United States (Buchalski et al. 2016; Delaney et al. 2010; Fisher and Shaffer 1996; Tuma et al. 2016), including the puma (*Puma concolor*) (Beier 1995; Gray et al. 2016), which is becoming a model for studying genetics of isolated populations (Ernest et al. 2014; Gustafson et al. 2017; Johnson et al. 2010; Riley et al. 2014). Despite the long-distance dispersal ability of pumas (Hawley et al. 2016; Newby et al. 2013; Pierce et al. 1999; Thompson and Jenks 2005), gene flow among adjacent puma populations has been nearly negated by freeways in densely populated Southern California (Ernest et al. 2014; Gustafson et al. 2017; Riley et al. 2014). Consequently, some California puma populations have become functionally isolated and have experienced rapid population divergence and inbreeding (Ernest et al. 2014; Gustafson et al. 2017; Riley et al. 2014; Vickers et al. 2015) with concerns for extinction (Benson et al. 2016). Given that *P. concolor* and other wide-ranging species serve as umbrella species (Carroll et al. 2001; Maehr et al. 2002; Thorne et al. 2006)—the conservation of which indirectly provides protection for many other species (Roberge and Angelstam 2004)—the low genetic diversity of puma populations in human-fragmented habitats suggests that a large-scale ecological problem may be occurring in some of the most biologically-diverse regions of North America (Calsbeek et al. 2003; Dobson et al. 1997).

During the late Pleistocene, pumas were extirpated from North America and repopulated by migrants from South America (Culver et al. 2000). As a result, pumas in North America compose a single phylogenetic group (based on mtDNA) and exhibit founder effects (i.e., reduced population genetic diversity based on mtDNA and microsatellites) compared to pumas in South America and Central America (Culver et al. 2000). Therefore, it is critical to understand effects of fragmentation on populations from this North American lineage. A previous genetic analysis along the west coast of the United States indicated that pumas in California did not exist as a single population and suggested urbanization may have led to genetically-depauperate, fragmented populations (Ernest et al. 2003). In addition, a population

genetic analysis in Nevada indicated there were asymmetric migration rates between the two states, and that pumas from Nevada were a genetic source for genetic-sink populations in California (Andreasen et al. 2012). However, these previous reports relied on a limited number of genetic loci ( $\leq 13$  microsatellites) and investigators did not sample across the two states. In this study, we attempted to address these limitations and provide a more comprehensive view of puma genetic diversity and gene flow within and among California and Nevada.

Our aim was to identify the number and spatial structure of puma populations across California and Nevada and the extent of gene flow among the populations. In doing so, we were able to identify genetic source and sink populations as well as isolated populations with limited gene flow. We expected pumas would exhibit genetic structure associated with both natural geographic features and anthropogenic development. Given the complex structure of ecoregions and large human population in California ( $> 39$  million people;  $92.5/\text{km}^2$ ; US Census Bureau 2016), we hypothesized pumas in California would exhibit more population divergence and less interpopulation gene flow relative to pumas in Nevada, which have access to more contiguous ecoregions with fewer humans ( $< 3$  million people;  $10.3/\text{km}^2$ ; US Census Bureau 2016). To address these hypotheses, we genotyped 992 pumas at 42 microsatellite loci across California and Nevada. We then identified regional populations using population assignment models and evaluated functional connectedness of puma populations by modeling population divergence and computing bi-directional migration rate estimates.

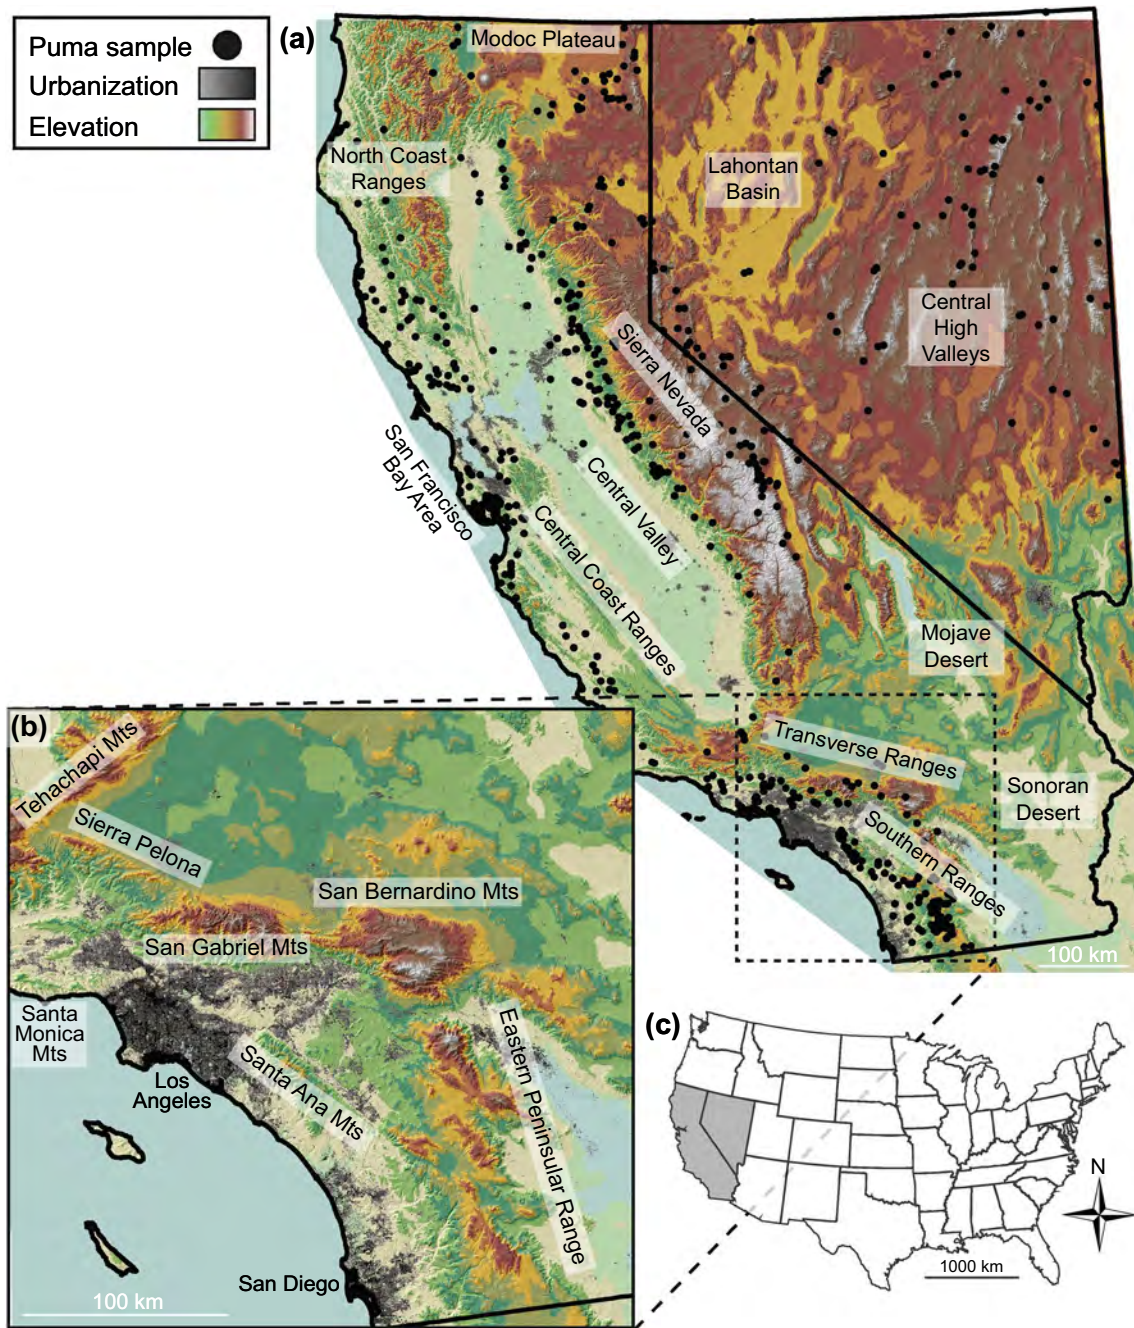

## Materials and methods

### Sampling and extractions

We obtained tissue or blood samples from 992 pumas captured alive, found dead, or legally killed by authorized agencies for livestock depredation, public safety, or sport hunting (Nevada only) during 1992–2016 (Fig. 1). Approximately 49% of individuals sampled were legally killed, 31% were from captures, 11% were hit by vehicles, and the rest were found dead of other causes. We isolated genomic DNA using QIAGEN DNeasy Blood & Tissue kits (QIAGEN Inc., Valencia, CA, USA).

### Genotyping

We genotyped each individual puma at 42 previously developed microsatellite loci, plus a single sex-linked locus (Ernest et al. 2003, 2014; Riley et al. 2014) and ran polymerase chain reactions on ABI 2720 thermocyclers (Life Technologies, Carlsbad, CA, USA) using QIAGEN

**Fig. 1** Map of our study system, including **a** sampling locations of 992 pumas and ecoregions, **b** specific mountain ranges within the Transverse and Southern Ranges, and **c** an inset map of the United States of America showing the locations of California and Nevada. Elevation data source: USGS national elevation dataset (<http://natio>

[nalmap.gov](http://natio)). Dark circles indicate locations where pumas were sampled, the gray to black scale indicates low to high urbanization, and the blue to white scale indicates 0 m elevation (sea level) to 4,421 m elevation

Multiplex PCR kits with Q solution (Table S1) following the protocols of Gustafson et al. (2017). We included negative and positive controls in each PCR run and visualized fragments with STRand version 2.3.69 (Toonen and Hughes 2001). For each locus, we confirmed heterozygous

genotypes at least twice and homozygous genotypes at least three times.

## Population genetic structure

The spatial arrangement of sample locations can confound population genetic analyses (Meirmans 2012; Schwartz and McKelvey 2009). Thus, we used spatially-explicit hierarchical Bayesian clustering programs TESS 2.3 (Durand et al. 2009a) and GENELAND 4.0 (Guillot et al. 2005b). We tested for consistency among programs because TESS has been shown to identify finer-scale hierarchical puma population genetic structure compared to GENELAND (Gustafson et al. 2017). In general, TESS outperforms GENELAND in the presence of isolation-by-distance (Safner et al. 2011) whereas GENELAND outperforms TESS at detecting genetic barriers to dispersal (Blair et al. 2012; Safner et al. 2011).

In TESS, the number of populations ( $K$ ) must be specified and tested over a range of possible values. Model selection must be used to determine the  $K$  with the best fit to the data. We followed developer instructions for determining  $K$  and population assignments. First, we ran 10 non-admixture models for each  $K$  from 2 to 20. For model comparisons, TESS computes a deviance information criterion (DIC). We ran 10 spatially-conditional auto-regressive admixture models for each  $K$  to the DIC plateau of non-admixture models (Figs. S1, S2). All models included pairwise great circle geographic distances for weighting the Voronoi neighborhood, 100,000 iterations, and a 25,000 iteration burn-in period. We retained 20% of the models exhibiting the lowest DIC scores and used CLUMPP 1.1.2 to perform model-averaging (Jakobsson and Rosenberg 2007).

In GENELAND,  $K$  is optimized by the model. We followed developer recommendations for determining  $K$  and individual population assignments (Guillot et al. 2005a). First, we identified a distribution of  $K$  from initial models, and then we ran correlated allele frequency models allowing  $K$  to vary within its distribution from the initial models (Fig. S1). Finally, we ran 5 spatial, correlated allele frequency models with  $K$  fixed at the mode and selected the model with the highest negative log-likelihood value for further inference. Each run included an uncertainty on GPS coordinates of 0.1 decimal degrees ( $\sim 11$  km), 1,000,000 iterations, a thinning interval of 10,000, and a 25% burn-in period prior to extracting model output. We assigned individuals to populations based on their highest assignment probability. To visualize the probability of population membership across the study area, we used package POPSutilities 1.0 in R 3.3.0, which interpolates admixture coefficients using geospatial kriging (Jay et al. 2012).

Temporal variation in sampling can bias spatial population genetic analyses; however, spatially-explicit Bayesian clustering models should account for most temporal variation (Durand et al. 2009b; François and Durand 2010). Populations did not group based on sampling date in TESS

or GENELAND. Additionally, isolation-by-distance was significant across our study area ( $R^2 = 0.15$ ,  $P < 0.001$ ). Although TESS and GENELAND showed nearly identical results, we used TESS admixture models for analyses and inferences because TESS outperforms GENELAND in the presence of isolation-by-distance.

## Genetic diversity

We tested for linkage disequilibrium, deviations from Hardy–Weinberg proportions, and null alleles in GENEPOP 4.5.1 (Rousset 2008). For each identified population, we calculated standard measures of genetic diversity and used 1000 permutations to test for significant genetic isolation-by-distance in GenAlEx 6.502 (Peakall and Smouse 2006, 2012). To measure the number of alleles, we calculated allelic richness using rarefaction methods which correct for sample size in FSTAT 2.9.3.2 (Goudet 1995). To assess inbreeding, we calculated internal relatedness using package Rhh 1.0.2 in Program R 3.3.0 (Alho et al. 2010). We calculated effective population size ( $N_e$ ) for each population using NeEstimator 2.01 using the linkage disequilibrium method assuming random mating (Do et al. 2014). Because the inclusion of low-frequency alleles can upwardly bias estimates of  $N_e$  (Waples and Do 2010), we ran two separate models including alleles with frequencies  $\geq 5\%$  or  $\geq 1\%$ . To test for evidence of recent reductions in  $N_e$  (i.e., genetic bottlenecks), we used program BOTTLENECK 1.2.02 to determine if a population exhibited a significant number of loci with heterozygote excess (Piry et al. 1999). For each population identified by assignment models, we performed bottleneck analyses using two-phase (70:30 step-wise:infinite-alleles) microsatellite mutation models for 100,000 iterations.

We used biotools 3.1 (da Silva et al. 2017) in R to obtain spatial unbiased genetic diversity estimates [uHe: unbiased expected heterozygosity; (Nei 1978)] based on the interpolation of individual estimates (Manel et al. 2007). We minimized spatial extrapolation by using a radius of 500 m and reduced bias by setting the neighborhood size (i.e., minimum number of individuals used to calculate uHe) to 2. The mean size of each neighborhood was 14.6 and 42.5% of the neighborhoods contained at least 10 individuals.

## Population differentiation and genetic source–sink dynamics

We used three complementary approaches to assess functional population connectivity, including a discriminant analysis of principal components (DAPC), pairwise estimates of population divergence ( $F_{ST}$ ), and pairwise estimates of bi-directional migration rates ( $m$ ). The DAPC uses linear combinations of alleles to maximize between-population genetic variation and provides a graphical representation

of functional connectivity among genetic clusters (Jombart et al. 2010).

We implemented the DAPC in program R using package *adegenet* 2.0.1 (Jombart 2008). The identified number of genetic clusters in *adegenet* agreed with TESS and GENELAND (Fig. S3). Because the algorithm for individual assignments in *adegenet* is not as powerful as Bayesian population assignment algorithms (Jombart et al. 2010), we defined populations in the DAPC using results from the Bayesian population assignments. Because we were not assigning individual membership probabilities in the DAPC, we retained all information (i.e., 344 PCA axes and all 9 discriminant functions) in the analysis. Our results from retaining all information did not differ from results when only retaining an estimated optimal number of PCA axes using the  $\alpha$ -score method. Pairwise population divergence estimates ( $F_{ST}$ ) were calculated in GenAlEx using 999 permutation tests for significance. To conform to the expectations of genetic isolation-by-distance, rather than an island model, we also calculated Rousset's  $F_{ST}/(1 - F_{ST})$  (Rousset 1997).

We used program BayesAss 3.0 to estimate migration rates ( $m$ ) among populations identified by population assignment models (Wilson and Rannala 2003). We used 10 randomly-seeded runs each with 5,000,000 iterations, a burnin of 1,000,000, and thinning interval of 1000. Posterior mean parameter estimates were nearly identical among runs, and all trace files indicated convergence of model parameters (Meirmans 2014). We tested the hypothesis of Andreasen et al. (2012) that Nevada pumas were a genetic source for California pumas by summing emigration rates and subtracting the sum of immigration rates for each population (Andreasen et al. 2012). Positive numbers indicate the population was a genetic source whereas negative numbers indicate a sink. We used package *circlize* 0.3.7 in program R to visualize bi-directional migration rates estimated in BayesAss (Gu et al. 2014).

## Results

### Population genetic structure and diversity

Our analyses revealed that pumas in California exhibited strong population genetic structure and some California populations had extremely low levels of genetic diversity. We identified nine genetic clusters in California and one genetic cluster in Nevada (Figs. 2, S1, S2, S4). We classified these 10 genetic clusters as genetic populations, including the Nevada (NV), Eastern Sierra Nevada (ESN), Western Sierra Nevada (WSN), North Coast (NC), Northern section of the Central Coast (CC-N), Central section of the Central Coast (CC-C), Southern section of the Central Coast (CC-S),

San Gabriel/San Bernardino (SGSB), Santa Ana (SA), and Eastern Peninsular Range (EP) populations (Fig. 2).

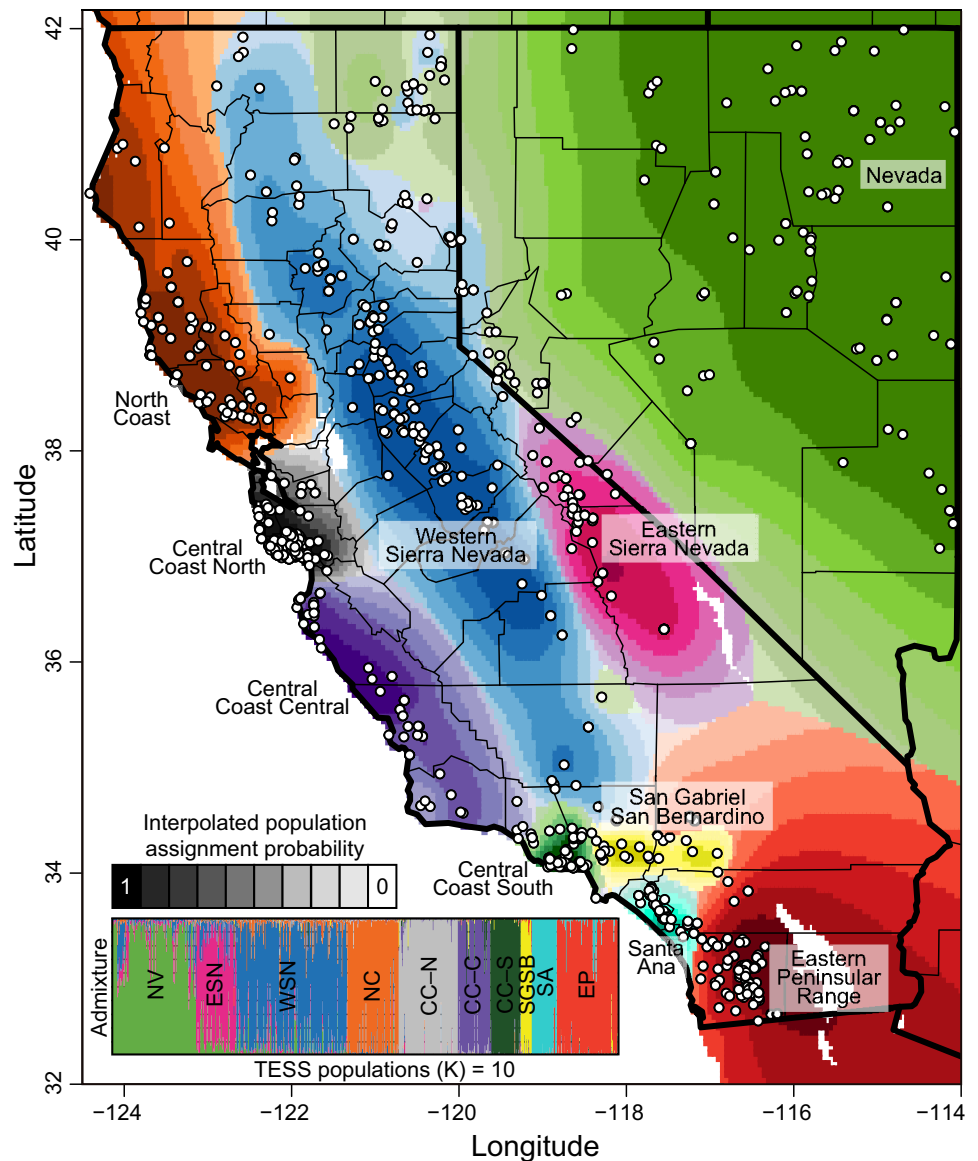

The genetic diversity of California puma populations exhibited a large amount of variation with some populations having estimates similar to other large populations and some exhibiting estimates nearly as low as the endangered Florida Panther. The NV, ESN, and WSN populations had the highest estimates of genetic diversity compared to other populations (Table 1). Regionally, the Modoc Plateau and Sierra Nevada contained individuals that had consistently high genetic diversity (Fig. 3). Although the NV population had high genetic diversity, the individual-based analysis indicated spatially-heterogeneous genetic diversity across Nevada with low levels occurring near the Lahontan Basin (Fig. 3). The CC-C population had relatively intermediate levels of genetic diversity (Table 1). The SA population had the lowest genetic diversity observed across all estimates, followed by the SGSB, NC, CC-S, and CC-N populations. SA also had the highest measure of internal relatedness. WSN had the largest effective population size ( $N_e$ ), followed by NV, NC, and CC-C (Table 2). All other populations had an  $N_e$  of  $< 50$  (often given as a desirable minimum from a conservation genetics point of view; Frankham 1995; Mace et al. 2008), and CC-S and SGSB had extremely low effective population sizes ( $\leq 5$ ). All populations except NV and NC exhibited evidence of a prior genetic bottleneck (Table 2).

### Population differentiation and genetic source–sink dynamics

Our discriminant analysis of principal components (DAPC) revealed that puma populations in California had low connectivity compared to pumas in Nevada which were composed of a single genetic population that exhibited high connectivity with several California populations. The first axis (x-axis; 33.3% of total variation) of the DAPC broadly corresponded to a latitudinal population separation with north to the left and south to the right (Fig. 4a). The second axis (y-axis; 24.4%) separated populations longitudinally and primarily separated central coast populations from southern populations (Fig. 4a). The NV, ESN, WSN, and NC populations grouped together, as did the CC-N, CC-C, and CC-S populations. The SA and EP populations grouped slightly but were separated from all other populations (Fig. 4a). Lastly, the SGSB was intermediate relative to all other populations, but was most closely-related to the WSN population (Fig. 4a).

Bi-directional migration rate models indicated there were 5 genetic source populations (i.e., ESN, WSN, CC-N, CC-C, EP) and 5 genetic sink populations (i.e., NV, NC, CC-S, SGSB, SA), however, there was only weak evidence indicating CC-N and NC were source and sink populations, respectively. Bi-directional migration

**Fig. 2** Population genetic structure of pumas across California and Nevada. Individual admixture proportions from TESS (inset barplot) were spatially-interpolated. Each color represents a genetic population. The decay in color intensity on the map represents lower probabilities of population assignment and indicates areas with admixture between populations. State and county borders are displayed for reference. *NV* Nevada, *ESN* Eastern Sierra Nevada, *WSN* Western Sierra Nevada, *NC* North Coast, *CC-N* Northern section of the Central Coast, *CC-C* Central section of the Central Coast, *CC-S* Southern section of the Central Coast, *SGSB* San Gabriel/San Bernardino, *SA* Santa Ana, *EP* Eastern Peninsular Range

rate estimates showed connectivity patterns similar to the DAPC (Fig. 4). Although there was gene flow among the NV, ESN, and WSN populations based on bi-directional migration rates, the NC population primarily exchanged migrants with the ESN and WSN populations (Fig. 4b). The populations in the Sierra Nevada (ESN, WSN) were the greatest genetic source populations but exhibited limited gene flow with the populations along the central coast of California (CC-N, CC-C, CC-S), and neither NV nor NC exhibited appreciable gene flow with central coast populations (Fig. 4b; Table S2). The SA population exhibited gene flow only with the EP population, and

the EP population had low connectivity with the SGSB population (Fig. 4b). The puma population in the Transverse Ranges (SGSB) was the largest genetic sink but exchanged some genetic material with the WSN, CC-C, and EP populations (Fig. 4b). Populations in the Southern Ranges (SA, EP) were largely disconnected from all other populations (Fig. 4b).

**Table 1** Allelic and genetic diversity of puma populations, including sample-size corrected allelic richness, the number of private alleles, the percent of polymorphic loci, observed heterozygosity, unbiased expected heterozygosity, and average internal relatedness (a measure of inbreeding)

Population	N	Allelic richness	Private alleles	Polymorphic Loci (%)	Observed heterozygosity	Expected heterozygosity	Internal relatedness
NV	166	3.47 (0.09)	9	100	0.50 (0.03)	0.52 (0.03)	0.15 (0.01)
ESN	79	3.46 (0.13)	5	100	0.52 (0.03)	0.53 (0.03)	0.11 (0.01)

### Discussion

We identified 10 genetically-distinct puma populations within California and Nevada that varied considerably in genetic diversity (uHe range 0.33–0.53) and effective population size ( $N_e$  range 5–157). Some of our previous

analyses identified family-level genetic structure which was not observed here (Ernest et al. 2014; Gustafson et al. 2017; Riley et al. 2014), indicating these genetic populations are not the result of sampling related individuals. The large number of populations ( $N=9$ ) and the strong genetic differences among neighboring puma populations in California differed from other studies at similar spatial scales (Anderson et al. 2004; Holbrook et al. 2012; Loxterman 2011; McRae et al. 2005), including Nevada (Andreasen et al. 2012). Most state-wide studies have been conducted in less-developed locations with more continuous habitat and showed that geographic distance and natural landscape components were the most common factors associated with the broad-scale genetic structure of puma populations (Anderson et al. 2004; Holbrook et al. 2012; Loxterman 2011; McRae et al. 2005; Wright 1943). In contrast, mountain ranges in California are variable in size and arrangement and there are vast areas of inter-mountain anthropogenic development throughout the state. Previous local studies in California have identified individual roadways and associated human development as major barriers to puma movements (Ernest et al. 2014; Gustafson et al. 2017; Riley et al. 2014; Vickers et al. 2015), and our study confirms, on a broad geographic scale, strong population structure among adjacent puma populations. The considerable variation in genetic diversity and effective population size among California and Nevada populations is likely attributable to the variation in the amount of suitable habitat and their degree of isolation. The Western Sierra Nevada population had the largest effective size and was closely related (i.e., lowest  $F_{ST}$  values) to every population except for the Northern Central Coast population and populations south of Los Angeles (Santa Ana, Eastern Peninsular Range), suggesting puma populations form a

**Table 2** Summary of effective population size and bottleneck analyses for each population

Parametric 95% confidence intervals are presented in parentheses. Bottleneck P-values from standardized differences tests are presented

**Fig. 4** Functional connectedness of puma populations, based on **a** a discriminant analysis of principal components and **b** bi-directional migration rate estimates (multiplied by 100 for visualization). Each dot represents an individual (**a**). Each color **a, b** represents a population. Black lines **a** indicate the most closely-related population based on genetic dissimilarities. The inset barplot **a** shows which axes are being displayed (i.e., discriminant functions 1 and 2) and the relative proportion of variation explained by each of the 9 discriminant functions. Two-thirds of the individuals in each population are contained within the corresponding ellipsoid. For a biologically meaningful interpretation, only estimates of interpopulation migration

rates with 95% confidence intervals that do not cross 0 are presented (**b**; Table S2). Net genetic source-sink migration rates are presented next to population names with positive values indicating a net genetic source and negative values indicating a net genetic sink (e.g., WSN exported 9% of migrants and received 2%, so its net rate is +7.0). NV Nevada, ESN Eastern Sierra Nevada, WSN Western Sierra Nevada, NC North Coast, CC-N Northern section of the Central Coast, CC-C Central section of the Central Coast, CC-S Southern section of the Central Coast, SGSB San Gabriel/San Bernardino, SA Santa Ana, EP Eastern Peninsular Range

“horseshoe” network around the Central Valley with San Francisco Bay acting as a major barrier along the coast (Hooper 1944). The large National Parks and National Forests (e.g., Sequoia–Kings Canyon and Yosemite National Parks) in the Sierra Nevada provide contiguous habitat for pumas with minimal anthropogenic infrastructure (Ernest et al. 2000).

Our results are consistent with a previous report (Andreasen et al. 2012) indicating pumas from Nevada form a single genetic cluster and are distinct from pumas in the Sierra Nevada of California, but our results contrast with their suggestion that pumas from Nevada are a genetic source for pumas in California. There are several differences between the studies that could explain the inconsistencies. Andreasen et al. (2012) used considerably fewer genetic markers than the present study (9 microsatellites vs. 42). Because the number of loci used in bi-directional migration rate models has the largest effect on the accuracy of the estimates (Faubet and Gaggiotti 2008; Wilson and Rannala 2003), we expect the differences are driven by the different number of loci. Although we sampled fewer pumas from Nevada and more pumas from California, sample size differences generally only affect the variance and not the accuracy of the bi-directional migration rate estimates (Faubet and Gaggiotti 2008; Wilson and Rannala 2003). Further, sample size alone likely does not explain the contrasting results and the multiple lines of evidence supporting the Sierra Nevada populations as a genetic source for the surrounding populations, including Nevada.

Both our population-level and individual-based analyses clearly indicated that the Western Sierra Nevada population had the highest genetic diversity, which is likely being maintained by the large effective population size and not via migrants from the Nevada population, which had lower genetic diversity estimates. Further, instead of testing migration rates among the two populations ( $K=2$ ) which had the highest model support in their study, Andreasen et al. (2012) tested among five genetic clusters ( $K=5$ ) which had average within-cluster migration estimates of only 54% (and a large SD of 8.4%) compared to our within-population migration estimates of 94% ( $\pm 1.9\%$ ). Thus, their examination of genetic source–sink dynamics was based on significantly less distinct genetic units ( $F_{ST}=0.05–0.09$  compared to our study where Rousset’s  $F_{ST}=0.05–0.39$ ), which is computationally problematic with a small number of loci (Faubet and Gaggiotti 2008; Wilson and Rannala 2003). Additionally, puma hunting is legal in Nevada but not California, and puma densities that have been reduced regionally from hunter harvest are known to be compensated by higher immigration rates from neighboring populations (Cooley et al. 2009; Robinson et al. 2008), which is biologically consistent with our observations.

The North Coast and inland populations (Nevada, Eastern Sierra Nevada, Western Sierra Nevada) appear to be large (i.e., high  $N_e$ ), genetically diverse, and well-connected, and may form an evolutionary significant unit (ESU: a group of populations that have accumulated adaptive differences from other populations in part from reproductive isolation; Palsbøll et al. 2007). However, genome-wide data and gene–environment correlation studies will be needed to evaluate whether these population are exhibiting adaptations to specific habitats or ecoregions. Within this group of populations, we detected evidence for bottlenecks in the Eastern Sierra Nevada population and Western Sierra Nevada population. The bottleneck in the Eastern Sierra Nevada population is not surprising given that the puma abundance in this region may have been reduced by 50% after a severe decline in mule deer (Pierce and Bleich 2014; Pierce et al. 2000; Villepique et al. 2011). Besides the North Coast and Nevada populations, all of the other populations also exhibited evidence of genetic bottlenecks; however, we do not know if this was caused by urbanization, a decrease in prey abundance, or some other factor, because the demographic and genetic histories of these populations are not well-documented.

The Central population of the Central Coast exhibited intermediate levels of genetic diversity, and maintaining gene flow from this population to the genetically-depauperate Northern and Southern Central Coast populations is critically important for their long-term viability (Benson et al. 2016; Gray et al. 2016; Riley et al. 2014). A previous report examined the southern area of the central coast region specifically and observed extremely low genetic diversity in the Santa Monica Mountains, south of Highway 101 in the Los Angeles Area (Riley et al. 2014). At a statewide level, we found pumas in the Santa Monica Mountains to be part of a larger genetic population including pumas in the Simi Hills and Santa Susana Mountains; however, our larger sample from the Southern Central Coast population revealed only slightly higher estimates of genetic diversity than pumas sampled from the Santa Monica Mountains alone (Riley et al. 2014). Road-isolated pumas in the Santa Monica Mountains only receive rare migrants from the Simi Hills and Santa Susana Mountains and are at a high risk of extirpation from isolation and subsequent demographic and genetic stochasticity (Benson et al. 2016). These results emphasize the need to conserve within-population connectivity, specifically from the Coast Ranges and the Sierra Nevada through the Santa Susana Mountains and Simi Hills to the Santa Monica Mountains.

Despite being very close geographically, the puma populations around Los Angeles (Southern Central Coast, San Gabriel/San Bernardino, Santa Ana) are highly diverged. For example, the Santa Ana and Southern Central Coast population are among the closest populations geographically

(~ 100 km apart) but are among the most genetically distant populations we observed (Rousset's  $F_{ST}=0.32$ ). Additionally, the Southern Range populations (Santa Ana, Eastern Peninsular Range) are largely disconnected from all other populations in this study, including those just to the north of the Los Angeles Basin. These observations are consistent with the hypothesis of reduced connectivity from habitat fragmentation by human development (i.e., the Los Angeles metropolitan area), including major roads (i.e., I-10, I-15, I-210, etc.) (Ernest et al. 2003). The San Gabriel/San Bernardino population was most genetically similar to the Western Sierra Nevada, Central region of the Central Coast, and Eastern Peninsular Range populations, indicating it is an area of intersection between multiple populations. We suggest the small mountain ranges in this area (i.e., Tehachapi, Sierra Pelona, San Gabriel, and San Bernardino Mountains) are necessary for contiguous statewide genetic connectivity and that pumas occupying those ranges, and the wildlands habitat in those ranges, should be considered conservation priorities (Beier et al. 2009; Ernest et al. 2003; Wildlands 2008).

The Santa Ana population exhibited the lowest measures of genetic diversity and the highest measures of inbreeding among all populations, with levels nearing those of Florida panthers (most recent estimates of  $He=0.24$ ), which nearly went extinct from genetic factors prior to artificial genetic rescue (Johnson et al. 2010). It is important to note, however, that out of the 42 microsatellite loci used in this study, only 4 were shared with the 23 microsatellite loci used in the Florida panther study. A set of shared markers would be most appropriate for direct interpopulation comparisons (e.g., Culver et al. 2000). A single immigrant from the Eastern Peninsular Range recently enhanced the genetic diversity of Santa Ana pumas and is likely responsible for the higher effective population size than previously observed (Ernest et al. 2014). Nevertheless, genetic diversity of Santa Ana pumas will decline without additional immigration (Gustafson et al. 2017). The Eastern Peninsular Range population had the highest genetic diversity and effective size among the populations in the Los Angeles—San Diego area (Southern Central Coast, San Gabriel/San Bernardino, Santa Ana, Eastern Peninsular Range). Restoring connectivity with the Eastern Peninsular Range and reducing further impacts from development on gene flow among the adjacent populations, including pumas from Arizona and Mexico (Gustafson et al. 2017), are critically important to avoiding extirpation of genetically-depauperate populations (Benson et al. 2016).

By identifying puma populations and measuring gene flow among them, our analyses can help guide and inform puma conservation and management. Whenever possible, government agencies and other stakeholders should consider population connectivity and prevent further fragmentation by human development both within and among populations.

In contrast to other studies in 7 western states that generally indicated weak puma genetic structure (Anderson et al. 2004; Holbrook et al. 2012; Loxterman 2011; McRae et al. 2005), our study showed strong genetic structure. Although puma habitat in California is aggregated and separated by valleys, it is unlikely these valleys would have been such strong barriers to gene flow pre-development given that pumas have been documented to move across the entire Central Valley post-development (Ernest et al. 2003; McClanahan et al. 2017). Further, similar geographic features, such as the Wyoming Basin, have not been reported to structure puma populations (Anderson et al. 2004). Instead, we hypothesize that human-associated infrastructure within the valleys are artificially isolating pumas beyond what they would naturally experience among ecoregions.

Population-level conservation strategies are needed to reintegrate fragmented, at-risk populations into a connected multi-state, multi-landscape population network (Zeller et al. 2017). Gene flow via maintenance of existing occupied habitat combined with improved and additional networks of wildlife corridors (Bennett 2017; Gloyne and Clevenger 2001; Johnson et al. 2010; Sawaya et al. 2013) will ultimately be necessary to promote the long-term persistence of isolated populations (Benson et al. 2016; Ernest et al. 2014; Gustafson et al. 2017; Riley et al. 2014). Without such measures, it is likely too late to expect a natural increase in genetic connectivity or selection for increased dispersal (Burdett et al. 2010; Cheptou et al. 2017), and assisted gene flow may be needed in perpetuity for several populations to remain viable (Benson et al. 2011, 2016; Ernest et al. 2014; Gustafson et al. 2017; Johnson et al. 2010; Vickers et al. 2015).

In some of these populations, individual migrants are of immediate conservation importance, and human-induced mortality should be avoided to the extent possible. The effects of fragmentation on multiple populations of this umbrella species are likely indicative of a larger ecological problem in one of the most biologically diverse regions of North America (Calsbeek et al. 2003; Dobson et al. 1997; Thorne et al. 2006). We strongly encourage land owners and managers to proactively consider broad-scale wildlife connectivity in future development proposals. However, in the absence of maintaining habitat of a spatial scale grand enough to ensure the persistence of prey and predator populations, the issue of connectivity will become a moot point.

We conducted an analysis of global forest cover to reveal that 70% of remaining forest is within 1 km of the forest's edge, subject to the degrading effects of fragmentation. A synthesis of fragmentation experiments spanning multiple biomes and scales, five continents, and 35 years demonstrates that habitat fragmentation reduces biodiversity by 13 to 75% and impairs key ecosystem functions by decreasing biomass and altering nutrient cycles. Effects are greatest in the smallest and most isolated fragments, and they magnify with the passage of time. These findings indicate an urgent need for conservation and restoration measures to improve landscape connectivity, which will reduce extinction rates and help maintain ecosystem services.

## INTRODUCTION

Destruction and degradation of natural ecosystems are the primary causes of declines in global biodiversity (1, 2). Habitat destruction typically leads to fragmentation, the division of habitat into smaller and more isolated fragments separated by a matrix of human-transformed land cover. The loss of area, increase in isolation, and greater exposure to human land uses along fragment edges initiate long-term changes to the structure and function of the remaining fragments (3).

Ecologists agree that habitat destruction is detrimental to the maintenance of biodiversity, but they disagree—often strongly—on the extent to which fragmentation itself is to blame (4, 5). Early hypotheses based on the biogeography of oceanic islands (6) provided a theoretical framework to understand fragmentation's effect on extinction in terrestrial landscapes composed of “islands” of natural habitat scattered across a “sea” of human-transformed habitat. Central to the controversy has been a lingering uncertainty about the role of decreased

fragment size and increased isolation relative to the widespread and pervasive effects of habitat loss in explaining declines in biodiversity and the degradation of ecosystems (7). Observational studies of the effects of fragmentation have often magnified the controversy because inference from nonmanipulative studies is limited to correlation and because they have individually often considered only single aspects of fragmentation (for example, edge, isolation, and area) (8). However, together with these correlative observations, experimental studies reveal that fragmentation has multiple simultaneous effects that are interwoven in complex ways and that operate over potentially long time scales (9).

Here, we draw on findings of the world's largest and longest-running fragmentation experiments that span 35 years and disparate biomes on five continents. Their rigorous designs and long-term implementation overcome many limitations of observational studies. In particular, by manipulating and isolating individual aspects of fragmentation while controlling for others, and by doing so on entire ecosystems, they provide a powerful way to disentangle cause and effect in fragmented landscapes. Here, we present experimental evidence of unexpected long-term ecological changes caused by habitat fragmentation.

Highlighting one ecosystem type as an example, we first present a global analysis of the fragmentation of forest ecosystems, quantifying for the first time the global hotspots of intensive historical fragmentation. We then synthesize results from the set of long-term experiments conducted in a wide variety of ecosystems to demonstrate consistent impacts of fragmentation, how those impacts change over time, and how they align with predictions from theory and observation. Finally, we identify key knowledge gaps for the next generation of fragmentation experiments.

## GLOBAL ANALYSIS OF THE EXTREME MAGNITUDE AND EXTENT OF FRAGMENTATION

New satellite data sets reveal at high resolution how human activities are transforming global ecosystems. Foremost among these observations are those of forest cover because of the high contrast between forest

and anthropogenic land cover types. Deforestation, which was already widespread in temperate regions in the mid-18th to 20th centuries and increased in the tropics over the past half century, has resulted in the loss of more than a third of all forest cover worldwide (10, 11). Beyond the direct impacts of forest loss and expanding anthropogenic land cover (for example, agricultural fields and urban areas), remnant forests are likely to suffer from being smaller, more isolated, and with a greater area located near the edge of the forest (12).

We analyzed the world's first high-resolution map of global tree cover (13) to measure the magnitude of forest fragmentation. This analysis revealed that nearly 20% of the world's remaining forest is within 100 m of an edge (Fig. 1, A and B)—in close proximity to agricultural, urban, or other modified environments where impacts on forest ecosystems are most severe (14). More than 70% of the world's forests are within 1 km of a forest edge. Thus, most forests are well within the range where human activities, altered microclimate, and nonforest species may influence and degrade forest ecosystems (15). The largest contiguous expanses of remaining forests are in the humid tropical regions of the Amazon and Congo River Basins (Fig. 1A). Large areas of more disjunct forest also remain in southeastern Asia, New Guinea, and the boreal biomes.

Historical data enable the study of the process of forest fragmentation over time. We reconstructed the historical forest extent and timing of fragmentation in two forested regions of Brazil that provide a stark contrast in land-use dynamics. The Brazilian Amazon is a rapidly changing frontier (10), yet most of its forests remain contiguous and far from an edge despite recent increases in fragmentation (Fig. 1, C and D). In contrast, the Brazilian Atlantic Forest is a largely deforested landscape, cleared for agriculture and logged for timber over the last three centuries (11). This remaining forest is dominated by small fragments, with most fragments smaller than 1000 ha and within 1000 m of a forest edge (Fig. 1, E and F) (16). In the Brazilian Amazon, the proportion of forest farther than 1 km from the forest edge has decreased from 90% (historical) to 75% (today), and in the Brazilian Atlantic, from 90% to less than 9%.

These two forested regions of Brazil define extremes of the fragmentation process and are representative of the extent of fragmentation in forested landscapes worldwide (Fig. 1), as well as many other biomes including temperate grasslands, savannas, and even aquatic systems (17). For example, although a spatial analysis similar to that of forest is not currently possible in grasslands, 37% of the world's grassland eco-regions are classified as “highly fragmented” (18, 19).

**Fig. 1. The global magnitude of forest fragmentation.** (A) Mean distance to forest edge for forested pixels within each 1-km cell. Lines point to locations of ongoing fragmentation experiments identified and described in Fig. 2. (B) Proportion of the world's forest at each distance to the forest edge and the cumulative proportion across increasing distance categories (green line). (C and E) In the Brazilian Amazon (C) and Atlantic Forests (E), the proportion of forest area at each distance to forest edge for both the current and estimated historic extent of forest. (D and F) In the Brazilian Amazon (D) and Atlantic Forests (F), the number of fragments and the total area of fragments of that size. The total number of fragments in the smallest bin (1 to 10 ha) is an underestimate in both the Atlantic Forest and Amazon data sets because not all of the very smallest fragments are mapped.

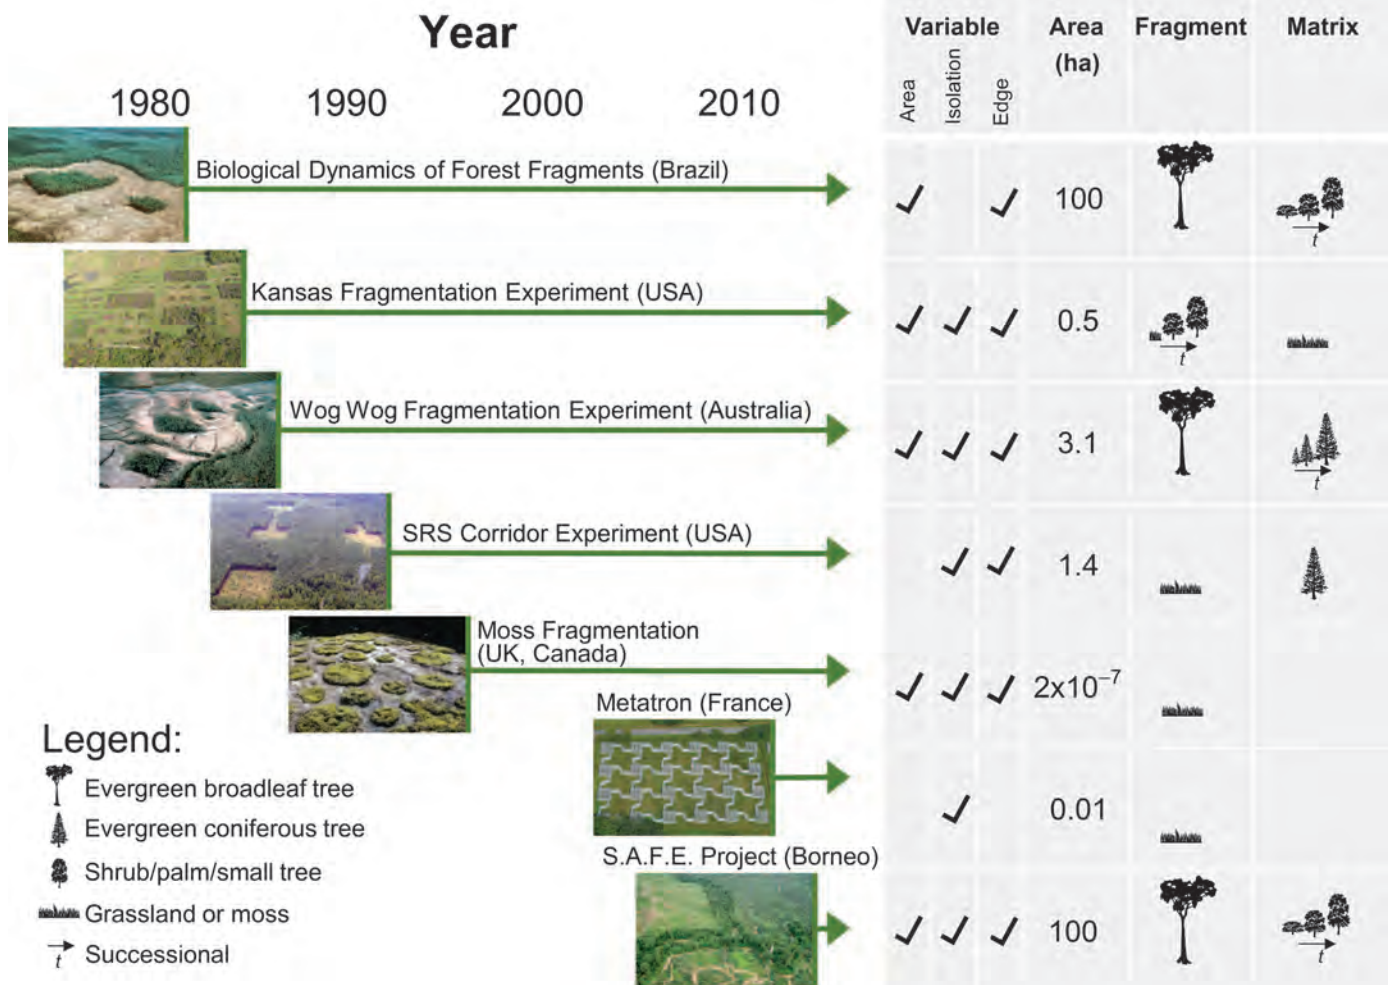

Robust knowledge of how habitat fragmentation affects biodiversity and ecosystem processes is needed if we are to comprehend adequately the implications of this global environmental change.

**THE VALUE OF LONG-TERM FRAGMENTATION EXPERIMENTS**

Long-term experiments are a powerful tool for understanding the ecological consequences of fragmentation (20). Whereas observational studies of fragmented landscapes have yielded important insights (9, 21), they typically lack rigorous controls, replication, randomization, or baseline data. Observational studies have limited ability to isolate the effects of fragmentation from concomitant habitat loss and degradation per se (4, 7, 22). Remnant fragments are embedded in different types and qualities of surrounding habitat, complicating interpretation because the surrounding habitat also influences biodiversity and ecosystem productivity (23).

The long-term fragmentation experiments we analyze here comprise the entire set of ongoing terrestrial long-term experiments. They

occur in several biomes (Fig. 2 and Supplementary Materials) and were designed to manipulate specific components of fragmentation—habitat size, isolation, and connectivity—while controlling for confounding factors such as the amount of habitat lost across a landscape (Fig. 2). The largest fragments across these experiments match the size of fragments commonly created by anthropogenic activities (Figs. 1 and 2). Distances to the edge of experimental fragments range to 500 m, encompassing edge distances found in more than half of forests worldwide (Fig. 1B). In each experiment, different fragmentation treatments with replication were established, starting from continuous, nonfragmented landscapes and controlling for background environmental variation either by experimental design (blocking) or by measurement of covariates for use in subsequent analyses. Tests were conducted within fragments that varied experimentally in area or edge, within fragments that were experimentally isolated or connected, or within experimental fragments compared to the same area within continuous habitat. All treatments were replicated. Experiments were created by destroying or creating precise amounts of habitat across replicate landscapes, allowing tests of fragmentation effects independent of habitat loss. The robust

**Fig. 2. The world’s ongoing fragmentation experiments.** All experiments have been running continuously since the time indicated by the start of the associated arrow (with the exception of the moss fragmentation experiment, which represents a series of studies over nearly two dec-

ades). The variables under study in each experiment are checked. The area is that of the experiment’s largest fragments. Icons under “Fragment” and “Matrix” indicate the dominant community and its relative height, with multiple trees representing succession.

and comparable experimental designs allow for powerful tests of the mechanisms underpinning the ecological impacts of fragmentation, and the long-term nature of ensuing studies has revealed consistent emergent effects.

These experiments mimic anthropogenic fragmentation; they are whole-ecosystem manipulations in which all species and processes experienced the same treatment (24). Emergent responses thus reflect the multiple direct and indirect effects of interacting species and processes. Further, because experimentally fragmented ecosystems are open to fluxes of individuals and resources, fragmentation effects can manifest across multiple levels of ecological organization (Fig. 3). Long-term experiments have the power to detect lagged and/or chronic impacts.

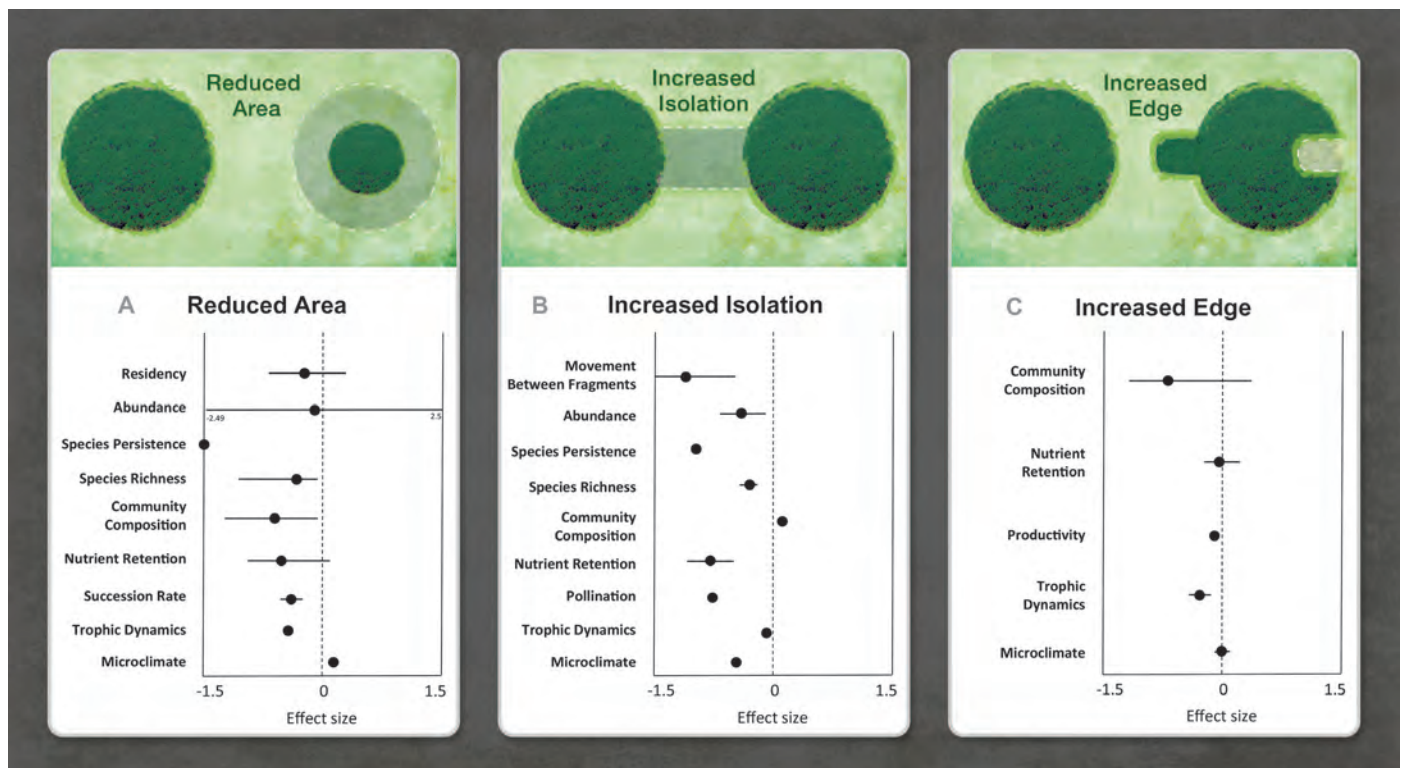

The first fragmentation experiments, now more than three decades old, were created to test effects of fragment area on both species persistence and patterns of immigration, reflecting concern in conservation biology about the role of fragmentation in reducing population sizes below viable levels (25) (Fig. 2). Subsequent experiments, created two decades ago, shifted focus to modifying habitat isolation, reflecting recognition of the potential to mitigate negative effects of fragmentation by recreating habitat—specifically with corridors—to increase connectivity among fragments (26) (Fig. 2). The newest experiments test emerging questions about potentially deleterious synergies between fragmentation and global changes in climate and land use (Fig. 2).

We synthesized results available 31 January 2014 for all studies within these experiments that were conducted in all treatments and replicates, and tested fragmentation effects on dispersal, abundance, extinction, species richness, community composition, and ecosystem functioning. We first calculated effect sizes of fragmentation as log response ratios (Fig. 3). Data from 76 different studies across the five longest-running experiments were drawn from published and unpublished sources (table S1). We synthesized results according to three fragmentation treatments: reduced fragment area [the focus of Biological Dynamics of Forest Fragments Project (BDFFP), Wog Wog, and Kansas; see Fig. 2 for identifiers of experiments], increased fragment isolation [Savannah River Site (SRS) and Moss], and increased proportion of edge (all experiments). Fragmented treatments were compared directly to non- or less-fragmented habitats that were either larger or connected via structural corridors (table S1).

### Strong, consistent, and accumulating effects of habitat fragmentation

Our synthesis revealed strong and consistent responses of organisms and ecosystem processes to fragmentation arising from decreased fragment area, increased isolation, and the creation of habitat edges (Fig. 3).

Community and ecosystem responses emerge from observed responses at the level of populations. Reduced area decreased animal

**Fig. 3. Fragmentation effects propagate through the whole ecosystem.** (A to C) For each fragmentation treatment [reduced area in BDFFP, Wog Wog, Kansas (A); increased isolation in SRS and Moss (B); and increased edge in all experiments (C)], we summarize major findings for ecological processes at all levels of ecological organization. Each dot represents the mean effect size [computed as log response

ratio:  $\ln(\text{mean in more fragmented treatment}/\text{mean in non- or less-fragmented treatment})$ ] for an ecological process. Effect sizes are statistical, such that negative or positive values could represent degrading function. Horizontal bars are the range when a dot is represented by more than one study. Details, including individual effect sizes for each study, are reported in table S1.

residency within fragments, and increased isolation reduced movement among fragments, thus reducing fragment recolonization after local extinction (Fig. 3, A and B). Reduced fragment area and increased fragment isolation generally reduced abundance of birds, mammals, insects, and plants (Fig. 3, A and B). This overall pattern emerged despite complex patterns of increases or declines in abundance of individual species (Fig. 3A) with various proximate causes such as release from competition or predation, shifts in disturbance regimes, or alteration of abiotic factors (14, 27–29). Reduced area, increased isolation, and increased proportion of edge habitat reduced seed predation and herbivory, whereas increased proportion of edge caused higher fledgling predation that had the effect of reducing bird fecundity (represented together as trophic dynamics in Fig. 3, A to C). Perhaps because of reduced movement and abundance, the ability of species to persist was lower in smaller and more isolated fragments (Fig. 3, A and B).

As predicted by theory (6, 30, 31), fragmentation strongly reduced species richness of plants and animals across experiments (Fig. 3, A and B), often changing the composition of entire communities (Fig. 3, A to C). In tropical forests, reduced fragment size and increased proportion of edge habitat caused shifts in the physical environment that led to the loss of large and old trees in favor of pioneer trees (Fig. 3, A and C), with subsequent impacts on the community composition of insects (32). In grasslands, fragment size also affected succession rate, such that increased light penetration and altered seed pools in smaller fragments impeded the rate of ecological succession relative to that of larger fragments (33) (Fig. 3A).

Consistently, all aspects of fragmentation—reduced fragment area, increased isolation, and increased edge—had degrading effects on a disparate set of core ecosystem functions. Degraded functions included reduced carbon and nitrogen retention (Fig. 3, A to C), productivity (Fig. 3C), and pollination (Fig. 3B).

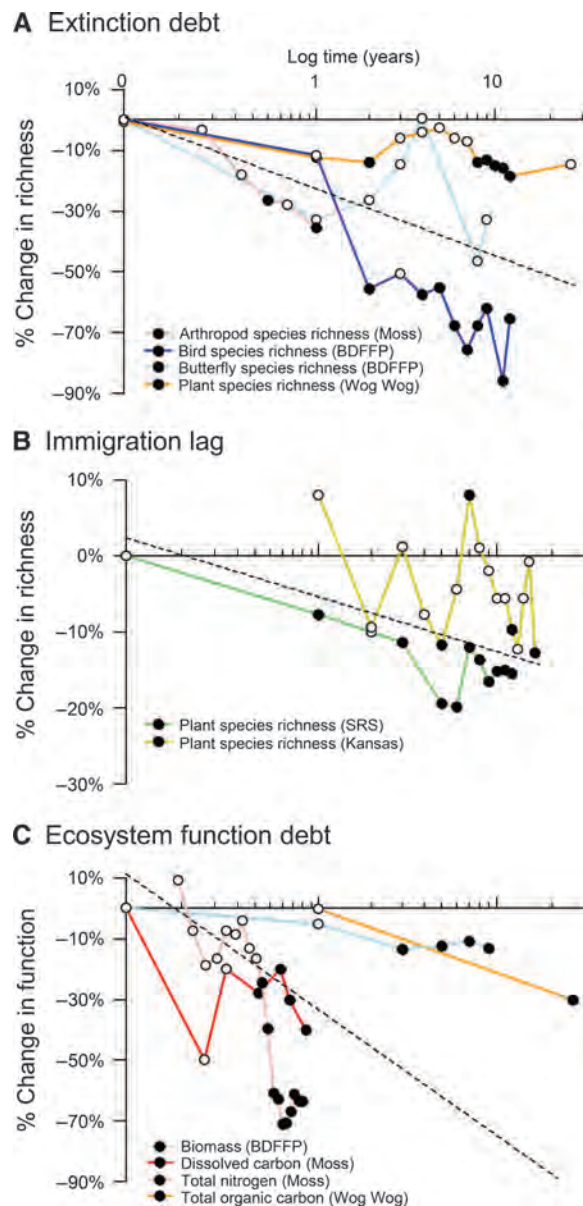

In summary, across experiments spanning numerous studies and ecosystems, fragmentation consistently degraded ecosystems, reducing species persistence, species richness, nutrient retention, trophic dynamics, and, in more isolated fragments, movement.

### Long-term consequences of fragmentation

To synthesize all time series of species richness and ecosystem functioning gathered across experiments, we measured effects of fragmentation over the course of each study. The effect of fragmentation was calculated over time as the proportional change in fragmented relative to non- or less-fragmented treatments (Fig. 4).

In most cases, the large and consistent effects of fragmentation revealed by the experiments were predicted from theory. However, we were struck by the persistence of degradation to biodiversity and ecosystem processes and by the increase in many of the effects over time (Fig. 4). For example, extreme rainfall events at Wog Wog appeared to delay the decline in plant species richness for 5 years after fragmentation. In the Kansas Experiment, a lag of 12 years occurred before fragmentation effects on plant succession were detected. Our results thus reveal long-term and progressive effects of fragmentation and provide support for three processes proposed by recent studies in spatial ecology: extinction debt, immigration lag, and ecosystem function debt (Fig. 4).

First, we found strong evidence for temporal lags in extinction [that is, “extinction debt” (30)] in fragments. Species richness of plants, arthropods, and birds sampled in the experiments conducted in mature forest fragments and replicated moss landscapes showed decreases of

**Fig. 4. Delayed effects of fragmentation on ecosystem degradation.**

(A) The extinction debt represents a delayed loss of species due to fragmentation. (B) The immigration lag represents differences in species richness caused by smaller fragment area or increased isolation during fragment succession. (C) The ecosystem function debt represents delayed changes in ecosystem function due to reduced fragment size or increased isolation. Percent loss is calculated as proportional change in fragmented treatments [for example, (no. of species in fragment – no. of species in control)/(no. of species in control) × 100]. Fragments and controls were either the same area before and after fragmentation, fragments compared to unfragmented controls, or small compared to large fragments. Filled symbols indicate times when fragmentation effects became significant, as determined by the original studies (see table S2). Mean slopes (dashed lines) were estimated using linear mixed (random slopes) models. Mean slope estimates (mean and SE) were as follows: (A) –0.22935 (0.07529); (B) –0.06519 (0.03495); (C) –0.38568 (0.16010).

20 to 75% after fragmentation (Fig. 4A). Some declines were evident almost immediately after fragmentation, whereas others increased in magnitude over the experiment's duration. Across experiments, average loss was >20% after 1 year, >50% after 10 years, and is still increasing in the longest time series measured (more than two decades). The rate of change appears to be slower in larger fragments [in BDFFP, 50% decline in bird species after 5 years in 1-ha fragments, but after 12 years in 100-ha fragments; in Moss, 40% decline in arthropod species richness of small fragments and 26% reduction in large fragments after 1 year (34, 35)]. As predicted by theory (36), the extinction debt appears to take longer to pay in larger fragments.

Second, we observed that reduced richness was coincident with an "immigration lag" (37), whereby small or isolated fragments are slower to accumulate species during community assembly (33, 38) (Fig. 4B). Immigration lags were observed in experiments conducted in successional systems that were initiated by creating new habitat fragments, rather than by fragmenting existing habitats. After more than a decade, immigration lags resulted in 5% fewer species after 1 year, and 15% fewer species after 10 years in small or isolated fragments compared to large or connected fragments (Fig. 4B).

Third, we observed an ecosystem function debt caused by fragmentation (39) in forest and moss fragments (Fig. 4C). An ecosystem function debt is manifest both as delayed changes in nutrient cycling and as changes to plant and consumer biomass. Loss of function amounted to 30% after 1 year, rising to 80% after a decade in small and isolated fragments when compared to larger and more connected fragments (Fig. 4C). Functional debts can result from biodiversity loss, as when loss of nutrients and reduction in decomposition are caused by simplification of food webs. Alternatively, the impact is exhibited through pathways whereby fragmentation changes biotic (for example, tree density in successional systems) or abiotic conditions (for example, light regimes or humidity) in ways that alter and potentially impair ecosystem function [for example, biomass collapse in fragments; Figs. 3 and 4; altered nitrogen and carbon soil dynamics (40)].

### A new understanding of the effects of fragmentation

By testing existing theory, experiments play a pivotal role in advancing ideas and developing new theory. We draw on experimental evidence to highlight two ways that the understanding of fragmentation has been enriched by the interplay between long-term experiments and development of theory.

First, island biogeography (6) was among the earliest theories to predict extinction and immigration rates and patterns of species richness in isolated biotas, which were later used to predict the effects of fragmentation on these variables. Experiments in continental settings tested the theory and gave rise to fresh perspectives. For example, islands are surrounded by sea, a thoroughly inimical matrix for island-dwelling species. Habitat islands, or fragments, are surrounded by a matrix that may not be so unsuitable for some species. In terms of all of the ecological variables studied in our long-term experiments, our results support the conclusion that ecological dynamics in human-modified fragments are a stark contrast to the dynamics in intact habitats that remain. Observational studies that have devoted more detailed consideration to the countryside within which fragments are embedded explain the diversity of ecological responses in remaining fragments (41). At the same time as experiments supported the core predictions of classical theories about effects of fragment size and isolation (Figs. 3 and 4), they spurred and tested new theories such as metacommunity theory (42) to account

for variation in connectivity and habitat quality within and between fragments (33, 43–45), spatial dynamics (14, 46), and spatially varying interspecific interactions (47).

Second, experiments have demonstrated that the effects of fragmentation are mediated by variation in traits across species. More realistic predictions of community responses to fragmentation emerged after explicit consideration of species traits such as rarity and trophic levels (48, 49), dispersal mode (50–52), reproductive mode and life span (29, 53), diet (54), and movement behavior (55, 56). Increasingly, the simple theoretical prediction that fragmentation reduces species richness is being modified to account for species identity through models that focus on how species vary in their traits (4, 21, 36, 48, 57, 58). Consideration of traits may help to interpret variation around the overarching pattern that fragmentation consistently reduces species richness across many species and biomes (Figs. 3 and 4).

### A NEW GENERATION OF FRAGMENTATION EXPERIMENTS

New foci are emerging for studying ecosystem fragmentation, including (i) synergies between fragmentation and global changes, (ii) eco-evolutionary responses of species to fragmentation, and (iii) ecological responses to fragmentation in production landscapes—that is, ecosystems whose services are under extreme appropriation by humans (59).

First, conclusions from experiments thus far are likely to have been conservative because impacts from other environmental changes have been mostly excluded. Most forms of global change known to reduce population sizes and biodiversity will be exacerbated by fragmentation (58, 60), including climate change (61), invasive species (62, 63), hunting (64), pollution [including light, noise, and chemicals (65)], and altered disturbance regimes (66).

More complex experiments with unparalleled control and capacity to simultaneously manipulate fragmentation and other global changes are now under way (53). The Metatron, created in 2011 in southern France (67), enables ecologists to assess effects of variation in temperature and other abiotic factors in addition to habitat isolation. The SAFE Project is being created in the rainforest of Borneo (68) and will embed a fragmentation experiment within a production agricultural plantation in which poaching will occur. Other synergies should be investigated experimentally, including the interaction between fragmentation and hunting, fire, infectious disease outbreaks, or nitrogen deposition. Within these experiments, fragmentation and loss of habitat can then be varied independently.

Second, current experiments have stopped short of examining how fragmentation drives evolution through genetic bottlenecks, ecological traps, changing patterns of selection, inbreeding, drift, and gene flow (69–72). Extensive fragmentation has occurred over many years, and in some regions over millennia (11). Changes caused by fragmentation undoubtedly lead to altered patterns of selection and trait evolution. Evolutionary responses to fragmentation have already been suggested (73, 74), and it is likely that such changes will, in turn, feed back to influence population persistence and ecosystem resilience in fragmented landscapes. Linking long-term experiments with the tools of landscape genetics (75) may provide powerful insights into the evolutionary dynamics of species inhabiting fragmented landscapes.

Third, new experiments should address the management of natural habitats in production landscapes by monitoring vegetation, networks of interacting species, and ecosystem services at ecologically relevant

spatial and temporal scales (76–78). Some ecosystem services have global consequences, for example, local carbon sequestration affects global atmospheric CO<sub>2</sub>. However, in many cases the benefits obtained by people depend on their proximity to habitat fragments (79). For example, crop pollination and biological pest control from natural areas adjacent to farms are made available by the very process of habitat fragmentation, bringing people and agriculture closer to those services. Yet, further fragmentation reduces access to many services and ultimately may push landscapes past tipping points, beyond which essential ecosystem services are not merely diminished but lost completely (80). This complex relationship creates a double-edged sword, for which locally optimal levels and arrangements of habitat must be sought. New fragmentation experiments should consider how multiple fragments in a landscape interact, creating an ecological network in which the collective benefit of ecosystem services may be greater than the sum of services provided by individual fragments (81, 82). Experimental inferences may then be tested beyond their spatiotemporal domains and, if successful, extrapolated across scales. Such research will be aided by satellite monitoring of ecosystems and human land use across the globe. The most powerful research programs will integrate experiments, observational studies, air- and space-borne imaging, and modeling.

## CONCLUSIONS

Fragmentation experiments—some of the largest and longest-running experiments in ecology—provide clear evidence of strong and typically degrading impacts of habitat fragmentation on biodiversity and ecological processes. The findings of these experiments extend to a large fraction of the terrestrial surface of the Earth. Much of the Earth's remaining forest fragments are less than 10 ha in area, and half of the world's forest is within 500 m of the forest edge—areas and distances matched to existing long-term experiments (Figs. 1 and 2) from which consistent effects of fragmentation have emerged (Figs. 3 and 4).

Reduced fragment area, increased isolation, and increased edge initiate changes that percolate through ecosystems (Fig. 3). Fragmentation has the capacity to generate persistent, deleterious, and often unpredicted outcomes, including surprising surges in abundance of some species and the pattern that long temporal scales are required to discern many strong system responses. In light of these conclusions and ongoing debates, we suggest that fragmentation's consistency, pervasiveness, and long-term degrading effect on biodiversity and ecosystem function have not been fully appreciated (9).

Without gains in yield and efficiency of agricultural systems (83), the expansion of human populations will inevitably continue to reduce and fragment natural areas. The area of Earth's land surface devoted to cropland already occupies 1.53 billion hectares (83) and may expand 18% by the middle of this century (84), and the area committed to urban centers is predicted to triple to 0.18 billion hectares by 2030 (85). The capacity of the surviving forests and other natural habitats to sustain biodiversity and ecosystem services will hinge upon the total amount and quality of habitat left in fragments, their degree of connectivity, and how they are affected by other human-induced perturbations such as climate change and invasive species. Long-term experiments will be even more needed to appreciate, explain, and predict long-term effects. New efforts should work in concert, coordinating a network of experiments across ecosystems and spatial extents.

The effects of current fragmentation will continue to emerge for decades. Extinction debts are likely to come due, although the counteracting immigration debts may never fully be paid. Indeed, the experiments here reveal ongoing losses of biodiversity and ecosystem functioning two decades or longer after fragmentation occurred. Understanding the relationship between transient and long-term dynamics is a substantial challenge that ecologists must tackle, and fragmentation experiments will be central for relating observation to theory.

Experimental results to date show that the effects of fragmentation are strong and markedly consistent across a diverse array of terrestrial systems on five continents. Increasingly, these effects will march in concert with other global changes. New experiments should be coupled with emerging technologies, landscape genetics, and detailed imagery of our planet, and should be coordinated with current ecological theory to understand more deeply the coupled dynamics of ecological and social systems. These insights will be increasingly critical for those responsible for managing and prioritizing areas for preservation and ecological restoration in fragmented landscapes.

### ABSTRACT

Climate change creates new challenges for biodiversity conservation. Species ranges and ecological dynamics are already responding to recent climate shifts, and current reserves will not continue to support all species they were designed to protect. These problems are exacerbated by other global changes. Scholarly articles recommending measures to adapt conservation to climate change have proliferated over the last 22 years. We systematically reviewed this literature to explore what potential solutions it has identified and what consensus and direction it provides to cope with climate change. Several consistent recommendations emerge for action at diverse spatial scales, requiring leadership by diverse actors. Broadly, adaptation requires improved regional institutional coordination, expanded spatial and temporal perspective, incorporation of climate change scenarios into all planning and action, and greater effort to address multiple threats and global change drivers simultaneously in ways that are responsive to and inclusive of human communities. However, in the case of many recommendations the how, by whom, and under what conditions they can be implemented is not specified. We synthesize recommendations with respect to three likely conservation pathways: regional planning; site-scale management; and modification of existing conservation plans. We identify major gaps, including the need for (1) more specific, operational examples of adaptation principles that are consistent with unavoidable uncertainty about the future; (2) a practical adaptation planning process to guide selection and integration of recommendations into existing policies and programs; and (3) greater integration of social science into an endeavor that, although dominated by ecology, increasingly recommends extension beyond reserves and into human-occupied landscapes.

## 1. Introduction

Climate change poses major new challenges to biodiversity conservation. As atmospheric CO<sub>2</sub> increases over the next century, it is expected to become the first or second greatest driver of global biodiversity loss (Sala et al., 2000; Thomas et al., 2004). Global average temperatures have increased 0.2 °C per decade since the 1970s, and global average precipitation increased 2% in the last 100 years (IPCC, 2007a). Moreover, climate changes are spatially heterogeneous. Some locations, such as the Arctic, experience much larger changes than global means, while others are exposed to secondary effects like sea level rise (IPCC, 2007a). Climate change may have already resulted in several recent species extinctions (McLaughlin et al., 2002; Pounds et al., 2006). Many species ranges have moved poleward and upward in elevation in the last century (Parmesan and Yohe, 2003; Root et al., 2003) and will almost certainly continue to do so. Local communities are disaggregating and shifting toward more warm-adapted species (Parmesan, 2005). Phenological changes in populations, such as earlier breeding or peak in biomass, are decoupling species interactions (Walther et al., 2002).

These changes raise concerns about the effectiveness of existing biodiversity protection strategies (Halpin, 1997; Hannah et al., 2002; Peters and Darling, 1985; Scott et al., 2002). Biodiversity conservation relies predominately on fixed systems of protected areas, and the mandated goals of many conservation agencies and institutions are to protect particular species assemblages and ecosystems within these systems (Lemieux and Scott, 2005; Scott et al., 2002). With the magnitude of climate change expected in the current century, many vegetation types and individual species are expected to lose representation in protected areas (Araujo et al., 2004; Burns et al., 2003; Lemieux and Scott, 2005; Scott et al., 2002). Reserves at high latitudes and high elevations, on low-elevation islands and the coast, and those with abrupt landuse boundaries are particularly vulnerable (Sala et al., 2000; Shafer, 1999). Landscapes outside of protected areas are hostile to the survival of many species due to human infrastructure and associated stressors, such as invasive species, hunting, cars, and environmental toxins. Such fragmentation directly limits species migration and gene flow. Projected rates of climate change are also faster than they were in the past – so rapid that in situ genetic adaptation of most populations to new climate conditions is not likely

(Jump and Penuelas, 2005), nor is migration likely to be fast enough for many species (Davis and Shaw, 2001). Moreover, even if major global action reduced emissions significantly within the next years or capped them at year 2000 levels, the thermal inertia of the oceans will continue to drive climate change for decades and will require adaptive responses (Meehl et al., 2005; Wigley, 2005). A recent update of atmospheric CO<sub>2</sub> growth rate, which has more than doubled since the 1990s as global economic activity increases and becomes more carbon-intensive, makes clear that significant global emissions reductions are a distant goal at best (Canadell et al., 2007).

How should we modify our biodiversity protection strategies to deal with climate change? Here we focus on adaptation strategies. Adaptation is broadly defined as adjustment in human or natural systems, including structures, processes, and practices (IPCC, 2007b). Scientists have written about adaptation with increasing frequency over the last two decades, but developments in this area have progressed slowly. For years, emissions mitigation has largely been the only game in town, with little governmental or private support for climate change adaptation. For instance, the United States National Park Service (NPS) in collaboration with the Environmental Protection Agency (EPA) has created a ‘Climate Friendly Park’ program. It aims to reduce greenhouse gas emissions, but it does not include measures or incentives to park managers to build and test adaptation strategies to preserve biodiversity under climate change. In many ways, adaptation science has begun to develop only very recently in response to recent widespread acceptance by governments and private citizens of the certainty of climate change.

In this paper we review the growing, published literature specifically addressed at biodiversity management and adaptation in the face of climate change. We consider biodiversity to include all types of organisms at all scales, from genes to ecosystems. The genesis for our review was the 2006 annual meeting of the California Invasive Plant Council, where climate change was identified by both researchers and practitioners as a key issue for action. Discussions throughout the meeting, however, made clear that practitioners felt at a loss for practical steps to take. Managers working at local preserves were particularly uncertain about what, if anything, they could do to prepare for climate change. We use this review in order to highlight what actions and actors scientists have so far identified to address climate change, and to

explore how recommendations inform an adaptation planning process at various management scales. Scott and Lemioux (2005) reviewed a similar literature but focused on park management. Here we explore adaptation planning across scales and in both protected and unprotected areas.

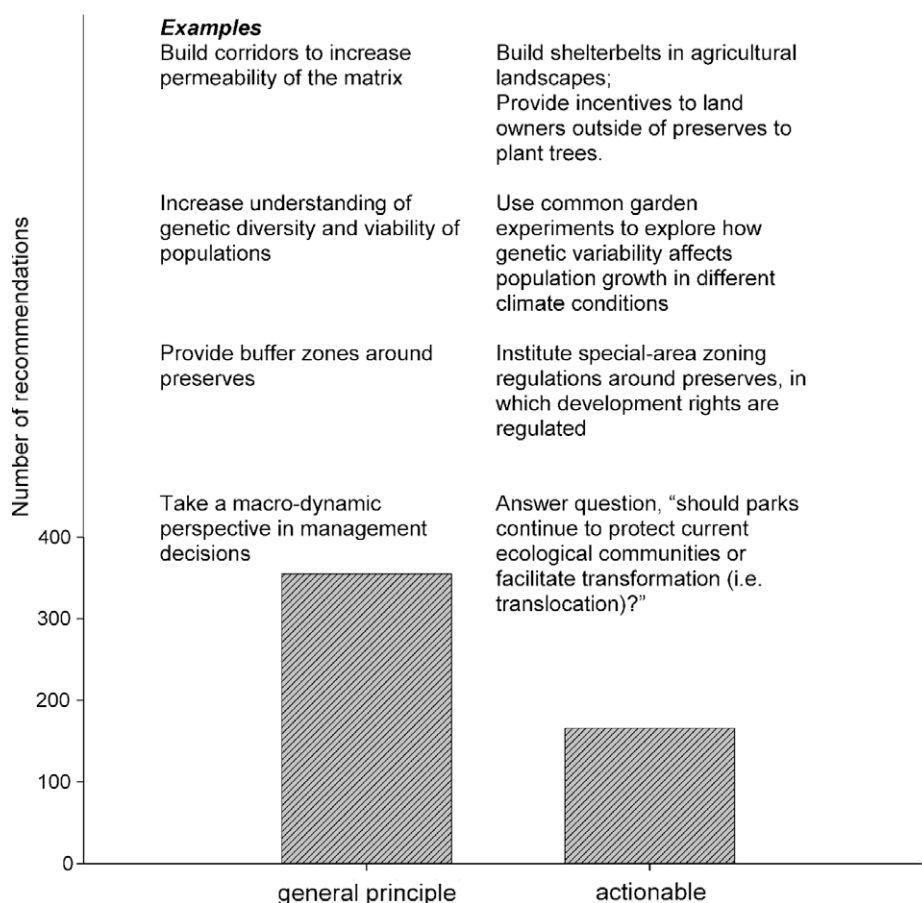

## 2. Methods

We used Web of Science, including Science Citation Index Expanded, Social Science Citation Index, and Arts and Humanities Citation databases from 1975 to March 2007, to search for published journal articles on climate change and biodiversity management. We used the search terms “climate change”, “global warming”, “climatic change”, “climate-change” and “changing climate” in all possible combinations with the search string “management OR biodiversity OR adaptation OR conservation OR restoration OR planning OR reserve design OR strategy OR land-use OR landuse OR landscape OR protected area OR park”. Articles that discussed strategies for both biodiversity and related ecosystem services were included, but we excluded articles that only addressed ecosystem services such as management strategies for carbon stocks, human infrastructure, and food security. We also did not attempt to review studies that explore climate

impacts on ecosystem components and processes without making explicit recommendations for biodiversity management. This literature is large and has been reviewed elsewhere (Kappelle et al., 1999; McCarty, 2001; Walther et al., 2002). From these searches, we identified and read 281 prospective articles, and from these culled those that provided explicit recommendations for management in the face of climate change. An additional four articles published after March 2007 were included, which were found through personal communication.

To analyze recommendations, we created a database in which we recorded every recommendation for action or information in the exact language used in the paper and answered a series of questions designed to synthesize recommendations and identify biases in the literature to date. We asked:

- (1) *In what formal and informal contexts does action need to occur?* To answer this question, we categorized recommendations into broad spheres of activity: (1) policy reform, (2) science and technology effort and advances, (3) changes in conservation sector activity including restoration, or (4) changes in individual and community behavior, such as by farmers, ranchers, and other private landowners.

**Fig. 1 – Examples and distribution of recommendations classified as “general principle” and “actionable”. Most recommendations offer general principles for climate change adaptation but lack specificity needed for implementation.**

- (2) *What is the basis for the recommendation?* We recorded what information an author used to formulate their recommendation. Categories included empirical experimental data, simulation, literature review, case studies, interviews, or workshops. We also included the term ‘ecological reasoning’ to encompass studies based predominately on theory and opinion.
- (3) *Is the recommendation a general principle or actionable?* A recommendation was considered a “general principle” if it provided a guiding concept, such as “build flexibility”, but was generic open-ended and without example of who should act or what one should do (see Fig. 1). “Actionable” was given to those recommendations that identified a very clear who and what and often gave examples, such as, “[in restoration] use a broader range of species than prescribed solely on local basis to build system resilience (Harris et al., 2006)”.
- (4) *Is the recommendation for biodiversity or for biodiversity and related ecosystem services?*
- (5) *Is there a geographic context for the recommendation?*
- (6) *Does the article focus on a biome or ecosystem-type?*
- (7) *Where in the landscape would the recommendation apply?* We categorized recommendations as applying to reserve (any public or private land-holding dedicated to biodiversity protection and maintenance, synonymous with protected area), or human-use lands (the matrix), or non-specific, meaning the recommendation could be enacted in either reserve or matrix land.
- (8) *Does the recommendation describe an information need or a necessary action?* All recommendations for research were categorized as information needs, while the ‘action’ category included recommendations such as building corridors, reforming policy or buying more land.

To minimize variation in how articles were classified as a function of when they were read (i.e. the 1st paper entered compared to the 100th), records in the database were periodically shuffled by different criteria (i.e. year published or geographic context) and then re-classified. In addition, both authors coded a sub-sample of recommendations. After compiling the database, similar records were grouped into ‘recommendation’ categories. We tabulated the most common recommendations and ranked them by frequency cited overall.

### 3. Results and discussion

We recorded 524 recommendations from 113 papers, published in 57 different source journals and three books. Recommendations ranged from calls for specific types of modeling (e.g. inexact-fuzzy multiobjective programming (Huang et al., 1998) to broad shifts in governance structures (Tompkins and Adger, 2004) (Table 1). The number of papers published on this topic has increased dramatically in recent years (Fig. 2). Thirty-three percent of recommendations addressed biodiversity protection in conjunction with related ecosystem services, including forest products, fisheries and hunting, agriculture and grazing, and human health. Recommendations call for research, leadership and reform by a

range of actors in several sectors; Emphasis in this set of literature is on science and nature conservation rather than on social or political adaptation measures (Fig. 3), with an emphasis somewhat more focused on reserve land over the matrix (Fig. 4a). Action is weighted more than information needs (Fig. 4b). When information needs were identified, they were overwhelmingly calls for more ecological rather than social scientific data (Fig. 4c). Recommendations are biased toward North America and Europe (Fig. 5a) and forests ecosystems (Fig. 5b).

Recommendations address various stages in an adaptation process, from research needs to methods for impact assessments to large-scale changes in policies by governmental, academic or non-governmental institutions (Table 1). About 70% of recommendations were classified as general principles under our classification scheme rather than specific, actionable strategies or tactics (Fig. 1). For example, seven authors suggest flexibility in management approaches, but only Millar et al. (2007) suggest flexibility and follow with a definition of what that means: willingness to change course, risk-taking including doing nothing, and capacity to reassess conditions frequently. Climate change adaptation work, at least in this literature, is still largely at the “idea” stage – it is based predominately on ecological reasoning rather than specific research, case studies, or empirical data (Fig. 5c), and it is largely nonspecific in the geographic areas or biome types that it targets (Fig. 5a and b). Many articles based on concrete modeling work or empirical studies of species responses to climate change tended either to not elaborate their results to management directives, or to present recommendations in vague terms such as, “restoration should be considered”. Alternatively, very specific recommendations were proposed and not generalized for use outside of the target system. There appears to be a need for a happy medium between highly specific recommendations useful only in target areas and highly generalized recommendations that fail to inspire application (Halpin, 1997). This happy medium is likely to emerge rapidly as climate change adaptation science grows.

In the literature reviewed here, few recommendations suggested a process a manager could use to develop an adaptation plan and evaluate its usefulness (but see Hannah et al., 2002). More information on adaptation frameworks are developed in reports by Parks Canada (Welch, 2005), the NCEAS Conservation and Climate Change Working Group 2 (personal communication), and England’s Department for Food Environment and Rural Affairs (<http://www.defra.gov.uk/wildlife-countryside/resprog/findings/ebs-climate-change.pdf>), which were not reviewed here. In practice, planners and managers could apply recommendations in at least three ways. At the broadest scale, long-term planning and policy formulation should tackle adaptation for whole landscapes and regions, with tools like reserve selection, ecosystem management, and landuse zoning schemes. Second, managers of individual reserves might want to know what they can do at their sites, individually or in concert with other sites. Third, rather than initially pursuing an idealized regional, landscape, or site-scale plan, the first practical step for many managers, conservation stakeholders and policymakers is to evaluate and adapt existing conservation plans. In the following

**Table 1 – List of recommendations for climate change adaptation strategies for biodiversity management assembled from 112 scholarly articles. 524 records were condensed into 113 recommendation categories and are ranked by frequency of times cited in different articles.**

Rank	Recommendation	No. articles	References

	Use simple decision rules for reserve planning	1	Meir et al. (2004)
	Use social networks for education about climate change	1	Huang (1997)
	Use triage in short-term to prioritize action	1	Millar et al. (2007)

sections, we discuss how recommendations in the literature to date inform these three scales of application.

#### 4. Regional policy and planning

Species historically respond to changing climate with distributional shifts, and many species are expected to lose current habitat representation in the future. In light of this, many recommendations call for greater integration of species protection plans, natural resource management, research and development agendas across wider geographic areas, on long-

er time-scales, and involving more diverse actors than in current practice. (1) Long-term, regional perspective and (2) improved coordination among scientists, land managers, politicians and conservation organizations at regional scales are among the most frequently cited recommendations to protect biodiversity in the face of climate change (Rank 10 and 6 respectively, see references in Table 1 and for all ranks mentioned hereafter). Increased interdisciplinary collaboration (Rank 9) as well as regional-scale impact assessments are also frequently identified (Rank 12). Recommendations for adaptation to regional policy and planning focus on two comple-

**Fig. 2 – Frequency distribution by publication year of papers included in this review, including articles addressing biodiversity only (black) or biodiversity in conjunction with ecosystem services (grey). Records from 2007 were only partially covered in this review and not included.**

**Fig. 3 – Distribution of recommendations calling for climate change adaptation among different activity sectors: conservation (e.g. reserve purchases, management, restoration and regional coordination), science and technology (e.g. research and modeling), policy (e.g. land-zoning, governance structure and institutional capacity), and individuals and communities (e.g. private landowner practices and grassroots action). Recommendations were counted in all applicable sectors.**

mentary strategies: reserve planning and improving landscape connectivity. We discuss these issues further in the following two sections.

#### 4.1. Reserve planning

Basing reserve acquisition priorities on predictions of future biome, community or individual species distributions under

different climate scenarios is one method for climate change adaptation. The guiding principle is that reserves should be accumulated in areas predicted to be hotspots for biodiversity in the future or to provide habitat for species of high conservation value, warranting increased effort to model species distributions in the future (Rank 12). There are, however, several limitations to the accuracy and precision of simulation and analytical models of future species, biome or community distributions, leading some authors to recommend improved modeling capacity as the first step (Rank 9).

Model prediction error results from variation in model types, emissions, landuse and socio-economic scenarios. There are little-understood, but important, interactions between climate change and other global change drivers that could influence where species and habitats occur in the future (Rank 9). Insufficient data on species distributions (Rank 10) the effects of species interactions on distribution (Ferrier and Guisan, 2006; Kappelle et al., 1999), dispersal (Rank 10) and species, community or ecosystem responses to climate change (Rank 4) are also widely expressed concerns and lead authors to advocate for increased research in these areas before models are accepted. For example, bioclimatic envelope modeling uses current species distributions to predict future distributions as a function of climate. For many species such models can be productive, but in cases where species distributions are limited by factors other than climate, this extrapolation will prove misleading. Willis and Birks (2006) discuss the accuracy of bioclimatic models. Species-envelope model runs were conducted for backward predictions of species distributions and compared to paleo-ecological records. Many species distributions were predicted well, but some were largely inaccurate.

Problems of scaling also raise uncertainty (Rank 6), including scaling-down global climate models (GCMs) to fit management scales, or scaling-up empirical observations typically made at small spatial scales to predict larger scale processes (Root and Schneider, 1995). The scales of global climate models (GCM) and management activities simply do not match. Most reserves are smaller than a single grid cell in a GCM. Climate can vary sharply within this scale, and this variation often drives local patterns of species distribution and abundance – particularly in mountainous or coastal areas. Regional climate models, which are only available for small areas of the globe, are a more appropriate choice for management and planning (Dale and Rauscher, 1994; Guisan and Thuiller, 2005; Kueppers et al., 2005; Mulholland et al., 1997), though they remain limited by key uncertainties, assumptions and costs (Root and Schneider, 1995).

Not surprisingly, these inherent limitations of bioclimatic envelope models generate debate about whether and how to apply them to reserve selection. Some strongly advocate including climate change in reserve selection models and locating new reserves with expected changes in climate (Araujo et al., 2004; Bush, 1996; Dyer, 1994; Pearson and Dawson, 2005). Araujo et al. (2004) compare the ability of six existing reserve selection methods to secure European plant species in the context of climate change. They found species loss from protected reserves on the order of 6–11% of taxa for all models, and they conclude that new reserve-selection models specific to climate change are needed. Hannah et al. (2007)

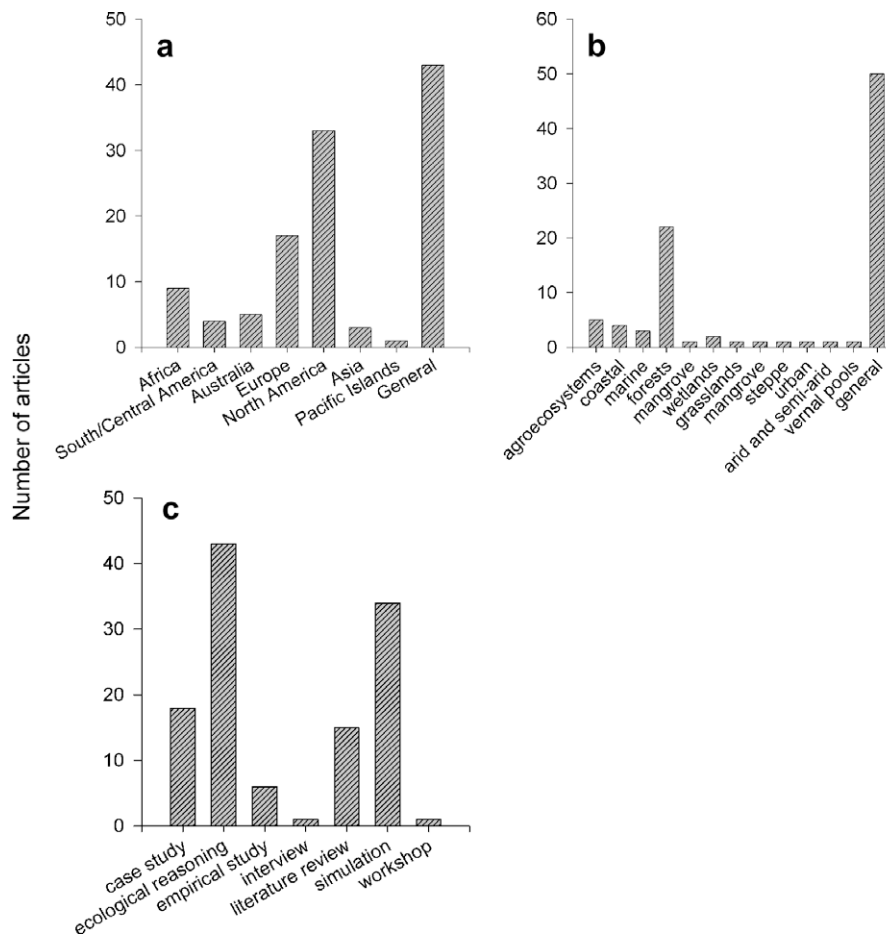

**Fig. 4 – Distribution of recommendations among broad categories referring to (a) type of land targeted, (b) information need or action, (c) type of information need, and (d) management goal. Y-axis ranges vary across graphs because not all recommendations fit into every set of categories.**

make a compelling case for not waiting to incorporate climate change forecasts into reserve selection models despite uncertainty. They use bioclimatic envelope models to explore the need for additional protected areas to achieve representation for thousands of species in three regions (Mexico, South Africa Cape, and Europe) in current and future climate and find that less land is needed in the long-term if planning models are designed to solve for both current and future conditions simultaneously.

Others argue, however, that given tremendous uncertainty, the priority should be to acquire new reserves in locations that minimize the spatial distances among new and existing reserves so that species can migrate (Allison et al., 1998; Collingham and Huntley, 2000; Halpin, 1997; Opdam and Wascher, 2004; Shafer, 1999). Williams et al. (2005) used a simulation model to estimate that 50% more protected land area in particular locations was needed to create reserve corridors to protect *Proteaceae* in the South African Cape region through 2050. Citing a number of sources of potential error in model results, however, they recommend that as much reserve area as possible be set aside. Such strategies do not require extensive modeling capacity and resources and instead focus on rapid acquisition of land as it becomes available to create porous landscapes. Other authors reason that to facilitate migration and adaptation potential, reserves should be

located with reference to focal species or community distributions, such as in their cores (Araujo et al., 2004; Halpin, 1997) or at their northern boundaries (Peters and Darling, 1985; Shafer, 1999). There seems to be little consensus or data to inform this debate. More research is needed about where in a species' range individuals are most likely to survive, migrate or adapt to rapid environmental change (Willis and Birks, 2006).

Debate also arises around the relative advantages of few large versus several small reserves in the context of climate change. The tension is whether large reserves will be large enough to allow species to track changing climate and remain inside reserve boundaries, and whether small preserves along latitudinal, elevational or other climate gradients will be close enough together for species to move between them. Eleven sources recommend protecting large areas (Beatley 1991; Bellwood and Hughes 2001; Burton et al. 1992; Bush 1996; Halpin 1997; Hulme 2005; Morecroft et al. 2002; Peters and Darling 1985; Shafer 1999; Soto 2001; Watson 2005), while two advocate focusing on many small areas (Opdam and Wascher, 2004; Pearson and Dawson, 2005). Eight suggest a compromise strategy of creating ecological networks of small and large reserves embedded within intermediate land uses (Allison et al., 1998; Collingham and Huntley, 2000; de Dios et al., 2007; Gaston et al., 2006; Opdam et al., 2006; Opdam and Wascher, 2004; Shafer, 1999; Welch, 2005).

**Fig. 5 – The (a) geographic focus, (b) biome focus, and (c) evidence basis for recommendations addressing climate change adaptation strategies for biodiversity management.**

What all of the recommendations for reserve selection share is an urge to protect more land rapidly (Rank 5). This push will certainly help buffer biodiversity against climate change as well as other threats. However, climate change is likely to exacerbate existing tensions and tradeoffs between protecting areas and meeting basic human needs. Creating more new reserves might be feasible in some settings but must be guided by targeted, well-informed strategies likely to maximize effectiveness in the face of climate change. In most areas, action in lands outside of reserves must also be a part of climate change strategies for biodiversity conservation (Franklin et al., 1992; Lovejoy, 2005).

#### 4.2. Landscape connectivity

To improve landscape connectivity, so that species can move, is the most frequent recommendation for climate change adaptation in the literature reviewed here (Rank 1). Authors recommend some form of corridor creation via the designation of new parks (de Dios et al., 2007; Halpin, 1997; Scott et al., 2002) oriented longitudinally (Eeley et al., 1999; Noss, 2001; Shafer, 1999), or through actions in non-reserve land, such as protecting riparian habitat and railway lines in cities (Wilby and Perry, 2006), or by planting trees and shrubs to cre-

ate shelterbelts and hedgerows in farmlands (Donald and Evans, 2006; Guo, 2000; Schwartz et al., 2001). There was little guidance in this literature set for corridor implementation beyond common-sense reasoning, however. Illustrative examples of current corridor projects or elaboration of specific ecological or political tactics for corridor creation might help jump-start this process. For example, case studies of the Dutch Ecological Network and other similar national models to plan and link protected areas may be particularly informative at this stage of adaptation planning (Gaston et al., 2006). Further, despite widespread favor for ecological networks, assessment of their effectiveness remains in its infancy. Similarly, the field of corridor ecology, while recognized as integral to conservation practice in fragmented landscapes for years, is still young (see Hilty et al., 2006). Some authors warn of a significant need for more empirical data to support the effectiveness of corridors, optimize their spatial arrangement, and minimize risks of increased transmission of disease or invasive species before the conservation community embraces corridors uniformly as the tool to combat biodiversity loss in the face of global climate change (Graham, 1988; Halpin, 1997; Scott and Lemieux, 2005; Williams et al., 2005).

A second popular recommendation for improving landscape connectivity is to change how we manage the matrix

(Da Fonseca et al., 2005; Eeley et al., 1999; Lovejoy, 2005). Many authors advocate creating buffer zones around reserves (Rank 8) or flexible landuse zoning at reserve boundaries to allow for land swaps in the future as species distributions shift (Rank 14). Others recommend urban planning and zoning to avoid climate-related risks (Rank 14). In general, enlisting people and human communities to ‘soften’ landuse through sustainable or less damaging practices (e.g. low intensity forestry or alternatives to building sea walls) (Rank 9) and to restore habitat (Rank 9) will facilitate species movement and persistence in the future.

Despite wide acknowledgement, these connectivity strategies were among the most poorly developed recommendations, limited mainly to very general actions (e.g. “build flexibility”, “manage the matrix”, “modify landuse practices”) without identification of kinds of actors that might need to be involved (e.g. reserve managers, policymakers, individuals) or information gaps. Landuse reform likely needs to bring together local governments, urban planners, community groups and conservation organizations and to involve high degrees of coordination across multiple jurisdictions to provide landscape cohesion (Press et al., 1995). Substantial work to flesh out this process, as well as to guide information acquisition, is needed before new forms of management across landuse types can be implemented.

Even with good landscape connectivity, some species will not be able to migrate. For these species – such as dispersal-limited species, those restricted to rare or confined habitat types, or those with life history traits like low reproductive rates – translocations from within their current range to locations suitable in the future are widely advocated (Rank 4). Translocations are a contentious issue because of the challenges associated with moving populations successfully and predicting suitable future habitats, as well as the potential for unintended consequences from introducing new species into existing communities (Lemieux and Scott, 2005; McLachlan et al., 2007). Empirical evidence suggests that animal translocations tend to be unsuccessful and costly (Fischer and Lindenmayer, 2000). Despite these real problems, we did not find discussion of the feasibility of such programs. Climate change adaptation strategies would likely necessitate moving at least some species outside of their current range, an action that has rarely been pursued thus far. To fully evaluate the feasibility of translocations would require stronger understanding of best available methods, potential risks, and policies for regional coordination to avoid situations in which different conservation objectives are put in conflict (McLachlan et al., 2007).

## 5. Site-scale action

Many land managers feel that there is little they can do about climate change beyond what they are already doing, such as trying to maintain basic ecosystem functioning and mitigate other threats like invasive species and pollution. To a certain extent, recommendations we reviewed validate this perspective. A number of “business as usual” recommendations rank high in their frequency in the literature, e.g. mitigating current threats, such as invasive species and habitat loss (Rank 2), increasing or continuing basic monitoring programs (Rank

7) or managing populations for natural disturbance dynamics (Halpin, 1997; Noss, 2001; Shafer, 1999). Franklin et al. (1992) describe how in forest ecosystems mature trees slow the effects of climate change because they tolerate a wide range of temperatures, while seedling establishment is far more sensitive. Under climate change, removal of long-lived trees will therefore act to intensify and speed-up the rate at which forest ecosystems change compared to intact forests. Restoration and greening efforts function as proactive management to mitigate local-scale warming (Halpin, 1997; Mulholland et al., 1997; Wilby and Perry, 2006). Mulholland et al. (1997) point out that restoration of riparian vegetation, needed to secure wildlife populations and ecosystem services now, will also function to decrease stream temperatures in the future. Wilby and Perry (2006) highlight how green building and landscaping techniques, such as planting green roofs, neighborhood trees, and water structures, will help to counter increasing problems of urban heat-island effects.

Other authors point out that business as usual is probably not enough in many cases. Peters and Darling (1985) suggest that managers consider rescue measures such as adding irrigation or drainage systems to secure sensitive populations. Buckland et al. (2001) anticipate that soil fertility in some grasslands may require manipulation to impede species invasions under warmer conditions. Advice to incorporate a broader range of species and genotypes in restoration and forestry than prescribed based on local provenance was common (Rank 11). This type of strategy would depart significantly from the preference for local genotypes prevailing in restoration and forestry practice to date (Millar and Brubaker, 2006; Millar et al., 2007; Scott and Lemieux, 2007) and warrants increased experimentation to better understand potential costs and benefits (Harris et al., 2006; Rice and Emery, 2003).

### 5.1. Resilience versus resistance

A first step for managers will be to wrestle with the question of whether and when they will attempt to resist biotic change, such as by adding irrigation if precipitation declines, rather than try to build resilience to change, such as by facilitating population adaptive capacity through introduction of a wider range of genotypes. In theory resistant strategies attempt to bolster a system’s defenses to rapid environmental change, while resilience strategies attempt to bolster a system’s ability to absorb rapid environmental change. More recommendations advocate resilience than resistance strategies (Fig. 4d). However, intensive management actions to protect historical species in their current distributions are widely advocated (Rank 4). The latter align best with a fixed-reserve approach focusing on local species precedence, an approach that will be increasingly costly and challenging to maintain as directional global changes accelerate.

For some species and systems, options other than intervention might not exist. Resistance approaches designed to maintain the status quo are nevertheless risky – they may leave systems vulnerable to total collapse if interventions are not maintained or compromise other system components (Harris et al., 2006; Walker et al., 2002). For example, the removal of invasive species has sometimes resulted in unpredicted and negative impacts to ecosystem structure and

function (Zavaleta et al., 2001). Managing for resilience (sensu Holling, 1973) on the other hand explicitly focuses on increasing the flexibility and ability of systems to adapt and self-organize in response to change. To build resilience to climate change into systems, however, may require radical shifts in perspective for many conservation stakeholders and re-evaluation of conservation goals (Rank 10). Land managers might need to view a broader range of ecosystem states as desirable, such as novel or dynamic local assemblages that maintain functioning and trophic complexity but not necessarily species identity (Hulme, 2005), or to re-evaluate operational definitions and guidelines, such as what constitutes an invasive species or when a species can be added to a risk list (Scott and Lemieux, 2005; Scott et al., 2002).

Examples of broad perspective shift are found in the restoration literature. Millar and Brubaker (2006) emphasize the use of paleo-ecological perspectives to guide restoration goals and interventions. They ask that managers and restoration practitioners “make friends with physical and climatic change,” arguing for instance that which species are deemed ‘natural’ or ‘invasive’ depends on the spatial and temporal resolution of data used to inform perspective. For example, Monterey pines (*Pinus radiata*) are considered native to a small region of California in which they were found at the time of European colonization. The species has since naturalized widely in California from landscaping plantings and is targeted for removal as an unwanted exotic in these regions. Paleo-ecological records of *P. radiata* reveal strong climate-driven dynamics in range, with widespread distribution during favorable periods and retreat during unfavorable periods. Millar and Brubaker (2006) suggest that naturalized populations be restored rather than removed in locations where *P. radiata* thrived when the climate was similar to the present or predicted future. Pearsall (2005) describes an experimental landscape-scale project in North Carolina, USA designed to test a range of restoration options for combating peat-land loss as a result of rising sea level. Options include oyster bed formation, dune formation, native plant establishment, as well as nonnative plant establishment. The experiment is scheduled to run for 25 years with regular evaluation intervals. Bradley and Wilcove (in press) imagine a “transformative restoration” in which the plant species used to repopulate restoration sites are determined by future climate conditions rather than historical presence. For example, based on results of bioclimatic envelope models, areas in the Great Basin ecoregion of the Western US may be restored best with plants introduced from the Mojave Desert, a more arid, neighboring biome. These projects share a broad, long-term and pragmatic perspective on acceptable restoration outcomes, one that may be necessary to tackle climate change.

A key strategy for building the adaptive capacity of systems is to enhance diversity at various scales. Diverse populations tend to be more adaptable, placing a premium on protecting and managing for high genetic diversity (Rank 13). Capturing the full range of bioclimatic variability within preserves and across landscapes and designing high species, structural, and landscape diversity into constructed and managed systems are also recommended (Rank 9). Pockets of outlier vegetation, areas of high endemism, ecotones, and refugia that protected species during climate shifts in the past

are anticipated to be important sources for species re-colonization and radiation in the future, as well as provide retreats for migrating or translocated species (Rank 12). Willis and Birks (2006) discuss methods that combine genetic and paleo-ecological evidence to identify sites with distinctive patterns of genetic diversity that resulted from past geological events and refugial isolation.

Resistance and resilience strategies are not mutually exclusive. Very special communities or organisms that are of high conservation value may warrant highly invasive, intense and costly management regimes to maintain them. Regimes for intensive management are likely to be implemented through existing threatened species management frameworks, such as recovery plans. For more widespread populations, communities and ecosystems, which often provide important ecosystem services, a focus on resilience might be most appropriate. At the site-scale, managers need to address a host of practical issues such as the cost and cost-effectiveness of adaptation options, their compatibility with existing regulatory and institutional constraints, and their likely effectiveness in the absence of coordination with adjoining private lands.

---

## 6. Adapting existing conservation plans

The existing literature does provide an array of actions for managers to build on and consider incorporating into existing conservation plans. A practical first step to climate change adaptation planning is to evaluate the likely outcomes for biodiversity of continuing current management and conservation directions. Most conservation policies and management plans do not yet explicitly consider climate change (Chambers et al., 2005; Groves et al., 2002; Hannah et al., 2002; Scott and Lemieux, 2007). A consistent theme in the literature is at the very least to immediately appraise current conservation and management practice in the context of climate change (Rank 2) with the goal of developing and adopting specific climate change adaptation policies in the near future (Rank 11). The literature here contained some suggestions for how to do this. A few articles emphasized the use of models to guide evaluation and adaptation of existing practices. For example, Christensen et al. (2004) used a simulation model to investigate a coupled system of plants and grazers in the Inner Mongolia Steppe under different climate scenarios. They determined that grasslands were likely to undergo a state-transition to shrublands if existing grazer densities are maintained, and they advocate reducing grazers in this area as well as in other semi-arid managed grassland systems. Hulme (2005) provided a general overview of how mathematical models can integrate long-term demographic and climate data to set climate change-appropriate harvest or stocking schedules or to forecast pest outbreaks.

Some authors highlight existing efforts that are well-suited to tackle climate change and warrant increased funding and research. Donald and Evans (2006) argue that agri-environment incentives and easement programs in the US and the EU, which are growing due to shifts in farm policies, warrant increased funding priority because of their potential to improve habitat availability and landscape connectivity across managed ecosystems. They discuss how these policies

could be modified to tackle climate change directly. Site-specific climate conditions and biotic responses could be mapped on to landscapes and used to prioritize locations for farm diversification. Similar gains could be made by targeting other private landowner biodiversity enrichment programs, like the USDA Forest Legacy Program (<http://www.fs.fed.us/spf/coop/programs/loa/flp.shtml>) or the National Wildlife Federation's Urban Backyard Wildlife Program (<http://www.nwf.org/gardenforwildlife/>).

6.1. Holistic strategies

Issues that currently challenge conservation practice may need to be addressed before the added stress of climate change complicates them further. Communities of local users are often in conflict with conservation objectives (Chan et al., 2007; Suffling and Scott, 2002). Identifying opportunities for reduced conflict and increased synergy between conservation and local communities will become more important as climate changes. A number of authors warn that conservation policies must create positive economic outcomes for local peoples to buffer them against potentially dramatic shifts in livelihoods that will accompany climate shifts (Rank 9). Adaptation requires community buy-in and participation (Chapin et al., 2006). To this end, conservation policies that foster learning and participation (Ramakrishnan, 1998) and provide options that are culturally and economically appropriate, such as those that honor traditional management systems and do not rely on expensive technologies, are more likely to be embraced and implemented (Rank 14). McClanahan et al. (2008) argue that climate-informed conservation planning necessitates site-specific understanding of environmental susceptibility and societal capacity to cope and adapt. They illustrate this process for five western Indian Ocean countries with respect to coral reef conservation. Locations with high environmental susceptibility and low adaptive capacity will be most difficult to secure effectively in the future, while those with low environmental susceptibility and

high adaptive capacity will be easiest. Locations with low environmental susceptibility and low adaptive capacity are good candidates for biodiversity investment, but to be effective these locations also require investments in human infrastructure, livelihood diversification and social capital.

Climate change is acting in concert with multiple other drivers of biodiversity loss including habitat degradation, soil loss, nitrogen enrichment, and acidification. Strong policies must simultaneously address more than one issue (Watson, 2005) or risk exacerbating environmental problems in the process of trying to combat them. Emission reduction programs are a significant push for many governments, organizations and individuals. They warrant an important place in any climate change combat strategy (Rank 13). A number of authors in this review urge, however, that emissions reduction programs and the Clean Development Mechanisms (CDMs) in the Kyoto Protocol be implemented in ways that simultaneously address carbon sequestration, biodiversity conservation and human livelihoods, rather than carbon sequestration in isolation (Rank 11).

Finally, climate change provides a much-needed impetus to evaluate how conservation policies respond to change in general. Climate change is only one of several global environmental trends to which biodiversity and its conservation must respond. Uncertainty in the climate change arena and about the future in general should not limit action to strengthen existing conservation strategies, with a focus on enhancing the ability of ecosystems to absorb and recover from rapid and unpredictable change.

7. A complete strategy

Climate change challenges conservation practice with the need to respond to both rapid directional change and tremendous uncertainty. Climate change adaptation therefore requires implementation of a range of measures, from short- to long-term and from precautionary and robust to more risky or deterministic, but specifically anticipatory (Fig. 6). To cer-

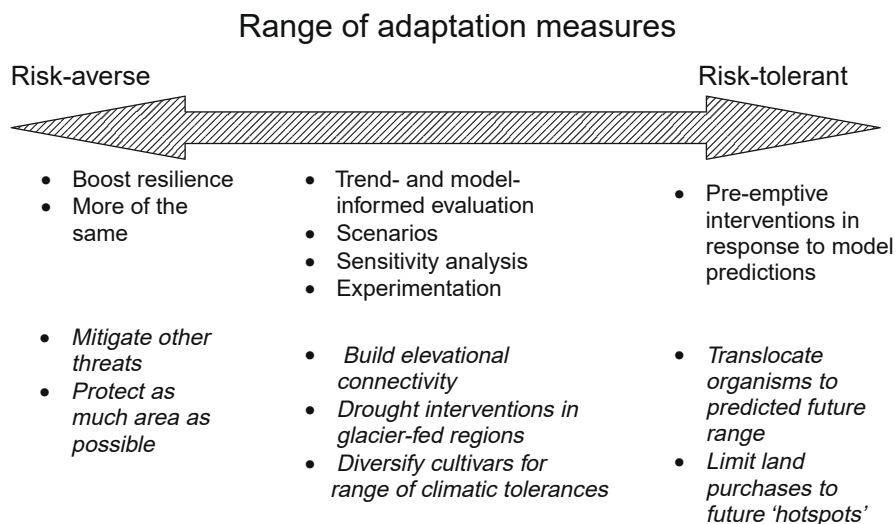

Fig. 6 – Adaptation measures classified along a risk continuum. Under each risk category are examples of general approaches followed by examples of specific adaptation measures. A complete strategy should span a risk continuum.

tain degree, risk tolerance of individual actors will guide strategy selection. Millar et al. (2007) discuss how managers must proactively decide whether to adopt deterministic or indeterministic approaches.

Each type of approach has benefits and drawbacks. Precautionary measures such as restoration, increased monitoring of species distribution, and increased investment in reserve protection do not necessarily require highly certain and precise climate change predictions, but such precautionary steps will help managers respond to current biodiversity threats as well as threats that emerge in the future. Precautionary measures alone, however, will not expand our ability to absorb and respond to rapid directional changes in climate, nor do they capitalize on available predictive information and efforts. In worst-case climate scenarios, over-reliance on betting measures may spread resources too thin or prove insufficient to help biodiversity weather the rapid changes underway. On the other hand, forecast-interventions bear significant risks if they are too deterministic, not robust to alternative futures or have negative unanticipated consequences (Suffling and Scott, 2002). They could also deliver great rewards and should be weighed with sensitivity analyses and scenarios, tested in pilot programs, and implemented initially at small scales (McLachlan et al., 2007). Scenario building – done in ways that are amenable to local data limitations

and useable by policymakers and managers – is particularly apt for exploring the range of magnitudes and direction of possible futures and trends without commitment to specific forecasts (Brown, 2006; Millar et al., 2007).

While the range of recommendations in the literature is great, four consistent, broad themes emerge in this review for conservation stakeholders to apply to climate change planning and adaptation: (1) the need for regional institutional coordination for reserve planning and management and to improve landscape connectivity; (2) the need to broaden spatial and temporal perspective in management activities and practice, and to employ actions that build system resilience; (3) the need to incorporate climate change into all conservation planning and actions, which will require increased research and capacity to forecast future conditions and species responses and to deal effectively with unavoidable uncertainty; and (4) the need to address multiple threats and global change drivers simultaneously and in ways that are responsive to and inclusive of diverse human communities and cultures. Action along each of these fronts will involve difficult tradeoffs, barriers to implementation, and collaboration across diverse actors.

Action will also require an adaptation planning process or series of processes appropriate for various scales and applications. Most of the literature to date fails to distinguish adap-

**Fig. 7 – Adaptation planning involves at least a few key steps, each complex and requiring collaboration among actors such as land managers, the public, scientists, funders and lawmakers. Recommendations reviewed here address aspects of these steps, but without specifying where they fit in relation to one another.**

tation from climate change impact assessment, or adaptation planning from implementation. These are distinct steps in an as-yet largely undefined process that the recommendations we survey could inform. We propose a series of general steps that should be modified, elaborated, and tailored to specific needs (Fig. 7). Key to any adaptation planning process will be to follow the principles of adaptive management (Rank 7), in which later steps inform earlier steps in an iterative and on going process.

## 8. Conclusions

Widespread calls exist for immediate action to adapt conservation practice to ongoing climate change in order to ensure the persistence of many species and related ecosystem services. However, the majority of recommendations in the published journal literature lack sufficient specificity to direct this action. Over the last 22 years, general recommendations have been reiterated frequently without the elaboration necessary to operationalize them. Greater effort to increase the availability and applicability of climate change adaptation options for conservation—through concrete strategies and case studies illustrating how and where to link research agendas, conservation programs and institutions—is badly needed.

Recommendations to date also largely neglect social science and are overwhelmingly focused on ecological data (Fig. 4c). This bias is alarming given the obvious importance of human behavior and preferences in determining conservation outcomes (Watson, 2005) and the increasingly important role of multi-use public and private lands in conservation practice. A holistic landscape approach to conservation, driven by a vision of humans and other species co-mingling across reserves and developed lands, has gradually gained prominence over the last 20 years. In their seminal paper, Peters and Darling (1985) provided a number of recommendations that continue to be widely advocated (Table 1), but they did not address the roles of conservation and restoration in human-dominated landscapes. These ideas emerge strongly in more recent literature highlighting a need to integrate ecology with other disciplines and approaches that explicitly address the roles of institutions, policy, politics and people in successful conservation strategies.

Finally, few resources or capacity exist to guide an adaptation planning process at any scale (Hannah et al., 2002; Scott and Lemieux, 2007; Welch, 2005). Such a process would place the sea of adaptation ideas and recommendations in framework and provide practitioners with tools, roles and a structure to evaluate what ideas might be useful and feasible for particular situations. Large-scale adaptation efforts that incorporate many of the recommendations found in this review are currently underway, including governmental efforts such as by Parks Canada or DEFRA in England, and by international non-governmental organizations such as The Nature Conservancy and the Wildlife Conservation Society. Well-documented case studies that focus not only on the outcome but also on the development process of adaptation plans are a promising avenue. These efforts can best enhance and encourage more widespread climate change adaptation, particularly at smaller scales, by capturing what they learn and disseminating it widely.

Migratory threats

MaxEnt roadkill niche models

Insect roadkill hotspots

## ABSTRACT

Road mortality may contribute to the population decline of eastern monarch butterflies (*Danaus plexippus* L.). We estimated autumn monarch roadkill rates within the primary Oklahoma to Mexico southern migration corridor (i.e., Central Funnel). Dead monarchs were surveyed along Texas roadsides during four weeks of autumn migration in 2016 and 2017. Roadkill averaged 3.4 monarchs per 100 m transect, reaching 66 per 100 m in a roadkill hotspot in southwestern Texas. Extrapolations of Central Funnel roadkill based on survey data and road types were 3.6 and 1.1 million in 2016 and 2017, respectively. Spatial distribution of roadkill across the Central Funnel was projected from Texas survey data using 30 m resolution MaxEnt niche models. Highest roadkill probability was linked to arid climate and low human population density. The latter variables may not be directly related to roadkill, but instead represent indirect correlates of increased densities of monarchs where the migration corridor narrows southwards. The higher roadkill projected in southwest Texas and Mexico by MaxEnt models agrees with previously reported monarch roadkill hotspots. MaxEnt-based 2016–2017 projections for annual roadkill rates throughout the Central Funnel averaged 2.1 million. This figure is similar to the result by simple extrapolation, and represents about 3% of the overwintering monarch population for these years. Mitigation at roadkill hotspots in the Central Funnel could reduce monarch roadkill mortality during migration and contribute towards conservation efforts for the monarch butterfly.

### 1. Introduction

Wildlife-vehicle collision is the most widely acknowledged impact of roads on wildlife, and can contribute to the decline of species of conservation concern (Tok et al., 2011; Visintin et al., 2016; Bennett, 2017), including globally declining pollinator insect species (Baxter-Gilbert et al., 2015). Roadkill can result in high mortality and lower abundance for species with large area requirements, pronounced migratory movements, small population sizes, and slow reproduction rates (Seiler and Helldin, 2006; Fahrig and Rytwinski, 2009). Wildlife-vehicle collisions are often spatially and temporally aggregated and substantial annual and inter-annual variation has been associated with environmental factors and traffic volume (Seiler and Helldin, 2006; Shilling and Waetjen, 2015). This tendency for high spatio-temporal variability in roadkill can be difficult to interpret based solely on the mapping of field survey data. Accordingly, there is a trend to use predictive spatial models to account for the variability in investigating the impacts of roads on wildlife mortality (Bennett, 2017). Typical roadkill

niche models use a combination of environmental and anthropogenic variables and are often restricted to small areas (Visintin et al., 2016). Species distribution modeling has previously been used to project roadkill risk of mammals (Grilo et al., 2009; Roger and Ramp, 2009; Visintin et al., 2016, 2017) and owls (Gomes et al., 2009). Spatial models for insect roadkill have not yet been developed.

Only five out of 215 roadkill studies (2%) between 2011 and 2015 were specifically focused on invertebrates (Bennett, 2017). Despite this taxonomic bias in the literature, roadkill may be a substantial threat to certain insect populations. Baxter-Gilbert et al. (2015) projected that hundreds of billions of pollinating insects are lost annually to roadkill across North America. Although relatively few studies exist on butterfly road mortality, researchers have suggested that butterflies are one of the most common insect orders killed by vehicles (McKenna et al., 2001; Rao and Girish, 2007). Despite the high numbers of road-killed butterflies, the risk of Lepidopteran roadkill has been estimated as low to moderate (Baxter-Gilbert et al., 2015; Muñoz et al., 2015). Several studies have estimated butterfly roadkill numbers and examined

contributing factors (Munguira and Thomas, 1992; McKenna et al., 2001; Ries et al., 2001; Rao and Girish, 2007; Skórka et al., 2013), but most of these studies concentrate on local, relatively sedentary butterfly populations and their utilization of roadside habitats rather than migratory butterflies. Migratory danaine butterflies (Nymphalidae: Danaeinae) may be especially susceptible to roadkill during migration (Her, 2008; Taiwan Environmental Protection Administration [EPA], 2010; Santhosh and Basavarajappa, 2014), including the monarch butterfly (*Danaus plexippus* L.) in the United States (McKenna et al., 2001) and Mexico (Correo Real, 2015).

Significant population decline of the eastern migratory monarch butterfly has been observed at the overwintering sites in Central Mexico during the past two decades (Vidal and Rendón-Salinas, 2014; Thogmartin et al., 2017). Consequently, the persistence of the migratory phenomenon of the eastern population may be endangered (Brower et al., 2012). The long-distance migration of monarchs is unique among butterflies. Mortality during the autumn migration (often referred to as fall migration) has been suggested as a contributing factor to the decline (Badgett and Davis, 2015; Ries et al., 2015a; Inamine et al., 2016; Agrawal and Inamine, 2018). Road mortality may significantly affect monarch survival during migration, especially where monarchs become highly concentrated as the migration narrows in Texas and northern Mexico (Badgett and Davis, 2015). Only McKenna et al. (2001) have previously evaluated monarch butterfly roadkill. They reported monarchs as the second-most killed butterfly species during six weeks of autumn in Illinois. They estimated that > 500,000 monarchs were killed statewide along interstate highways during one week in early September 1999 (McKenna et al., 2001). There are several unpublished citizen-science reports of locally high monarch roadkill occurrence in West Texas and northern Mexico during the autumn migration, with observed roadkill reaching 5.7 monarchs per meter near Monterrey, Mexico (Correo Real, 2015; Journey North, 2017). Incidences of high monarch road mortality in northern Mexico have led to the placement of road signs along portions of highways in to reduce speed in the presence of monarchs (Vangaurdia, 2016).

Monarch roadkill has yet to be quantified in relation to an overall population estimate. Seiler and Helldin (2006) point out that any sustained mortality factor, such as roadkill, can be especially damaging for species that are either approaching or are in an annual population decline, such as the monarch. The extent of monarch roadkill needs to be assessed to estimate its potential contribution to the population decline and support conservation planning. Our goal was to develop MaxEnt niche models for monarch road mortality during the autumn migration within the main migration pathway in Texas. The MaxEnt algorithm has been employed before to spatially investigate vehicle-animal collisions of birds and mammals (Ha and Shilling, 2017). The roadkill models were also projected throughout the Central Funnel, which is the identified main southern autumn migratory pathway within the Central Flyway for monarchs from Oklahoma to Mexico (Tracy, 2018; Tracy et al., 2018a). This study includes the first analysis of monarch roadkill data outside of Illinois, and the first development of a spatial roadkill model for an insect. Our specific objectives were to (1) conduct monarch roadkill field surveys within the Central Funnel in Texas, (2) develop MaxEnt niche models for roadkill within the Texas survey area, and project these models throughout the Central Funnel, (3) estimate monarch roadkill numbers within the survey area and the Central Funnel using both simple field survey-based and model-based extrapolation techniques, and (4) discuss the results in the context of monarch conservation and potential applications to other species of conservation concern.

## 2. Methods

### 2.1. Study species

The monarch autumn migration is uniquely accomplished by one

generation. Adults begin migrating in late August to September from the summer breeding grounds, traveling to overwintering grounds in Central Mexico (Brower, 1995; Calvert and Wagner, 1999). Most migrants usually reach Oklahoma and North Texas in late September or early October (Calvert and Wagner, 1999; Monarch Watch, 2018a) and arrive at the overwintering grounds in November (Brower et al., 2006). There are two main migration routes, the Central Flyway and the Eastern or Coastal Flyway (Calvert and Wagner, 1999; Howard and Davis, 2009). The Central Flyway through the Great Plains is the most heavily traveled route (Howard and Davis, 2009), which narrows into the Central Funnel from Oklahoma southwards (Tracy, 2018; Tracy et al., 2018a).

Autumn migrants fly during the day and stop at night and during inclement weather to nectar and roost in trees and shrubs (Brower, 1996). These roosts may comprise a few individuals to several thousand individuals and may last one to several days (Davis and Garland, 2004; Howard and Davis, 2009). In the morning, roosting monarchs either resume migration or search for nectar. These behaviors are influenced by wind patterns or lipid levels (Brower, 1996; Davis and Garland, 2004). During unfavorable southerly winds, monarchs may roost for several days (Schmidt-Koenig, 1985). Migrating monarchs are observed to nectar in a variety of locations, including in right-of-ways (Brower et al., 2006), where they may be vulnerable to vehicle collisions. Brower et al. (2006) suggested that monarchs shift their behavior upon reaching Texas and spend more time nectaring to accumulate lipids for the winter and re-migration in the spring. Migrating monarchs regularly fly at high altitudes, around 300–500 m (Gibo and Pallett, 1979; Gibo, 1981, 1986), but may fly close to the ground, especially when facing headwinds or during overcast weather (Gibo, 1986; Brower, 1996), exposing them to road mortality. Citizen science observations also include reports of low flying fall migrating monarchs over roadways (Correo Real, 2015).

### 2.2. Monarch roadkill surveys and simple roadkill extrapolation

Monarch roadkill field surveys were conducted during the main autumn migration through the Central Funnel in Texas (Fig. 1). Four four-day surveys were conducted in each of the autumns of 2016 and 2017, between 10th October to 4th November and 3–27 October, respectively. The survey area was divided into four north to south sections, with surveys timed to generally occur after the dates of average peak migration (Journey North, 2017; Monarch Watch, 2018a) to allow time for the accumulation of road-killed monarchs. Observed monarch roadkill densities most likely represent accumulations of dead migrating monarchs over a period of one or two days to a few weeks during the main migration pulse through an area (Munguira and Thomas, 1992). Surveyed road types included (1) highways, (2) primary roads, and (3) secondary roads. Each survey location comprised at least a single 100 m by 1 m transect along the grassy edge of one side of the roadway. To assess if the side of the road surveyed influenced the number of dead monarchs, additional transects were surveyed across multiple edges of single and divided-lane highways at some sites. Transects were located using a handheld GPS device (accuracy up to  $\pm 3$  m). Roadkill transects were spaced according to travel and survey time constraints at about 30 to 100 km intervals along the primarily east to west pre-planned survey routes, with additional surveys in 2016 in the southwestern portion of the study area where high monarch roadkill was found (Fig. 1).

All dead monarchs or parts of monarchs were collected to estimate the total number and sex ratio of dead monarchs along transects. A similar spring monarch roadkill survey was conducted in Texas during April to May of 2017 (Fig. A.1; for details, see Appendix A, section 1.1). The boundary of the background evaluation extent for our roadkill study was defined by a 10 km buffer around a convex hull polygon formed using un-thinned 2016 to 2017 monarch roadkill survey data (Fig. 1). We extrapolated the mean roadkill counts for the three road

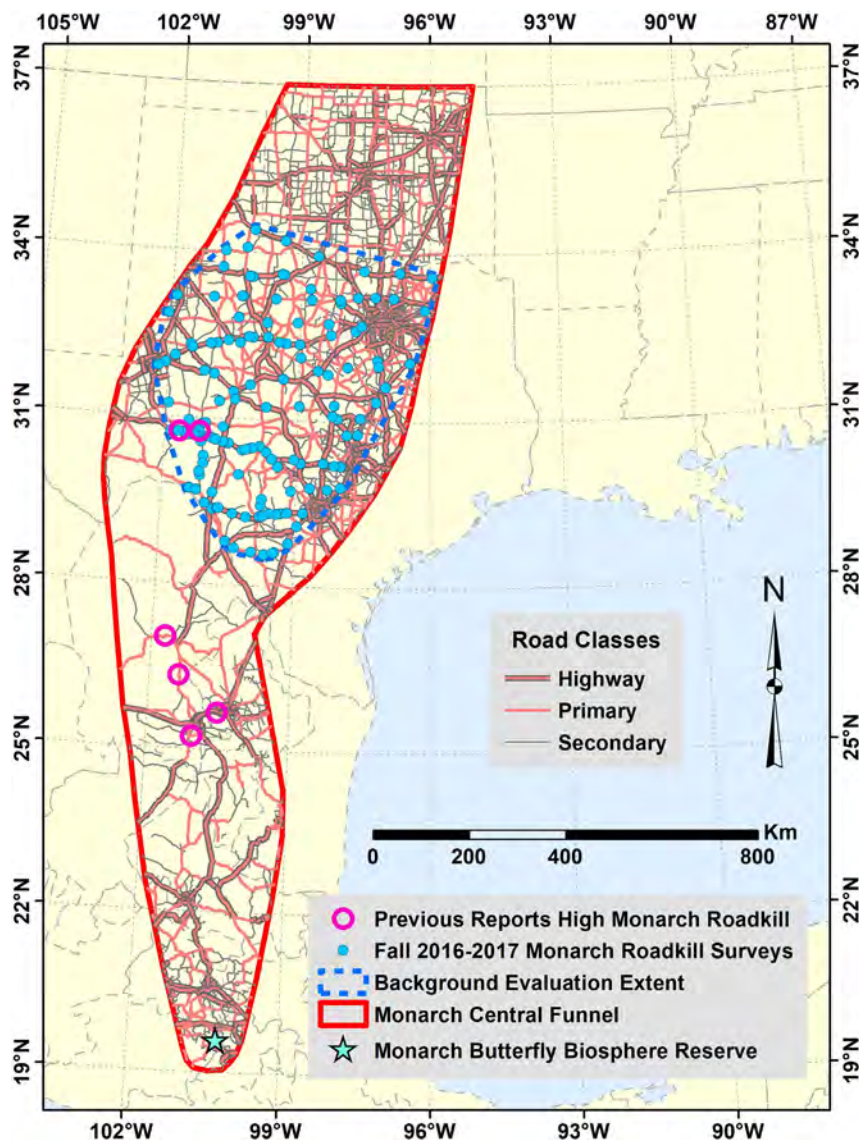

Fig. 1. Monarch roadkill survey 100 m transects for autumn 2016 and 2017 along three major road classes within the monarch Central Funnel in Texas.

types over the background evaluation extent and Central Funnel in a manner similar to that of McKenna et al. (2001). Roadkill rates in areas of locally high monarch roadkill (hotspots) can vary greatly between years and highly differ from other areas. Consequently, roadkill rates in hotspots can bias roadkill rates in larger areas if they are disproportionately represented in the sampling. Therefore, in some extrapolations, hotspot roadkill rates were considered separately for each year from non-hotspot locations. This separation allowed us to understand the importance of the roadkill hotspots within a year, and compare the hotspot differences between years. We also made roadkill extrapolations including hotspot roadkill rates with non-hotspot data and thinning the hotspot data in 2016 to be in proportion to the sample effort in non-hotspot locations (for details, see Appendix A, section 2.1).

### 2.3. Environmental variables

Thirty environmental variables were initially screened for use in the roadkill modeling (Table A.1, Fig. A.2). These variables were selected for their value in previous roadkill niche models and for their use in characterizing the environment of the study area. The variables consisted of nine topographic indices (including four stream indices), eight land cover indices, six road indices, three human population indices,

and four climatic indices. All indices were either calculated at 30.8 m spatial resolution or resampled with bilinear interpolation to the 30.8 m resolution, to match the resolution of the base layer of 1 arc sec Shuttle Radar Topography Mission (SRTM) digital elevation model (DEM) data obtained from USGS Earth Explorer (<https://earthexplorer.usgs.gov/>). The high spatial resolution of 30.8 m facilitated modeling of roadkill along individual surveyed roadways over a broad area (see more details in Appendix A, section 7).

### 2.4. Monarch roadkill models

Preliminary MaxEnt model runs indicated that there was not enough data from 2017 to obtain good accuracy statistics for both single year models. Consequently, we combined 2016 and 2017 roadkill presence data, which were randomly spatially thinned to 2 km to reduce spatial autocorrelation. Ten thousand background points were randomly generated within the road mask evaluation area. We calculated background/presence versions of the area under the curve statistic ( $AUC_{bgp}$ ) and true skill statistic ( $TSS_{bgp}$ ) using R software (R Core Team, 2018) and the PresenceAbsence package (Freeman and Moisen, 2008). In the same manner, we calculated a presence/absence version of AUC ( $AUC_{pa}$ ) and TSS ( $TSS_{pa}$ ) using transects with no observed monarch

roadkill as absence data, although we acknowledge roadkill may have occurred in these absence locations as well. We adjusted the MaxEnt beta regularization value to two and used only quadratic and hinge features to reduce model complexity and overfitting for improving model generalization (Jiménez-Valverde et al., 2008; Warren and Seifert, 2011; Tracy et al., 2018b).

Roadway rasters served as a mask for analysis of environmental variables. The original set of 30 environmental variables was decreased to 20 variables. We dropped nine variables exhibiting zero or negative testing gain of  $AUC_{bgp}$  from a MaxEnt threefold jackknife run (Table A.1, Fig. A.3). We also dropped traffic volume because data were not readily available for Mexico. Traffic volume was utilized in preliminary niche models for the Texas background evaluation extent. Preliminary runs indicated that no substantial gain in model performance was achieved with > 10 of the 20 variables, and that employing fewer variables (three) substantially increased undesired high spatial variability in roadkill among models. Consequently, final MaxEnt roadkill models were developed from ten random sets of ten of the 20 variables to represent model variability due to variable selection. The absolute Spearman rank correlation of variables within random variable sets was limited to < 0.7 using the multiple randomized sequential forward selection procedure within the random subset feature selection algorithm (RSFSA) of Tracy et al. (2018b). The final MaxEnt models were calibrated to binary presence/absence format using a threshold of maximum TSS<sub>pa</sub> (Liu et al., 2013) and combined using frequency consensus to form a feature subset ensemble. We also created presence/absence niche models for monarch roadkill using linear and quadratic binomial logistic regression with the R *Glmnet* package (Friedman et al., 2010) for the same ten random sets of ten of 20 variables. These presence/absence models produced lower  $AUC_{bgp}$  values and similar  $AUC_{pa}$  values compared to MaxEnt models, and these models were not investigated further (results not shown).

### 3. Results

#### 3.1. Monarch roadkill survey and simple roadkill extrapolation

We surveyed 16.1 km of roadsides (161,100 m transects), 8.8 km in 2016 and 7.3 km in 2017. We found 581 dead monarchs in 59 locations (102 absence locations) for an average of 3.4 monarchs per transect. We found 546 dead monarchs in 2016 and 35 in 2017 (for raw survey count data, see Appendix A, section 3.1). Of the 546 monarchs in 2016, 499 (91%) were located along or near IH-10 between Sonora and Sheffield (23 of 95 transects) (Fig. 2). This area was defined as a single large 2016 hotspot area extending 95 km along Interstate Highway (IH) 10 from Sonora to 24 km east of the Pecos River. This hotspot included a portion of Texas state highway (SH) 163 extending from 7.6 km south of Ozona to 5 km north of Ozona and a 2 km section of SH-137 extending west from the junction with SH-163. The hotspot was bounded along IH-10 in the west and east by counts of 15 and 10 roadkill per 100 m, and included counts of 21 and 6 roadkill per 100 m on SH-137 and SH-163, respectively. About 93% (466/499) of the dead monarchs in the 2016 hotspot occurred in 14 transects ranging from 10 to 66 per 100 m (Fig. A.4). A total of 257 monarchs were sexed in 2016–2017, of which ca. 38% were female ( $n = 98$ ). The portion of females was 41% in 2016 (132 males, 91 females) and 21% in 2017 (27 males, 7 females). After the 2 km spatial thinning for spatial modeling, the field survey data consisted of 151 transects (53 presence and 98 absence) and 249 individual dead monarchs. Only two road-killed male monarchs were found among 54 transects in our spring 2017 roadkill survey (Fig. A.1).

Southern edges of roadsides contained 43.8% ( $\pm 36\%$  SD,  $n = 13$ ) of the roadkill found in the northernmost edge for both single and divided-lane roads. This relationship was used to estimate roadkill across all two to four edges per roadway when extrapolating roadkill per km per year (for details, see Appendix A, section 5). Estimated roadkill per

km ranged from 6.15 to 645 monarchs per km depending on year, road type, and location in relation to the hotspot area (Table 1). In 2016, mean estimated roadkill per km along highways was significantly higher within the Sonora-Sheffield hotspot (645.38; SD = 446.92;  $n = 15$ ) compared to outside the hotspot (12.64; SD = 22.30;  $n = 22$ ) ( $P = 0.00008$ ; Welch *t*-test). Between years, the estimated roadkill per km generally varied widely among road types, and there was no evidence of any hotspot in 2017 (Table 1). Estimates of roadkill within the hotspot area in 2016 and 2017 ranged from about 74,000 to 5000, representing about 10% and 1% of the entire mortality within the Texas background evaluation extent. Using the field survey data from the whole area, including the randomly thinned hotspot data, the estimated roadkill for the Central Funnel in 2016 rose to over 3.5 million monarch butterflies (Table 1). The estimate for 2017 was 1.1 million road-killed monarchs. Combining the data from both of the years yielded an annual estimate of 2.1 million road-killed monarchs. When the hotspot data were separated from the survey data, total estimated annual roadkill rates in 2016 and 2017 were about 1.6 million and 1.0 million monarchs, respectively. In 2016, about 47%–49% of the roadkill within the Central Funnel was projected to occur within the Texas background evaluation extent, of which 5% was projected to occur in the Sonora-Sheffield hotspot area. In 2017, only about 0.3% of the roadkill within the Central Funnel was projected within the hotspot area, and the percent roadkill in the background area ranged from 31% when hotspot data were analyzed separately to 48% when data from the hotspot area were included (Table 1, Appendix A, section 2).

#### 3.2. Monarch roadkill model

The feature subset ensemble of ten MaxEnt roadkill niche models provided excellent discrimination of roadkill presence locations from background locations within the background evaluation extent, with  $AUC_{bgp}$  values ranging from 0.82 to 0.88 ( $0.86 \pm 0.02$ , mean  $\pm$  SD). The models provided marginally poor discrimination of roadkill presences from absences observed in the field, with  $AUC_{pa}$  values ranging from 0.60 to 0.67 ( $0.64 \pm 0.02$ , mean  $\pm$  SD). Among the top eight variables with the highest permutation importance in the MaxEnt models (Table 2) were three human population density indices and two climatic indices. Other top ranked variables included elevation (m), road density over a 3 km radius ( $\text{km}/\sim 28 \text{ km}^2$ ), and percent cover of artificial surfaces within a 500 m radius. Traffic volume (annual average daily traffic, AADT) ranked third in permutation importance in preliminary models but was not available for Mexico, precluding its use in our final models.

The MaxEnt response curves for population density indices all indicated that lower human population densities had higher association with monarch roadkill (Fig. 3A, E). The climatic indices indicated that roadkill was associated with more arid climates (Fig. 3B, C). Lower road densities and lower percent cover of artificial surface were also associated with higher monarch roadkill (Fig. 4F, G). The response curve for traffic volume, which was not used in the final models, indicated that the highest roadkill was associated with lower traffic volume. The traffic volume response curve was very similar to that of percent cover of artificial surface (Fig. 3G, H), with which it was moderately correlated ( $r_s = 0.58$ ).

The proportion of MaxEnt models projecting monarch roadkill generally increased from northeast to southwest within both the background evaluation extent and Central Funnel (Fig. 4; see Appendix Section 5 for embedded zipped shapefile of MaxEnt consensus model). The highest number of models projected roadkill within much of southwest Texas and Mexico in the Central Funnel. None of the MaxEnt models projected monarch roadkill over most of the northeastern Central Funnel, including the Dallas/Fort Worth metroplex and most of eastern Oklahoma.

Roadkill extrapolations for each of the ten individual MaxEnt models were made across each year and both years combined.

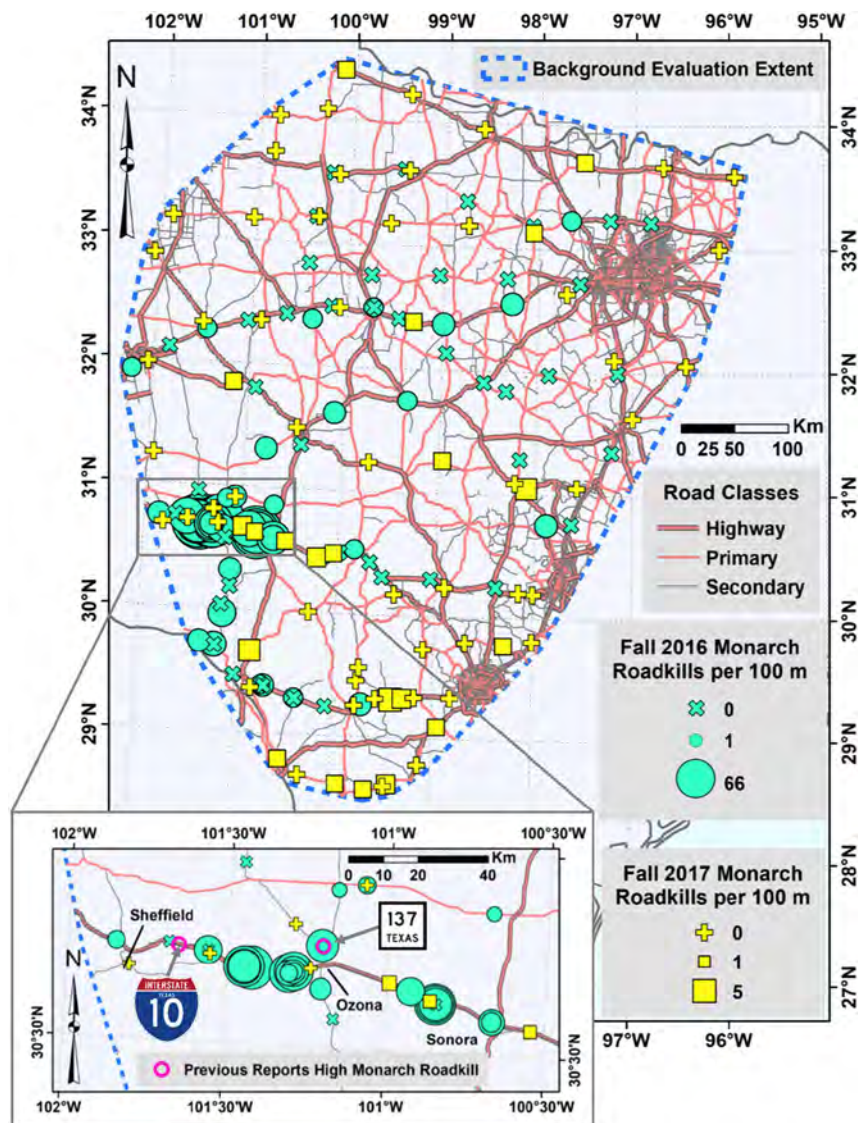

Fig. 2. Monarch roadkill autumn 2016 and 2017 survey results for 100 m transects along major road classes within the background evaluation extent in the monarch Central Funnel in Texas, including previously reported locations of high monarch roadkill.

Extrapolations were based upon roadkill rates per km for presence-only transects (no zero roadkill data) of each road type that were multiplied by the MaxEnt model predicted lengths of roadkill presence for the road type. Roadkill rate calculations for extrapolations included data from hotspot transects that were thinned for 2016 as done for simple extrapolations (for details, see Appendix A, sections 2.1, 5). Extrapolating roadkill rates across the Central Funnel, we estimated averages of  $3.0 \pm 0.7$  and  $1.1 \pm 0.3$  million (mean  $\pm$  SD) road-killed monarchs for 2016 and 2017, respectively (Tables 1, A.2). Combining roadkill data across both years for the Central Funnel yielded annual roadkill rates of  $2.1 \pm 0.5$  million. The mean projected percentage of road-killed monarchs in the Central Funnel that occurred within the Texas background evaluation extent ranged from 67% to 68% in 2016 and 2017 (Tables 1, A.4).

## 4. Discussion

### 4.1. Monarch roadkill survey

In our 2016 roadkill survey (but not 2017), we found a Sonora-Sheffield, Texas, monarch roadkill hotspot that corresponds to the only two previous citizen-science reports of monarch roadkill hotspots in the

US (Fig. 2). It is unclear why hotspots have repeatedly occurred in this area. The hotspot location may be partly related to higher densities of migrating monarchs in more southern areas of the Central Funnel. In addition, local stochastic weather events probably influence the occurrence of roadkill hotspots, such as unfavorable winds that may induce lower monarch flight patterns or extended roosting and nectaring behavior close to the ground in the vicinity of roadways. More research is needed to evaluate how frequently roadkill hotspots occur in this region. It is possible that one or both years represent an outlier, and that hotspots may occur in additional areas.

The variation in roadkill rates observed between the two years of our survey was consistent with other roadkill studies (Seiler and Helldin, 2006). Our overall roadkill rates varied from 6 to 646 dead monarchs per km depending on year, road type, and location (Table 1). This range falls within previous reports for monarchs of from 1.3 to 11.9 butterflies per km per week in Illinois (McKenna et al., 2001) to a very high number of 115 road-killed monarchs within a 20 m stretch along toll highway 40D southwest of Monterrey, Mexico in October 2015 (Correo Real, 2015; see Appendix A, section 8 for data). Reported roadkill rates for other butterflies have ranged from 0.45 to 80 per km per day in North America, Asia, and Europe (Rao and Girish, 2007, De la Puente et al., 2008, Yamada et al., 2010, Skórka et al., 2013, Baxter-

**Table 1**  
Monarch roadkill estimates per year for 2016 to 2017 over the Sonora-Sheffield roadkill hotspot, Texas background evaluation extent (BEE) and the Central Funnel (Figs. 1–2) from the field data by road type using simple extrapolation or MaxEnt model projections.

Year	Millions of monarch roadkill <sup>a</sup>

% Overwintering population <sup>c</sup>	0.09%	0.91%	1.82%	1.59%	3.33%	1.96 ± 0.71%	2.82 ± 0.66%
% Texas BEE mortality	10.25%						
% Central Funnel mortality	3.66%	35.75%		27.99%		67.90 ± 15.08%	

<sup>a</sup> Mean roadkill rates (roadkill/km/year) (Table A.2) by road type for extrapolations are calculated from transects in the Texas BEE and incorporate estimates for all road edges. Roadkill rates are multiplied by length of road in various areas to obtain extrapolations (see Table A.3 for road lengths used in simple road type extrapolation) (for all calculations, see Appendix A, section 5).

<sup>b</sup> See Table A.4 for individual MaxEnt model estimates.

<sup>c</sup> Based on 84.61 (2016) and 61.4 (2017) million overwintering monarchs (Monarch Watch, 2018b). Estimated from 21 million monarchs per hectares overwintering (Thogmartin et al., 2017).

Gilbert et al., 2015).

The observed sex ratios of roadkill monarchs were also consistent with previous studies. About 38% of the dead monarchs in our autumn field surveys were females, ranging from 21% in 2017 to 41% in 2016. These figures generally match two separate citizen science observations on the percentage of female monarch roadkill in Mexico of 27% and 36% in October 2015 (Correo Real, 2015). They also are within the range reported from the other roadkill study (McKenna et al., 2001), as well as studies of sex ratios during migration (Borland et al., 2004) or on the overwintering grounds (Steffy, 2015). Davis and Rendón-Salinas

(2010) found a decreasing trend (~10%) in percent female monarchs at the Mexican overwintering sites from 1976 to 2008, which they suggested could reflect female biased mortality due to the protozoan parasite *Ophryocystis elektroscirrha*.

While our estimates of monarch roadkill are likely conservative, carcass persistence is not likely to be a major source of bias. However, we did not evaluate persistence in our study, which could vary based on various factors, such as region, time of year, and weather conditions.

Munguira and Thomas (1992) placed butterfly specimens on roadsides and found that only one of their 50 specimens disappeared during

two weeks (daily loss rate of 0.15%). Several factors contribute to the conservative nature of our estimates, including the difficulty in detection of dead monarchs, especially in taller vegetation, shredding of dead monarchs by roadside mowing, and a portion of the monarchs remaining attached to the colliding vehicles (McKenna et al., 2001; Seiler and Helldin, 2006). However, several studies indicate that road killed butterflies are mostly blown to the roadside edge, with individuals rarely trapped in car grills (Munguira and Thomas, 1992; Ries et al., 2001). The overall agreement of our roadkill results with previous studies in terms of the range of roadkill rate variability and sex ratios supports the reliability of the data for extrapolating monarch road mortality according to road types and spatial modeling.

## 4.2. Monarch roadkill models

### 4.2.1. Roadkill projections

Most of the MaxEnt models projected monarch roadkill from the southwestern portion of the Central Funnel from West Texas to Mexico (Fig. 4). Our MaxEnt consensus projection agrees with all seven of the previously known citizen science reports of monarch roadkill hotspots in North America (Fig. 4), including two hotspots in West Texas

(Journey North, 2017) and five hotspots in northern Mexico (Correio Real, 2015; Rogelio Carrerra, Universidad Autonoma de Nuevo Leon, Nuevo Leon, Mexico, personal communication).

Our annual MaxEnt based roadkill estimates for monarch mortality throughout the Central Funnel was 3.0 to 1.1 million for 2016 and 2017, respectively. These MaxEnt roadkill estimates were similar to those based on simple roadkill extrapolation by road type when hotspot data were included (3.6 and 1.1 million, respectively). Most of the roadkill projected by MaxEnt models outside of the study area occurred in Mexico, indicating that more MaxEnt models are projecting roadkill along the sparser road network within the Central Funnel over northern and central Mexico than in the northern parts of the funnel (Fig. 4). As the autumn migration pathway narrows in the South, migrating monarchs become more concentrated in the Central Funnel. This higher concentration may contribute to higher roadkill densities in the southern parts of the Central Funnel in Mexico, where most previous reports of monarch roadkill hotspots originate (Fig. 4). Although our models project some increased southward mortality risk, additional data are needed to assess the extent of this risk in Mexico. The extrapolations including the hotspot data with other roadkill data and projecting higher annual roadkill of up to 3.6 million in the Central Funnel

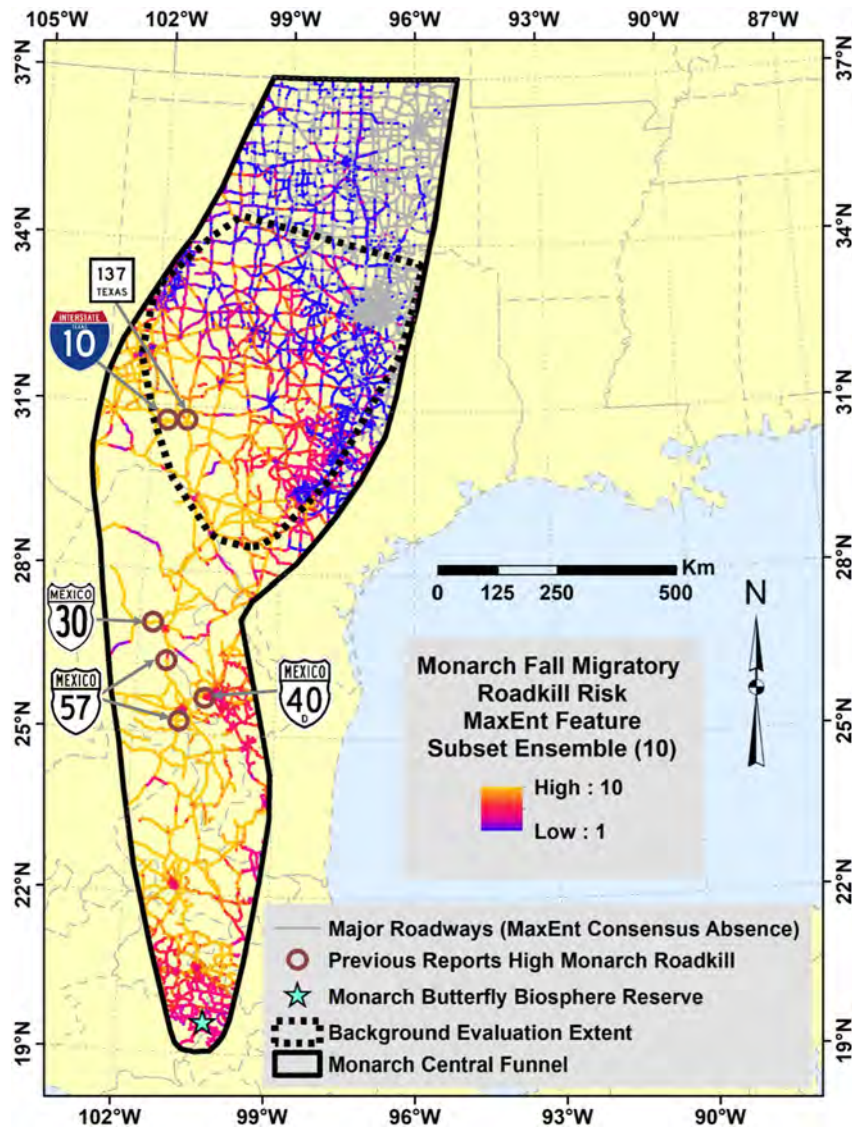

Fig. 4. MaxEnt frequency consensus for feature subset ensemble of ten models developed from random subsets of ten of 20 variables correlated  $< 0.7$  (see Appendix Section 5 for embedded zipped shapefile of MaxEnt consensus model).

should be more realistic considering the occurrence of multiple roadkill hotspots in Mexico of higher density than seen in Texas. The MaxEnt models project little to no roadkill in the northeastern part of the funnel area, including the Dallas/Fort Worth area and eastern Oklahoma. However, some roadkill likely does occur in this area, but possibly at a lower rate than in the more southern areas of the Central Funnel. Further research and field surveys are needed to verify roadkill rates outside of our survey area in the southern and northern parts of the Central Funnel. Additional data may allow effective use of roadkill density models, rather than presence only MaxEnt models used in this study. Roadkill density models can better reveal regional roadkill patterns useful in refining projections, especially for northern Mexico where roadkill could be much higher than in Texas. Roadkill field surveys from other parts of the autumn migration pathways could improve estimates for the total impact of roadkill on the monarch population.

#### 4.2.2. Factors affecting roadkill

MaxEnt projections of monarch roadkill within the Central Funnel were generally associated with more arid climate and less densely populated areas (Fig. 3). These conditions generally describe those for the seven previous monarch roadkill hotspots reported from Texas and

Mexico, with the possible exception of the roadkill hotspot in the vicinity of Monterrey, Mexico (Fig. 4). This could be related to a variety of factors. For example, autumn migrating monarchs have been observed to spend additional time flying lower to the ground during the afternoon in desert areas, perhaps to seek shelter from the heat or find nectar (Journey North, 2018). Monarchs may need to spend more time searching for nectar in arid environments, although this has not been evaluated. Finally, the increased roadkill rates may simply reflect the increased number of monarchs in more southern areas of the Central Funnel. This southern locality factor cannot be associated with most of the predictors, with the exception of latitude, but it may have the highest influence. Local climate, weather patterns, and geography affect monarch movement and behavior, and they all are likely important contributors to road mortality. Wind patterns (direction, duration, and speed) may especially be more important than anthropogenic factors, but short-term weather events could not be incorporated in the models. Occurrence of these weather events is also highly variable and difficult to predict.

Traffic volume has been noted as one of the most important variables in previous roadkill studies (Bennett, 2017). Traffic volume ranked high in importance in our preliminary roadkill models, but we found that model accuracy (AUC) was not significantly affected by its

removal. Other variables that were correlated with traffic volume likely compensated for its absence, including human population density, artificial surface cover, distance to urban areas (km to population  $\geq 300/\text{km}^2$ ), and road density. In our models including traffic volume, the highest roadkill was associated with fairly low AADT values, similar to the study by McKenna et al. (2001). In general, higher roadkill has been associated with higher traffic volume due to increased probability of vehicle collisions (Seiler and Helldin, 2006; Skórka et al., 2013). Samways (1994) suggested that roads with high traffic volume serve as corridors for high butterfly mortality. In our study, low traffic volume, along with related anthropogenic variables, is correlated with locations of monarch roadkill hotspots, but may not be directly related to the roadkill mortality. As the human population grows, traffic volume should increase, including in the lower traffic volume monarch roadkill hotspot areas, likely leading to higher roadkill rates (Bennett, 2017).

#### 4.2.3. Spatial and temporal variation

Over 70,000 monarch roadkill were estimated in the Sonora to Sheffield, Texas hotspot in 2016, compared to about 5000 in 2017. This illustrates the high spatio-temporal variability of roadkill and the potential contribution of hotspots to the monarch road mortality. The timing of our field surveys relative to the peak migration in those years may have varied among transect locations and years, which could have influenced our results. If peak migration occurred after our field surveys in one or both years, we may have underestimated roadkill numbers. For example, the autumn migration in 2017 was later than usual due to unusually hot summer (Agrawal and Inamine, 2018). Few other studies have identified roadkill hotspots for butterflies (but see Samways, 1994, Her, 2008). Monarch roadkill hotspots may vary from year to year and may be difficult to locate or may not occur in some years.

We observed much higher monarch road mortality during autumn migration than in the spring (Fig. A.1), indicating that seasonality is a factor contributing to monarch roadkill rates. However, the monarch spring migration is more spatio-temporally dispersed making comparisons difficult. Temporal variability can occur between years, within the migration phase, or even within a day. For example, monarch behavior, such as flying low in the mornings (McKenna et al., 2001), probably affects the risk of roadkill at different times of day. Temporal patterns affecting monarch roadkill should be investigated further. Other sampling methods may be effective in detecting additional roadkill hotspots, such as adaptive cluster sampling, which was developed for inventorying scattered and clustered phenomena (Thompson, 1990). More frequent samples in a given location can also be critical for detecting roadkill hotspots (Santos et al., 2015).

#### 4.3. Implications and impacts in relation to monarch conservation

##### 4.3.1. Autumn migration mortality

Butterfly roadkill is a density independent mortality factor (Rodewald and Gehrt, 2014) with the incidence of roadkill being subject to high variability. Consequently, roadkill percentage of the migrating population is very unpredictable in any given year. We estimated a conservative annual percentage of migrating monarchs subject to road mortality in the Central Funnel by dividing a roadkill estimate by the sum of overwintering populations and roadkill estimate (overwintering cohort). The size of the overwintering populations is calculated by multiplying the hectares of roosting monarchs at the Mexican overwintering sites from Rendón-Salinas et al. (2018) by the value of 21.1 million monarchs per ha suggested by Thogmartin et al. (2017). Based on these amounts, the estimated annual roadkill rates from our combined years of 2016–2017 MaxEnt models in the Central Funnel represent an average of 2.8% (2.1 million) of the overwintering cohort. In 2016, roadkill within the Central Funnel may have represented about 4.0% of the overwintering cohort (Table 1). The corresponding roadkill for 2017 ranges from 1.5% to 1.8% of the overwintering cohort. In contrast, the projection of 500,000 road-killed monarchs by McKenna

et al. (2001) in Illinois during one week in 1999 represents only 0.26% of the overwintering cohort that year (191 million, 9.05 ha), indicating potentially lower roadkill rates for areas north of the Central Funnel in some years.

The actual monarch population decline within a given year can be much higher than the differences in overwintering cohort sizes from year to year, since it includes the unknown quantities of butterflies recruited, or not recruited due to habitat loss, during spring and summer breeding. Mortality at the Mexican overwintering sites due to occasional winter storms can produce very high mortality, estimated at around 75% in 2002 (Brower et al., 2004) and > 40% in 2016 (Brower et al., 2017). Average monarch overwintering mortality is around  $36\% \pm 21\%$  ( $n = 7$ ; range 4–55%) based on data from Ries et al. (2015b; see their Fig. 24.7). Lowered recruitment due to loss of milkweed habitat has been identified as the primary factor in monarch population declines (Pleasants, 2017; Thogmartin et al., 2017), with losses of milkweed resources in Iowa estimated at 76% from 1999 to 2014 (Pleasants et al., 2017). Other studies place more importance on mortality during the autumn migration in the decline of monarchs (Badgett and Davis, 2015; Inamine et al., 2016; Agrawal and Inamine, 2018). Consequently, it is complex to evaluate the relative importance of roadkill to other factors in the monarch population decline, but it is probably lower compared to the factors of milkweed habitat loss and overwintering mortality. Northward expansion of the monarch summer breeding range is anticipated with climate change (Batalden et al., 2007; Lemoine, 2015), making the southward autumn migration route even longer, increasing both exposure to traffic and associated road mortality (Badgett and Davis, 2015). Monarch roadkill during autumn migration should be further evaluated in the context of other mortality factors along the migration path (Baxter-Gilbert et al., 2015).

Brower et al. (2012) fitted an exponential decline curve to the estimated monarch overwintering populations (ha) in Mexico from 1995 (winter 1994–1995) to 2011 ( $P = 0.015$ ,  $R^2 = 0.336$ ). Inclusion of seven additional years of data through 2018 (Vidal and Rendón-Salinas, 2014; Monarch Watch, 2018b) strengthens fit of an exponential curve ( $y = ae^{bx}$  Fig. 5) ( $P = 0.0009$ ; adjusted  $R^2 = 0.486$ ; ZunZun.com, 2018). A concave exponential curve represents the most serious form of species population decline, indicating constant proportional negative pressure on the population (Di Fonzo et al., 2013). A standard geometric population growth curve, fit to the modeled exponential curve,

Fig. 5. Annual monarch population in hectares in Mexican overwintering sites from 1995 to 2018 (original data, black circles; Vidal and Rendón-Salinas, 2014; Monarch Watch, 2018b) with fitted exponential curve,  $y = ae^{bx}$  (adjusted  $R^2 = 0.49$ ;  $P = 0.00009$ ; blue diamonds), and corresponding geometric population growth equation curve,  $P_t = P_0(1 + r/n)^t$ , where  $P_t$  is the final hectares (2.11),  $P_0$  is the initial hectares (11.79),  $t$  is the number of years (23),  $n$  is the number of sub-periods (1), and  $r$  is the population growth (or decline) rate (derived population decline of 7.21% per year; open red circles). Fifteen years to restore 6 ha of overwintering monarchs based on totally reversing the current decline to 7.21% growth per year (gold triangles). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

reveals an average – 7.21% annual population decline over the last 23 years associated with an overall 82% population reduction (for details, see Appendix A, section 8). In comparison, a fitted exponential curve until 2011, as used by Brower et al. (2012), yielded a slightly lower annual decline rate of 6.46%. The updated results indicate that the decline rate may have increased or at least has not slowed down. Continuance of the 7.21% rate of decline would result in an average of 0.24 ha of overwintering monarchs occurring in 29 years (by 2046–2047), greatly increasing the chance of extirpation of eastern migrating monarchs by an extreme winter storm mortality event as the overwintering population crosses below the 0.25 ha quasi-extinction threshold (Semmens et al., 2016). A total reversal of the 7.21% annual monarch decline, coupled with an annual 7.21% population increase (net change 14.4%), would be needed to restore the size of the overwintering population to current conservation goal of six hectares (Thogmartin et al., 2017) over the next 15 years. A 0.5% annual reduction in migrating monarch mortality through roadkill mitigation could significantly contribute to a reversal in the long-term 7.2% annual exponential decline in monarch populations (Fig. 5).

#### 4.3.2. Roadkill mitigation

While some major factors in the monarch decline are difficult to reduce, such as overwintering mortality, the opportunity for reducing road mortality is possible through roadkill mitigation (see Rytwinski et al. (2016) for a review on mammal roadkill mitigation). The potential ability to locate re-occurring monarch roadkill hotspots could facilitate more effective mitigation. Scattered and unpredictable monarch roadkill would be more difficult to mitigate. A variety of roadkill mitigation measures have been implemented for danaine migratory butterflies. In Taiwan, a four-meter high net was placed along a 400 m section of bridge on National Freeway 3 to successfully induce spring migrating purple crow butterflies (*Euploea* spp.) to fly over and above the traffic, reducing on site roadkill from around 2.5% to 0.5%. In addition, an outer traffic lane was closed when > 500 butterflies per minute were crossing (Her, 2008; Taiwan EPA, 2010). In response to heavy autumn migratory monarch roadkill observed in Coahuila state of Mexico, traffic signs were posted in 2015 limiting the maximum speed to 60 km per hour (37 mph) in the presence of monarchs (Miranda, 2015). Police have been observed slowing traffic in Nuevo Leon state in Mexico to reduce monarch mortality along a highway south of Monterrey (Dr. Orley R. Taylor, personal communication). Additional research is needed to test and assess the effectiveness of these types of butterfly roadkill mitigation strategies for monarch roadkill hotspots in west Texas and Mexico.

## 5. Conclusions

Our study represents a novel approach for projecting roadkill of a migratory insect through ecological niche modeling. Annual monarch roadkill rates during autumn migration varied substantially. We found close agreement between two methods of estimating monarch roadkill rates, simple extrapolation by road type and MaxEnt roadkill model projections. We project about 1.0 to 3.6 million road-killed monarchs per year during autumn migration over the Central Funnel, which could represent 2–4% of the Mexican monarch overwintering population. MaxEnt model roadkill projections also aligned with several previously known monarch roadkill hotspots, which suggests MaxEnt models could be used to identify additional monarch roadkill within the Central Funnel. Roadkill rates may differ throughout the Central Funnel compared to those observed in the Texas survey area, and should be further investigated. Monarch road mortality should also be investigated along the Coastal Funnel, especially from Texas to Mexico. We recommend more detailed investigation into the spatial and temporal variability in monarch road mortality in the Central Funnel, including how local and short-term weather events, especially related to wind, influence monarch roadkill hotspots. With the new information on monarch road

mortality in the Central Funnel, conservation efforts could be implemented to mitigate mortality at monarch roadkill hotspots. Reducing roadkill rate over the Central Funnel for the eastern monarch population is as an important step towards reversing the continuing decline of this iconic butterfly.

16. ABSTRACT <b>A Passage Assessment System (PAS) was developed to help the Washington Department of Transportation (WSDOT) evaluate existing transportation infrastructure for its ability to facilitate terrestrial wildlife movement from one side of a roadway to the other. The outcomes of this research provide mechanisms to allow transportation agencies to identify both opportunities and barriers to wildlife passage along roads. The PAS presented in this report provides an assessment process that differentiates – for different types of wildlife – between structures that are currently functional, those that could be enhanced to become more functional, and those that are not functional for wildlife passage. In this manner, the system enables transportation agencies to prioritize these enhancement opportunities for the greatest cost efficiency and identify locations where improved permeability will require new infrastructure investments.</b>  <b>This project involved three steps: 1) a review of the literature and refinement of classification systems for both wildlife and road structures; 2) field research of wildlife use of bridges and culverts across Washington; and 3) the development and refinement of an assessment system to evaluate the ability of bridges and culverts to move a range of wildlife species under or over roads. The study took data from previous research as well as monitoring data from remotely-triggered cameras to produce a system for classifying wildlife into Species Movement Guilds</b>		

based on how the wildlife respond to roads and crossing structures. Structural Functional Classes were also defined to classify road infrastructure, such as bridges, culverts and pipes, to create a common understanding of terminology related to wildlife crossings. The field research was conducted for six months in six locations in central and western Washington with the objective of ascertaining which species of wildlife approached and used different types of structures. The PAS was then developed on the basis of these field data, research on wildlife use of crossings across North America, and the organization provided by the Species Movement Guilds and Structural Functional Classes. The PAS guides practitioners through a series of targeted questions designed to characterize a bridge or culvert relative to its potential to function as a wildlife passage for the full range of wildlife known to occur at a given site. The PAS is intended as an evaluation tool to ensure that biologists ask the right questions in the field and fully document the conditions that may affect passage functionality for the diversity of target species. By answering questions about the structure characteristics, vegetation, land use, roadway, barriers and fencing, the biologist will have a complete passage assessment including preliminary ideas for improving the structure, which can be further refined during the project planning and design processes. The PAS provides an effective mechanism for determining which structures are suitable for enhancements to improve their functionality as wildlife passages or, if no such enhancements are appropriate, identify structure replacement needs for improved highway permeability for wildlife. A Passage Enhancement toolbox is provided to complement the PAS and presents a number of infrastructure adjustments and maintenance actions that may be implemented to help wildlife better move through structures. This toolbox may be used to help guide users in developing site-specific recommendations.

The Passage Assessment System supports timely inclusion of wildlife passage needs from the onset of highway corridor planning, project planning and design. It offers potential cost-savings and minimized project delays by identifying passage modifications that may be significantly less costly than new infrastructure. Where existing culverts and bridges can be shown to pass wildlife, it would help to reduce future construction costs for wildlife crossings in those areas and help to prioritize which areas are lacking in potential crossings and need additional mitigation.

The contents do not necessarily reflect the official views or policies of the Washington State Department of Transportation. This report does not constitute a standard, specification or regulation.

## **ACKNOWLEDGEMENTS**

This work was conducted as a project for the Washington State Department of Transportation Research Office. Thanks go to Kelly McAllister, Marion Carey and Rhonda Brooks of WSDOT for their guidance and consultation. Jacqueline Cramer was the research assistant for the project. WSDOT biologists who participated in the April 2011 workshop where the Passage Assessment System was first presented provided valuable feedback, and as the ultimate users of the PAS, are due special thanks for their input and ongoing support and involvement in improving the permeability of our road network. It is also with deep gratitude that we thank Sandra Jacobson of the USDA Forest Service for her collaborations and innumerable contributions to the concepts developed in this report.

## EXECUTIVE SUMMARY

State Departments of Transportation (DOT's) are exploring ways to mitigate the negative impacts of roads on wildlife, such as the fragmentation of natural landscapes and the mortality of animals that are hit by vehicles. While new bridges and culverts with fencing specifically designed for wildlife passage (wildlife crossings) offer the greatest opportunity for reducing these negative impacts, they may not always be economically feasible or constructed in a timely manner. Complementing new wildlife crossings, there are also numerous opportunities to enhance existing transportation infrastructure. Hundreds to thousands of culverts and bridges are currently part of the Washington's transportation system and may function to pass wildlife. With small modifications, many of these existing bridges and culverts could be upgraded to provide greater permeability for wildlife and ecosystem processes at lower cost and on shorter time frames than needed for new wildlife crossings.

The purpose of this project was to create an assessment methodology to evaluate existing transportation infrastructure for its ability to facilitate wildlife movement from one side of a roadway to the other. To accomplish this, the research team developed initial criteria for assessing the permeability of existing bridges and culverts for terrestrial wildlife based on the current body of knowledge on how wildlife native to Washington use wildlife crossing structures. The assessment methodology – named the Passage Assessment System (PAS) – was then field tested along Washington roads in linkage areas identified in the Washington statewide habitat connectivity assessment (WHCWG 2010). To complement and validate the field test, the team also conducted wildlife monitoring at seven locations using remote motion-triggered cameras. Data compiled through the monitoring effort served to refine an understanding of how wildlife used select culverts and bridges, which could then be generalized to other locations. The process was then brought to WSDOT biologists in April of 2011 and, through a field test with these future users of the system, the process was further refined. The PAS is a living document, able to be updated to incorporate new understandings of wildlife passage and behavior as they become available, and tailored to address regionally specific wildlife adaptations.

In developing the PAS, it became first necessary to create an explicit process for assessing the characteristics of the various types of bridges and culverts, as well as defining how landscape and structure attributes affect a species' willingness to pass through a structure. To create such an objective standardized process, the researchers began by refining classification systems for wildlife relative to their behavior and perceptions of potential crossing structure, and a second system to provide a common vocabulary for describing the variety of roadway structures that may function as wildlife passages (e.g., culverts, bridges and overpasses). These classification systems were based on a thorough review of the literature base; contributed knowledge from the researchers' concurrent field studies of wildlife and roads in Colorado, Utah, and Montana; and compiled research from colleagues across North America to formulate a more complete understanding of wildlife preferences

and behavior at crossing structures. The wildlife monitoring conducted in Washington as a part of this project further informed an understanding of regional preferences and behavior.

The resulting classification of ‘Species Movement Guilds’ (Chapter 2.2.) categorizes wildlife based on their modes of locomotion and preferred crossing structure characteristics as understood from past and current scientific studies. This is a unique classification designed to facilitate an understanding of ‘what works’ for different types of wildlife. The classification system allows transportation biologists to evaluate the physical and environmental conditions and potential constraints to movement from the perspective of groups of species, and develop mitigation strategies that carefully consider the behavior and preferences of each target species. The Guilds facilitate an understanding of why certain species have specific requirements and allow generalizations to be made across species in a given Guild thereby streamlining project planning and design processes.

Eight Species Movement Guilds are defined (Table 1): Low Mobility Small Fauna, Moderate Mobility Small Fauna, Adaptive High Mobility Fauna, High Openness High Mobility Carnivores, Adaptive Ungulates, Very High Openness Fauna, Arboreal Fauna, and Aerial Fauna. These Guilds provide a classification for mitigating impacts to wildlife whose habitat or movement paths are bisected by a transportation corridor. Interested biologists may not know if a particular species has been studied relative to the effectiveness of various mitigation strategies. By placing that species within its respective Species Movement Guild, generalizations can be made as to which mitigation solutions could be implemented for that species. The Species Movement Guild classification represents the best gathering of the current state of the science of wildlife and transportation in the United States and Canada.

Table 1. Species Movement Guilds

<b>Movement Guild</b>	<b>Typical Species of That Guild</b>
Low Mobility Small Fauna	Invertebrates, frogs, toads, some salamanders
Moderate Mobility Small Fauna	Squirrels, raccoons, hares, weasels
Adaptive High Mobility Fauna	Black bear, bobcat, coyote, lynx
High Openness, High Mobility Carnivores	Grizzly bear, mountain lion, wolf
Adaptive Ungulates	Deer, moose, mountain goat
Very High Openness Fauna	Elk, bighorn sheep, pronghorn antelope
Arboreal Fauna	Flying squirrels, some bats
Aerial Fauna	Songbirds, raptors, bats

The second classification scheme, ‘Structure Functional Classes’ (Chapter 2.3) provides a breakdown of the types of road crossing structures that can provide passageways for wildlife under or over a roadway (i.e., small underpasses, medium underpasses, large underpasses, extensive bridges, wildlife overpasses, specialized culverts and canopy bridges), and the types of wildlife that may use these structures.

The term ‘wildlife underpasses’ connotes many different structures from the smallest culverts that may pass a salamander, to the space under a highway viaduct. A classification of transportation infrastructure into defined Structure Functional Classes provides a definitive set of conditions for four different underpasses, the overpass, and two distinct designs for passages (Table 2). The critical dimensions for breaks among the four classes are based on heights and widths of structures, which are dictated by engineering design constraints as well as the characteristics that define individual species’ willingness to move through a structure. This classification of structure types can help transportation planners, biologists and engineers to relate wildlife passage needs to a specific structure type or types using a common vocabulary.

Table 2. Structure Functional Classes

<b>Class Type</b>	<b>Class Name</b>	<b>Typical Species the Structure Type is Known to Pass</b>
Class 1	Small Underpass	Amphibians, small mammals
Class 2	Medium Underpass	Coyote, bobcat
Class 3	Large Underpass	Deer, elk, black bear
Class 4	Extensive Bridge	Most wildlife – wary species
Class 5	Wildlife Overpass	Most wildlife, including birds
Class 6	Specialized Culverts	Reptiles & amphibians
Class 7	Canopy Bridges	Flying squirrels, arboreal rodents

Combined, the Species Movement Guilds and the Structure Functional Classes lay the foundation for evaluating the permeability of existing structures for wildlife. The team then developed initial structure evaluation criteria based on research in other states supplemented with published research and correspondence with colleagues to determine the factors that appear to influence wildlife passage and how they should be parameterized. These factors include structure dimensions, passageway substrate, vegetation cover, landscape attributes and human use, among other considerations.

A field research component of this project was conducted in conjunction with the development of the Passage Assessment System (PAS). This field component was carried out to better inform the knowledgebase specific to the use of transportation infrastructure by wildlife in Washington. Motion-triggered trail cameras were placed at seven sites across Washington. These sites were selected to best represent different geographic areas, roads with variable number of lanes and different traffic volumes, and different types of structures. Sites were monitored along US 101 in southwestern Washington, and I-90 in west-central Washington. At each site a camera was positioned at each end of the structure to best monitor all animal approaches and passes through the structures.

Monitoring information can help WSDOT determine which species will use certain structures more readily than others. Detailed summaries of the results are provided in the Appendices of this report. In general, every structure monitored passes either mule deer (East of Snoqualmie Pass) or black-tailed deer (western part of the state). These structures included bridges which were expected to pass these deer, and concrete box culverts less than five feet high, a surprising result, perhaps due to a local adaptation necessitated by high traffic volumes on I-90. Photographic data from the Mosquito Creek culvert under US 101 (milepost 76.5), and the double box culvert under I-90 at Tucker Creek (milepost 73) showed a surprising amount of black-tailed deer using the Mosquito Creek/US 101 culvert, and mule deer using the Tucker Cree/I-90 box culvert. The Mosquito Creek culvert is only seven feet (2.1 m) high, less than 16 feet (4.9 m) wide in span, and 138 feet (42 m) long. The I-90 double box culverts at Tucker Creek are less than five feet (1.5 m) high, nine feet (2.7 m) in span, and 58 feet (17.7 m) long for each of the two culverts under opposing lanes of traffic. These culvert heights are typically considered too small for more than occasional mule deer passage. The data from these cameras continue to inform our ideas of how deer will adapt to structures and suggest a need for additional research into the factors that affect passage use, such as traffic volumes, local adaptation, and habitat drivers, among others.

Research throughout the western United States has documented elk's reluctance to pass through confined spaces such as culverts or small, restricted bridges. This study documented elk use of two large bridged structures under I-90, one at the South Fork Snoqualmie River near milepost 33, the other at the Cle Elum River near milepost 79. This research project demonstrated elk movements under bridges that were wide, but less than 10 feet (3.1 m) high where the elk pass under the bridge. This new insight that elk may be willing to use low bridges so long as they are sufficiently wide helped inform the requirements quoted for elk in the Species Movement Guilds description (Section 2.2.1-6) and may help WSDOT and other agencies to better design cost-effective bridges suitable for elk.

Black bear were photographed using a set of large culverts near the town of North Bend, to navigate under I-90. The culverts are 12 feet (3.7 m) high and 29 feet (8.8 m) in span and are tied in to wildlife fencing in both directions. These culverts appears to be among the most successful black bear crossings in the western U.S., as demonstrated by 31 black bear observations during five months of study. In comparison, study sites in two states

combined (Montana and Utah) have tallied less than 12 successful black bear crossings over the course of two years. While the passage is very successful for black bear, only three bobcats approached and crossed through the structure, and seven of 19 approaches by coyotes were repelled. This may explain the low numbers of deer using it. It may also support the idea that in an area of high species diversity, multiple crossings may be necessary for prey, predator and even competitor species.

This compilation of nationwide and local monitoring information was incorporated for the development of a systematic process for evaluating existing transportation infrastructure. The Passage Assessment System (PAS) guides practitioners through a series of targeted questions designed to characterize a bridge or culvert relative to its potential to function as a wildlife passage. The PAS is one of several complementary tools to assist WSDOT in identifying important connectivity areas and design mitigation solutions to improve or restore permeability for native wildlife. While the Washington Wildlife Habitat Connectivity Analysis (WHCWG 2010) offers a broad-scale perspective of connectivity across the state, the PAS allows WSDOT biologists to assess permeability at the site scale, for example along targeted stretches of roadway identified as bisecting these landscape connections.

To begin the assessment process, it is necessary to first select the roadway segments of interests before conducting the PAS in the field. These may be areas that are identified connectivity zones; areas with high levels of animal-vehicle collisions, as determined from carcass removal data; areas that are slated for upcoming projects in short-term (3-5 year) planning or longer term (5-15 year) corridor planning; or, preferably, a combination of the above. The next step before taking the PAS into the field is to identify the species of interest whose habitat is bisected or adjacent to the roadway, and for which movement from one side of the road to the other may be of concern. In general, target species include those that are of danger in animal-vehicle collisions, such as deer, elk and moose; species of concern such as forest carnivores and threatened and endangered species; and other species that are sensitive to the barrier effect of roads. The Wildlife Habitat Connectivity Analysis identified 16 focal species for the connectivity analysis. These species, if they occur in the geographic area of interest, should be included as target species. Appendix A identifies target species and associated Species Movement Guilds for each ecoregion in the state.

The assessment questions that compose the PAS were derived from a similar assessment system used in Colorado (Kintsch et al. 2011) and were further refined through a field test in Florida conducted by one of the researchers (Cramer). Following an additional series of refinements in collaboration with WSDOT, the researchers conducted a one-week field test, visiting 17 sites in southern and central Washington, including sites representing multiple bioregions and a range of structure types (pipe culverts, box culverts, arch culverts, small bridge underpasses and large bridge underpasses) as well as road types (from two to six lanes, including both divided and undivided highways). See Appendix D for complete site summaries. Final refinements to the PAS were made based on monitoring results and feedback an April 2011 workshop where the PAS was presented to WSDOT biologists from across the state.

The PAS is composed of three sections: General Questions, Undivided Highway, and Divided Highway, as well as a User's Guide provided for additional reference. For each structure that is being evaluated the user will complete 1) the General Assessment Questions, and 2) either the Divided or Undivided Highway Assessment Questions, depending on whether the structure of interest is located on a divided or undivided highway. Each of the questions in all three sections is fully clarified in the User's Guide. The complete PAS is available in hardcopy format in Appendix B of this report, or a digital copy is available from the Fish and Wildlife page of WSDOT's intranet. It is recommended that two biologists conduct the PAS together to capture a more comprehensive picture of a structure's passage characteristics.

The General Assessment Questions record general information about the site, including a milepost, GPS point, a unique location code, the Structure Functional Class Type, the Species Movement Guilds present at that site, and whether the highway is divided or undivided. The answer to this last question – divided or undivided highway – will determine which form the user completes next, either the Divided or Undivided Highway Assessment Questions. While the questions posed are the same for a divided or undivided highway, they must be posed independently for each structure at a divided highway site.

At the start of the form the user is asked to respond to a set of preliminary questions. These are a collection of targeted questions designed to determine if there is a 'fatal flaw' with the structure relative to the Species Movement Guild(s) of interest. Each question should be considered relative to the Species Movement Guilds indicated. If a fatal flaw is identified, then the user need not complete the remaining PAS questions as the fatal flaw renders the structure unsuitable for enhancement; a redesigned and reconstructed structure is required to pass wildlife at that location. Fatal flaws may be specific to some or all Guilds and include situations where a culvert is too long for the target species to pass through or where there is a lack of visibility from one end of a structure to the other.

If no fatal flaws are identified, the user then continues with the remaining questions, which are divided into distinct sections to guide the evaluation process. The assessment questions address the structures size and shape, lanes of traffic, other nearby structures, inlet and outlet features, water flow, visibility, vegetation, nearby land use and fencing, evidence of wildlife use and any human use. Throughout the PAS, users are encouraged to take a number of photos from multiple directions to fully capture a visual record of the structure and its attributes.

Finally, the user is instructed to document their general impressions regarding the functionality of the structure for each of the Species Movement Guilds of interest. For each Guild, the user is instructed to rank the structure such that an A rank means that animals could pass through the structure as is or with small modifications; a C rank means that the structure could be functional with modest modification; and an F rank means that the structure cannot be enhanced to function as a wildlife passage. This section is a subjective assessment and responses should be based on the user's overall impression having completed the full PAS. Users are then asked which features could be changed to make the structure more functional for any Species Movement Guild of interest given an A or C rank.

This question offers an opportunity for the user to suggest potential improvements. These may be amended and refined later, but this evaluation is helpful for capturing preliminary ideas and impressions while still in the field.

Upon completing the PAS the user will be equipped to answer the question: ‘can this structure be improved to accommodate passage for the target species present in this area?’ It is possible, in some cases, that a given structure may be enhanced to accommodate one or several of the target species, but cannot be suitably improved to accommodate all target species.

Having determined that a structure *can* be enhanced for wildlife passage, biologists are then confronted with the question of *how* to enhance the structure to facilitate passage. Given the unique characteristics of every structure and the specific permeability objectives at each site, there is no simple answer to this question, however a number of commonly encountered situations are addressed in the Passage Enhancement Toolbox (Appendix C). The toolbox addresses a number of situations and provides examples of each. The user is encouraged to consider the range of possible enhancements and how they could be implemented at each site being assessed.

The Passage Assessment System supports timely inclusion of wildlife passage needs from the onset of highway corridor planning, project planning and design. It offers potential cost-savings over new structures and minimizes project delays by identifying passage modifications that may be significantly less costly than anticipated. If existing culverts and bridges can be shown to pass wildlife, it would help to reduce future construction costs for wildlife crossings in those areas and help to prioritize which areas are lacking in potential crossings and need immediate mitigation. The PAS can also be used to identify areas where maintenance and daily operations activities could significantly improve existing infrastructure for wildlife movement outside of projects. PAS should be considered a living document as new research reveals how passage characteristics affect permeability for different types of species.

There are a number of ways in which the PAS may be enhanced over time to facilitate the assessment process and guide the design of appropriate mitigation enhancements. Notably, while the PAS is currently available as hard copy data forms for use in the fields, it is also ready to be programmed into handheld GPS-data collection units. Two such units are currently being beta-tested by the USDA Forest Service (contact: S. Jacobson). These units provide a streamlined mechanism for collecting and compiling field data. Both the hard copy forms and the programmable units may be easily updated and refined as needed.

In addition, ongoing and new monitoring studies that help deepen our understanding of wildlife responses to crossing structures may also further inform and refine the PAS over time. With the deployment of field research cameras across Washington, WSDOT will be better equipped to record species’ responses to transportation infrastructure and traffic. These data will greatly assist WSDOT in developing wildlife crossing structures and enhancements to existing structures that will improve the permeability of the state’s road network for all wildlife.

As the knowledgebase of what works and doesn't work for different species evolves, DOTs will be increasingly equipped to design effective new wildlife crossing structures and improve the functionality of existing structures. Targeted monitoring where permeability enhancements have been implemented will create a positive feedback loop for maximizing the effectiveness of future improvements. Tools such as the PAS can help DOTs direct transportation dollars for maximum effectiveness and cost efficiency.

## CHAPTER 1. INTRODUCTION

The science and practice of transportation ecology is concerned with the effects of transportation on the natural world and the measures necessary to help avoid, minimize and mitigate those effects. In a world largely dependent upon motorized transport of people, goods and services, the negative consequences to individual plants and animals and entire ecosystems is inevitable. Both the road footprint and vehicular traffic pose threats to intact ecosystems and wildlife by creating barriers to movement of individuals and natural processes, fragmenting natural communities, and causing numerous vehicle collision-related deaths. At the heart of the practice of transportation ecology is the belief that new transportation projects should first avoid natural areas and crucial wildlife core areas and corridors; second, plans should minimize those effects; and lastly, mitigate for the effects of a project on wildlife, natural habitat and ecosystem processes. In the case of existing transportation infrastructure that is still in use, mitigation is the only option available for improving roadway situations to accommodate multiple wildlife species and their movements across the landscape, thereby promoting wildlife permeability.

The negative effects of roads including the fragmentation of natural landscapes and the mortality of animals that are hit by vehicles can be partially mitigated through improvements to existing infrastructure to enhance permeability for wildlife. While new crossing structures designed specifically for wildlife passage offer the greatest opportunity for reducing the negative impacts of roads on wildlife, such large infrastructure projects are often not economically feasible or constructed in a timely manner. Hundreds to thousands of culverts and bridges are currently part of the state's transportation infrastructure and may function to pass wildlife. With small modifications, many of these existing bridges and culverts could be upgraded to provide greater permeability for wildlife and ecosystem processes.

Efforts are underway nationwide to better plan new transportation projects and upgrades to existing transportation infrastructure in ways that help to minimize the negative effects of roads on the natural environment, natural process and wildlife movement. Such integrative planning efforts begin at the long-range planning stage, where initial environmental needs and mitigation costs are assessed. To properly inform these long-range planning efforts there is a need to assess existing infrastructure for its current and potential ability to function as passageways for different types of wildlife. Inclusion of wildlife permeability needs at the outset of project planning effectively promotes landscape connectivity to help minimize transportation impacts in a cost-effective fashion.

While there are many studies documenting individual species' preferences for crossing structures across the continent and the globe, until this research project, there has not been a complete analysis of functional crossing structure characteristics for diverse wildlife species. In addition, while transportation agencies across North America and Europe have instituted various types of enhancements to existing infrastructure to promote permeability for wildlife at a number of locations, a clear process for understanding and defining the structural and landscape characteristics that enhance or impede movement through a structure for diverse types of wildlife has been lacking.

Consequently, the Washington State Department of Transportation (WSDOT) has been without a means for understanding how transportation infrastructure currently functions to support or impede connectivity for terrestrial wildlife. In supporting this research, WSDOT identified a concrete need for protocols for evaluating existing structures – bridges and culverts – with regards to their potential to pass different types of wildlife. The outcomes of this research provide these mechanisms, allowing transportation agencies to identify both opportunities and barriers to wildlife passage. The Passage Assessment System (PAS) presented in this report provides an assessment process that differentiates – for different types of wildlife – between structures that are currently functional, those that could be enhanced to become more functional, and those that are not functional for wildlife passage. In this manner, the system enables transportation agencies to prioritize these enhancement opportunities for the greatest cost efficiency, and identify locations where improved permeability will require new infrastructure investments.

The Passage Assessment System supports timely inclusion of wildlife passage needs from the onset of highway corridor planning, project planning and design. It offers potential cost-savings over new structures and minimizes project delays by identifying passage modifications that may be significantly less costly than anticipated. If existing culverts and bridges can be shown to pass wildlife, it would help to reduce future construction costs for wildlife crossings in those areas and help to prioritize which areas are lacking in potential crossings and need immediate mitigation. The process also assists in ecological considerations because it targets priority areas where functional passages do not currently exist. The PAS, in conjunction with Washington's recently completed statewide Wildlife Habitat Connectivity Analysis (WHCWG 2010) and the statewide carcass removal database, form the basis for targeting mitigation dollars and incorporating wildlife needs early in the transportation planning process to inform infrastructure designs prior to project development and thereby help minimize delays. The PAS can also be used to identify areas where maintenance and daily operations activities could significantly improve existing infrastructure for wildlife movement outside of projects.

## **1.1. History of Landscape Permeability in Washington State**

Since 1991 WSDOT has managed a cooperative program to inventory, prioritize, and correct fish passage barriers along state roads. More recently, WSDOT has recognized the need for creating an analogous process for identifying and assessing connectivity needs for terrestrial wildlife across state roads, of which this Passage Assessment System is a step.

In July 2007, Washington State Secretary of Transportation Douglas MacDonald signed Executive Order 1031 'Protections and Connections for High Quality Natural Habitats', which directs the agency to protect ecosystem health and preservation of biodiversity through the road and highways programs. This order directs WSDOT to protect aquatic and terrestrial connectivity for fish and wildlife. As part of WSDOT's actions to fulfill this order, WSDOT and its partners in the Washington Wildlife Habitat Connectivity Working Group released the statewide Washington Wildlife Habitat Connectivity Analysis (WHCWG 2010). This document provides maps based on scientific analyses of how 16 target species of wildlife may need to move across the state through connected networks and where the most intact connected landscapes occur throughout the state. This connectivity assessment, in combination with other information, will influence road corridor plans and highway improvement projects, and will help to prioritize highway segments for receiving funds for wildlife-friendly improvements.

With these multiple approaches to identify and maintain terrestrial and aquatic connectivity across Washington roads, it is a logical next step to create a method to assess how well existing infrastructures passes terrestrial wildlife. The results of this assessment method could then in turn be used to improve existing structures in small and large ways to assist wildlife and natural process movement, such as the flow of water. It is an important step in the process of "protecting connections for high quality habitats" as directed by Executive Order 1031.

## **1.2. The Science of Wildlife Use of Transportation Infrastructure**

Designing wildlife crossings – new structures as well as enhancements to existing infrastructures – is based on research documenting how different species and taxonomic groups of wildlife have used wildlife crossings in past and current studies. In addition, more general information about the behavioral characteristics and habitat needs of that species can be used to further inform crossing designs, particularly where little or no research has been conducted on an individual species' use of crossings. Improving roads for wildlife permeability has been studied since

1975 when Colorado's first mule deer culvert under Interstate 70 was monitored for mule deer use (Reed et al. 1975). Since that time many states have benefited from the several dozen studies monitoring wildlife use of culverts and bridges across the continent. While the first wildlife crossings were constructed for a specific target species, such as deer or Florida panther, biologists soon learned that designing wildlife passages for the full suite of species found in an area can benefit all of the wildlife present in that area and can help maintain ecosystem processes, such as hydrologic flow (Foster and Humphrey 1995). It is now common, though perhaps not standard practice, to design new wildlife passages for suites of animals. Designing crossings and improving existing infrastructure therefore requires understanding how multiple species may perceive and, subsequently, use a passage. For example, a passage designed primarily for large ungulates can be modified to also accommodate smaller animals and aquatic species. As transportation agencies move towards incorporating more wildlife-friendly practices in their designs, construction and operations, such multi-species considerations are prudent.

### 1.2.1. Types of Wildlife Passages

A wildlife crossing is a structure that allows wildlife to pass over or under the road. A wildlife crossing structure is designed and built specifically or in part to assist in wildlife movement (Bissonette and Cramer 2008) and include both overpasses and underpasses. Overpasses are built to allow wildlife to move over the flow of traffic to get to the other side of the roadway (Fig.1). Underpasses are much more common and entail two different types of structures, culverts and bridges, both of which allow wildlife to move under the roadway. Bridged wildlife passages can be single span bridges where the structure rests on abutments with no intermediate support columns (Fig. 2). Multi-span bridges are on abutments as well but also have one or more intermediate support columns between abutments (Fig. 3). Culvert underpasses are conduits for wildlife under the road that have an embankment around the entire perimeter. Typically either

Figure 2. Single span bridge wildlife crossing in Utah, under US 6 © P. Cramer

concrete box culverts (Fig. 4) or corrugated steel plate arch culverts are used (Fig. 5). More recently, a new arch design for wildlife passages that is intermediate between bridges and culverts has been constructed. An arch crossing consists of pre-fabricated six foot-wide arch spans that rest on abutments and are fastened together to form an arched passageway beneath the road. There is some soil at the sides of the arches, but the abutments are large enough that there are two to one slopes coming off of them to the passage area, making the entrance appear more like a bridged structure than a culvert (Fig. 6)

### 1.2.2. Overview of Factors Affecting Wildlife Use of Crossings

There are many interrelated factors that affect an individual animal or a population's decisions to use crossings. The two main factors that affect these decisions can be grouped into characteristics of the external environment and internal motivations based on the biology of the species. Understanding why animals behave the way they do and their basic biological needs is an essential component to help planners, biologists and engineers design suitable wildlife crossings and enhance existing infrastructure that considers both the internal and external factors motivating animals to use or avoid a given structure.

Biological factors important to wildlife movement include the following (note that not all of these factors are of equal importance for all species):

- Mode of locomotion, i.e., crawling animals move differently than running animals and may spend more time in a crossing structure;
- Predator avoidance strategies, i.e., the need for prey species to feel safe using a crossing structure;
- Defense strategies, i.e., skunks stop to spray a threat, while porcupines back up to it, and rabbits and deer may run in a zigzag fashion;
- Herd mentality versus solitary movement;
- The need to access basic resources such as food and water;
- The need to find mates;
- The need to migrate to meet basic biological needs such as breeding, calving, egg laying, or access to winter and summer habitats;
- The need to escape human pressures such as development or recreational activities;
- The need to disperse to establish new territories;
- The need for specific types of habitat such as a semi-aquatic condition.

Environmental factors that affect how wildlife perceives structures for potential passage include (note that not all of these factors are of equal importance for all species):

- The presence of natural area or specific habitat on both sides of the road;
- The presence of human development or disturbance nearby or within the structure;
- Vegetative cover leading to the structure;
- Vegetative or woody debris cover within a structure;
- Visibility through the structure and at the approaches to the structure;
- Light contrast inside and outside of the structure;
- Elevation gradients that may affect water flow or large gradients that may affect an animal's approach to a structure;

- Traffic noise that is present outside the structure and that may be amplified inside or changed in pitch inside or beneath the structure;
- Traffic volumes, i.e., heavy traffic volumes may deter animals from coming near the road, and crossing through a structure, while low traffic volumes may encourage animals to cross at-grade rather than use structures unless they are otherwise prevented from doing so with fences or other funneling devices;
- Similarity of the conditions in, under or on a structure relative to the natural environment in which it is located;
- The feel of openness (rather than confinement) for an animal crossing through a structure.

Openness ratio has been a much-discussed and frequently misused metric for assessing the functionality of crossing structures for wildlife, and for this reason it is briefly addressed here. Openness ratio – defined as (height x width)/length, in meters – was originally derived as a threshold measure for comparing the relative openness of various box culverts for use by mule deer, given their preference for a clear line of site through a structure (Reed et al. 1979). This measure has since been extrapolated beyond its intended use and applied to all kinds of structure shapes, leading to confusion in how to measure structures other than boxes, and has been applied to a variety of species, with different minimum thresholds indicated for different species. Other complications in relying on openness ratio as a measure of structure functionality include how the ratio – which is unit-specific – is calculated; how skylights and grates affect the length metric; and a failure to differentiate between the value of height (rise) vs. width (span) in affecting the likelihood of animal using a structure (Jacobson and Jacobson 2007). While researchers agree that the concept of structure openness is an essential factor influencing passage functionality for some types of species, such as deer and elk, Clevenger et al. (2002) noted that openness may become a less important variable influencing culvert use as animals become familiar with particular structures, versus animals that are encountering a structure for the first time, in which case openness may play a greater role. For these reasons, it is not advised to use openness ratio to calculate thresholds for evaluating the functionality of a given structure, and it is not included in the Passage Assessment System.

Jacobson and Jacobson (2007) provide alternative measures to openness ratio for white-tailed deer that consider predator avoidance strategies. These include aspect ratio, a measure of structure length and height at the level of a deer's head; cross-sectional area, a measure of structure shape relative to a deer's perception of openness; brightness, a measure of perceived distance to safety; and presence of a ledge, which can influence an animal's willingness to pass through a structure. While these measures have not been tested or refined for other species, concepts such as

these were used in the development of the Passage Assessment System presented in this report.

Past and current research projects are typically designed to measure one or several of these factors and how they influence passage for a given species. Rarely have all of these factors been studied relative to the full suite of species present at a study location.

## **CHAPTER 2. RESEARCH APPROACH**

The purpose of this project was to create an assessment methodology to evaluate existing transportation infrastructure for its ability to facilitate wildlife movement from one side of a roadway to the other. To accomplish this, the research team developed initial criteria for assessing the permeability of existing bridges and culverts based on the current body of knowledge on how wildlife native to Washington uses wildlife crossings. The assessment methodology – named the Passage Assessment System (PAS) – was then field tested along Washington roads in linkage areas identified in the Washington statewide habitat connectivity assessment. To complement and validate the field test, the team also conducted wildlife monitoring at seven locations using remote motion-triggered cameras. Data compiled through the monitoring effort served to refine an understanding of how wildlife used select culverts and bridges, which could then be generalized to other locations. The process was then brought to WSDOT biologists in April of 2011 and, through a field test with these future users of the system, the process was further refined. It is a living document, able to be updated to incorporate new understandings of wildlife passage and behavior as they become available, and tailored to address regionally specific wildlife adaptations.

To create the PAS, it was first necessary to develop an explicit process for assessing the characteristics of the various types of bridges and culverts as well as how landscape and structure attributes affect a species willingness to pass through. Taking a synthesis approach, the team reviewed the current literature base and complimented this with knowledge gleaned from our concurrent studies in Colorado, Utah, and Montana and from research colleagues across North America to formulate a more complete understanding of wildlife preferences and behavior at crossing structures. The wildlife monitoring conducted in Washington as a part of this project further helped to develop a more definitive understanding of regional preferences and behavior.

Using this base of information, the team developed two interrelated classification schemes. The classification of ‘Species Movement Guilds’ (Chapter 2.2.) categorizes wildlife based on their modes of locomotion and preferred crossing structure characteristics as understood from past and current scientific studies. This is a unique classification designed to facilitate an understanding of ‘what works’ for different types of wildlife. The classification system allows transportation biologists to evaluate the physical and environmental conditions and potential constraints to movement from the perspective of groups of species, and develop mitigation strategies that carefully consider the behavior and preferences of each target species.

The classification ‘Structure Functional Classes’ (Chapter 2.3) provides a breakdown of the types of road crossing structures that can provide passageways for wildlife under or over a roadway (i.e., small underpasses, medium underpasses, large underpasses, extensive bridges, wildlife overpasses, specialized culverts and canopy bridges), and the types of wildlife that may use these structures. Combined, the Species Movement Guilds and the Structure Functional Classes lay the foundation for evaluating the permeability of existing structures for wildlife. The team then developed initial structure evaluation criteria based on research in other states supplemented with published research and correspondence with colleagues to determine the factors that appear to influence wildlife passage and how they should be parameterized. These factors include structure dimensions, passageway substrate, vegetation cover, landscape attributes and human use, among other considerations.

The Passage Assessment System is a tool for transportation biologists to evaluate existing bridges, culverts and overpasses relative to their functionality as potential wildlife crossings. The PAS does not and cannot provide a definitive answer as to how to modify existing infrastructure to better accommodate terrestrial wildlife passage; instead, the PAS guides the user through the thought process of identifying the characteristics that impede or promote wildlife passage for different types of species, ensuring that all the relevant factors are fully considered, from a species perspective. In combination with other resources, such as the Passage Enhancement Toolbox provided in Appendix C, users are provided with a framework for identifying if a structure can be modified to accommodate the target wildlife and, if so, which modifications are warranted.

## **2.1. Previous Roadway Infrastructure Evaluation Studies**

Across the country, DOTs are increasingly integrating permeability for terrestrial and aquatic wildlife into transportation projects to mitigate transportation impacts

or, in many cases, restore connectivity that has been lost. Efforts to evaluate permeability needs range from informal field visits to detailed manuals for enhancing aquatic connectivity through culverts (e.g., Washington Department of Fish and Wildlife 2000). While a number of states, particularly in the west, have conducted wildlife habitat connectivity assessments of varying levels of analysis and detail, to date, no states have a complete inventory and assessment of transportation infrastructure as it relates to identified wildlife connectivity zones for terrestrial wildlife. In-the-field assessments of potential modifications to existing infrastructure can be conducted well in advance of transportation planning schedules, allowing planners to incorporate wildlife permeability considerations into project designs and budgets. In addition, such assessments may reveal small modifications that can be made outside of project planning through ongoing operations and maintenance, with great benefits to wildlife movement, for example, by removing fencing blocking culvert entrances, clearing debris blocking passage through culverts, or by adding soil over riprap under bridges to create a dry, stable pathway for wildlife to cross over.

In Colorado, a three-year study of the Interstate 70 corridor developed a basic framework for evaluating existing bridges and culverts. This study was supplemented by camera monitoring at select locations in an effort to identify key segments of roadway for wildlife connectivity and to develop recommendations for improving permeability in these areas (Kintsch et al. 2011). The evaluation processes conducted on I-70 directly informed the development of the Passage Assessment System created for this research project.

The Massachusetts Department of Transportation published a report that presents considerations for evaluating existing structures at freshwater streams and offers best practices for accommodating wildlife passage at these road-stream crossings (Massachusetts Department of Transportation 2010). This evaluation system provides a simple field assessment for rating road-stream crossings for terrestrial and aquatic passage on a scale from 0 (severe barrier) to 10 (meets optimal standards). The rating system considers only three factors influencing terrestrial passage – the presence of barriers, openness ratio and minimum clearance – and does not distinguish among the diversity of wildlife species. In contrast, the PAS presented here includes a number of variables that influence the likelihood of successful passage and provides guidelines for assessing how crossing characteristics may affect different species differently.

Field-based assessments of existing transportation infrastructure in other states have occurred on an ad-hoc basis or, in the case of Utah, limited to a broad-scale and subjective evaluation of barriers to connectivity across specific highway corridors (Utah Department of Transportation 2007).

## 2.2. Species Movement Guilds

The Species Movement Guilds (Table 1) are a classification of terrestrial wildlife species based on their responses to roads and crossing structures – behavior that is largely influenced by predator detection and avoidance strategies, as well as an animal’s size and capacity for locomotion. Traditional species classifications are based on taxonomic groupings based on biologic similarities among species. In contrast, the Species Movement Guilds classification was developed specifically for the purpose of designing species-specific wildlife crossings and evaluating the influential characteristics that render a structure functional or non-functional. Previous studies in road ecology have proffered similar classifications more closely tied to taxonomic classifications (e.g., Grillo et al. 2010), or based on body size (Clevenger and Kociolek 2006) and how species respond to habitat fragmentation (Cavallaro et al. 2005). Clevenger and Huijser (2009) developed a size-based classification that considers fragmentation impacts as well as species area requirements.

The Species Movement Guilds presented in this report are intended to be a refinement of these previous classifications, including an in-depth discussion and justification for the groupings. The guilds categorize wildlife based on body size – which puts a physical limit on the structures that a given species can use – how they move, how they respond to roadway traffic or potential threats such as predators, and the crossing structure characteristics, such as vegetation cover, ambient conditions and visibility, that may affect their willingness to use different structures to move under and over roads. The guilds facilitate an understanding of why certain species have specific requirements and ‘what works’ for different types of species. Predator avoidance is a key factor for most wildlife. As different species have different detection and avoidance strategies, crossing structures must address the strategies of the target wildlife at a given location. In addition, some species are limited by their movement capacity (slow vs. fast-moving), by their mode of travel (ground, water, air), or by their need for consistent environmental conditions (e.g., some amphibians); these specific habitat requirements also need to be addressed. The type of preferred habitat that an animal lives in within an ecoregion also affects how they use a crossing. Populations of the same species may be more willing than others to use a crossing based on its similarity to the landscape it is placed in. A population’s experience with humans and other factors can also affect how they use a crossing; where some wildlife populations may be adapted to human presence, for others it causes a fear or avoidance reaction. The Species Movement Guilds are based on generalizations across populations and provide broad guidance for application within the context of the landscape and specific situations at hand. The guilds were developed with careful review of published and grey literature in wildlife and transportation ecology as well as the author’s and other colleagues

combined experience with wildlife movement and roads across the U.S. and Canada; pertinent references are included in the discussion of each of guild in the following section.

The purpose of Species Movement Guilds classification scheme is to provide a user-friendly framework for transportation biologists to determine how well the movement needs of target species are accommodated by existing transportation infrastructure and whether post-construction improvements could improve wildlife passage at a given location. This process allows biologists to better understand the permeability of the transportation network for different types of species. Although the classification was designed specifically with regards to improving bridges, culverts and overpasses, it could also be applied to the design of shoulder and median barriers, fences and related roadway infrastructure. By combining an understanding the movement needs of each Species Movement Guild with the situational and structural attributes that render a structure functional for those guilds, biologists are better positioned to evaluate suitable enhancement options at a given location or, if no such option is available, advise the design for a new, effective wildlife crossing. Developed in collaboration with a colleague at the U.S. Forest Service, the Species Movement Guilds were compiled with reference to the best available research and monitoring information (including the concurrent monitoring project in Washington), and were further validated and refined during the field test of the structure evaluation system.

Further conditions for defining Species Movement Guilds included culvert and bridge minimum size requirements and structure characteristics such as substrate, cover, openness, ambient conditions, lighting, lines of sight, sound buffering, shape, approach conditions, amount of human use/development, etc. Typically, when designing passage structures the movement needs of multiple types of species must be addressed as opposed to a single species or guild. Intuitively, large structures may be designed to accommodate smaller species, whereas small culverts cannot accommodate larger wildlife species. However, the specific design characteristics required by each target Species Movement Guilds must be individually addressed; a larger structure will not automatically accommodate small animals if it does not provide appropriate cover or other necessary attributes. This species classification offers a useful mechanism for an initial assessment of needs and opportunities. In all cases additional analysis is required to determine the best options for accommodating multiple species or regional variations in species preferences due to the presence or lack of predators, human activity, resource availability or other considerations.

**TABLE 1:** Terrestrial Species Movement Guilds. A functional categorization of terrestrial wildlife based on body size, predator avoidance strategies, and species behavior relative to road infrastructure, traffic and crossing structure characteristics. Developed by the authors in collaboration with Sandra Jacobson, U.S. Forest Service.

<b>Species Movement Guild</b>	<b>Species Examples</b>	<b>Species Attributes</b>	<b>Preferred Passage Attributes</b>	<b>Preferred Structures</b>
Low Mobility Small Fauna (LMSF)	Invertebrates, frogs, toads, some salamanders, some ground insects	Small, slow-moving species that require specific ambient conditions (including possibly moisture and light) to survive and disperse. Some species in this group may take several generations to move across a structure. Completely enclosed structures may interfere with directional movements for some species that navigate by reference to celestial features.	Crossings must provide species-specific habitat and consistent outside environmental conditions throughout the entire structure, including natural substrate, light, temperature and moisture. Species in this category may be found adjacent to water, but probably prefer dry pathways or pathways without flowing water through culverts.	<i>Extensive bridges, wildlife overpasses, trench drains</i>
Moderate Mobility Small Fauna (MMSF)	Ground squirrels, shrews, rabbit, hare, chipmunk, vole, mice, skunk, raccoon, some salamanders, lizards, turtles, snakes, badger, marmot, weasel, pika, fox, marten, fisher, river otter, beaver, mink, muskrat, some ground birds	Small animals that are fairly adaptable to different types and sizes of structures. Almost all of these species are prey for larger species and require some hiding cover for protection. Some may require a natural substrate or moisture to survive in structures, and most prefer natural substrates.	Functional crossing structures include a variety of structure types and sizes. A non-submerged pathway is almost always preferred and usually required by species in this guild. They may also use structures with artificial substrate or ramps. Cover provided within larger structures with rocks, vegetation or smaller pipes is usable.	<i>Small, medium or large underpasses (culverts and bridges), extensive bridges, wildlife overpasses</i>
Adaptive High Mobility Fauna (AHMF)	Black bear, bobcat, coyote, lynx	Medium-sized mammals that naturally use enclosed spaces for dens, and can tolerate a limited amount of enclosure in underpasses. Minimum crossing structure size is proportional to species body size.	Species in this group may use a variety of structure types and prefer to have suitable habitat directly adjacent to the structure entrances.	<i>Small, medium or large underpasses (culverts and bridges), extensive bridges, wildlife overpasses</i>
High Openness High Mobility Carnivores (HOHMC)	Grizzly bear, mountain lion, wolf	Highly mobile species that prefer good visibility. Typically larger animals that have a larger minimum structure size requirement than Adaptive High Mobility Fauna. These species range widely across the landscape and may need to cross multiple highways.	Open structures that provide good visibility but can be tolerant of longer structures (>100'). Species in this group tend to prefer more open structures than Adaptive High Mobility Fauna but are more tolerant of enclosed structures than Very High Openness Fauna.	<i>Large bridge underpasses, extensive bridges, wildlife overpasses</i>

<b>Species Movement Guild</b>	<b>Species Examples</b>	<b>Species Attributes</b>	<b>Preferred Passage Attributes</b>	<b>Preferred Structures</b>
Adaptive Ungulates (AU)	Mule and white-tailed deer, moose, mountain goat	Medium and large-sized ungulates that require good visibility on a horizontal plane and a moderate amount of cover. These animals prefer a natural substrate and adjacent cover, but may also use concrete-bottomed culverts. Ungulates in this group use structures in approximate proportion to their body size (i.e., deer can use smaller structures than moose).	Passages that have good visibility within and around the structure and clear lines of sight from one end of a crossing structure to the other. Preferred structures are wider than they are tall and are less than 100' in length. Mule deer may prefer more open structures than white-tailed deer.	<i>Medium or large underpasses (culverts and bridges), extensive bridges, wildlife overpasses</i>
Very High Openness Fauna (VHOF)	Elk, pronghorn, bighorn sheep, open habitat grouse	Ungulates in this group are particularly wary of predators and require very wide vistas and clear lines of sight. They tend to prefer a moderate amount of hiding cover that does not infringe on their ability to detect or escape predators. Structure size is dictated primarily life history attributes such as predator avoidance or maneuverability.	Large passages with wide openings (at least 15') that are less than 100' long, excellent visibility within and around the structure, and clear lines of sight from one end of a crossing structure to the other. Bridge underpass structures with natural earthen side slopes are preferred to those with concrete or metal walls. Features that may encourage passage include a natural substrate, and noise and light contrast moderating features.	<i>Large culvert or bridge underpasses, extensive bridges, wildlife overpasses</i>
Arboreal Fauna (ArbF)	Flying squirrels, some bats, arboreal voles	Species that move primarily through the canopy rather than on the ground surface.	Features for these species provide a continuous canopy-level structure across the roadway.	<i>Treetop rope bridges, towers, or modified wire or metal structures.</i>
Aerial Fauna (AerF)	Songbirds, raptors, bats, flying insects (including butterflies)	Species whose primary mode of movement is flying.	Features for these species aim to divert flying species out of the path of traffic.	<i>Diversion poles, extensive bridges, wildlife overpasses</i>

## **2.2.1. Research Summary of Species Preferences and Behavior**

This section provides an overview of each of the Species Movement Guilds and the research on individual species that informed the categorization scheme. For each guild, a discussion of the trends found in transportation ecology is presented and specific conditions preferred by different species are noted. This discussion is presented with the understanding that a given crossing may be constructed for suites of species rather than a single target species, in which case crossing designs should draw from the 'preferred characteristics' listed for the suite of species present at that site. There is no perfect crossing structure, as any structure is mitigation – at best, adequate compensation for the natural landscape connectivity that has been lost. As such, the potentially conflicting needs of multiple species must be balanced at any given site. Additional research and information sharing across states and countries will help to further improve crossing designs of the future.

### **2.2.1-1. Low Mobility Small Fauna**

Members of this guild include small, slow-moving animals that require specific ambient conditions (for example, moisture or light) through the length of a crossing structure, such as frogs, toads, some salamanders, invertebrates and some ground insects. Structures for these species may be open at the top to permit moisture and light to enter the structure and to allow navigation with respect to celestial navigation. The structures may be enclosed as well, thus protecting the animals from road pollution and traffic noise. Some species in this guild may take several generations to move the length of a crossing structure, such as insects. Species in this category are found across the spectrum of natural areas including near water (such as frogs and salamanders), dry upland areas (toads and tortoises), and even those amphibians willing to travel over snow to breed, such as long-toed salamanders. As a result of this extreme diversity in preferences of areas of movement, crossings must provide species-specific habitat and consistent outside environmental conditions throughout the entire structure, including natural substrate, light, temperature and moisture. These structures could be small culverts, or large bridges that provide natural substrate beneath them for contiguous movement.

### ***Specific Considerations for Amphibians and Reptiles***

#### **Salamanders and Frogs**

The first amphibian crossings in the United States were a pair of salamander crossings placed under a road in Amherst, Massachusetts in 1987. These tunnels were placed 200 feet (61 m) apart and connected with a system of 12-inch (30.5 cm) high drift fences to direct the salamanders towards the tunnels. Jackson (1996) found that salamanders need light to see inside the tunnel, and once artificial light was provided, the time it took for salamanders to enter and pass through the tunnels was dramatically reduced. Salamanders need moisture in their passages, and crossings designed for these species should include some mechanism for

allowing rain to enter and moisten the substrate within the underpass. Jackson (1996) suggests when considering more than two lane highways for tunnels, take into account animals freezing along the way and either minimize the length of the passage, or provide island-stop over habitat that could serve as half-way points for migrating amphibians.

A typical amphibian crossing is circular or rectangular; generally less than 1.6 feet (0.5 m) in cross section; as short as possible; and with a floor lined with a natural soil substrate (Aresco 2005, Jackson 2003). Specific guidelines for designing amphibian crossings include the following considerations:

- The tunnel should be open at top and fitted with iron grate flush with road surface to allow ample light, rain, and air to circulate (Jackson 2003). Brehm (1989) further notes that grated passages play an important role in providing aeration and equilibrium of ambient temperatures and moisture conditions.
- Because some amphibians and reptiles use olfactory cues to assist them in their movements, Jochimsen et al. (2004) suggest allowing for a layer of detritus and leafy substrate to remain undisturbed along the length of passages.
- Tunnels should be situated so that they can be easily accessed and not prone to flooding (Puky and Vogel 2004).
- Maintenance of amphibian tunnels is also extremely important for functional crossings; tunnels should be cleaned on an annual basis before the start of the migration period (Puky and Vogel 2004).
- Wing walls should angle out from each end of tunnel at approximately 45 degrees (Jackson 2003) and continue outward as guide fencing. This fencing can be plastic (polythene mesh) or concrete (Grillo et al. 2010), or even fashioned from metal guard rails stacked vertically.
- The height of the vertical guide walls can vary from 18 inches (45.7 cm) to over 3.3 feet (1 m; Fig. 7; Aresco 2005, Jackson 2003). The length should extend from the wing walls for 100-300 feet (30-90 m) on both sides of the road. The tops of these walls should be angled away from the road to prevent climbing organisms from getting over the fence. Jackson and Tyning (1989) also suggest that the drift fences should be sunk into the ground 2.5-4 inches (6-10 cm; Figure 8). Some animals do not follow fences. Jackson and Tyning (1989) found that wood

Figure 7. Amphibian and reptile barrier wall at Paynes Prairie State Preserve, along US 441 in Gainesville, Florida © P. Cramer

*Figure 8.* Drift fencing to funnel turtles under the highway to get to other side of Lake Jackson, Tallahassee, FL © P. Cramer

- frogs have been hesitant to move along the fencing.
- Crossing structures should be spaced within 200 feet (61 m) of one another (Jackson 2003); Puky and Vogel (2004) found a maximum spacing distance of 260-328 feet (80-100 m) to be adequate, but recommend determining the spacing between crossing structure on the basis of the migration radius of the target species under normal conditions.
  - Locate crossings in the center of migration routes rather than at the edges. To find these migration routes, the species need to be studied for at least two years because routes vary from year to year (Puky and Vogel 2004).
  - The authors conclude that close cooperation between engineers and biologists specializing in amphibians is of utmost importance to finding mutually acceptable solutions (Puky and Vogel 2004).

Drainage culverts and culverts designed to allow the flow of water can be modified to pass amphibians and reptiles via the installation of shelves or floating docks inside the culvert (Jochimsen et al. 2004). Jackson (1999) suggests channelizing the water through the culvert to create an extended bank area, although this action should be conducted only with careful consideration of aquatic connectivity needs through the culvert. Dry culverts can be enhanced with the placement of natural substrate inside the culvert to provide a suitable movement surface for amphibians. The addition of cover in the form of vegetation, logs or rocks inside the culvert can also improve conditions for these prey species.

While keeping the top of a culvert open allows for moisture, light, and a view of the night sky, it also allows for road runoff to enter the crossing. This may expose the moving animals to heavy metals such as copper, zinc, and lead, as well as petroleum derivatives. Further research is needed that helps in the design of crossings for this small fauna group. Perhaps multi-chamber designs could be created where outside chambers of a three-chambered culvert would catch the pollutants running off the road, while the middle third chamber is open and aerated but free of road runoff. Another idea would be to find a way to deliver moisture to the culvert from more pure sources outside of the road-right-of way, thus avoiding the need to deliver moisture from the road.

For further information on mitigation solutions for wildlife at locations with road-stream crossings, readers may reference a recent publication from Massachusetts Department of Transportation (Massachusetts Department of Transportation 2010), which offers very instructive recommendations on placing new structures and enhancing older ones to accommodate amphibians and aquatic species in a stream environment.

**BOX 1: Paynes Prairie Ecopassages**

Some of the most successful amphibian (and reptile) crossing structures and fencing are located in Florida. The Paynes Prairie ecopassages (concrete box culverts) and accompanying concrete wall have worked very successfully (Fig. 9; Dodd et al. 2004), with a 93% reduction in total numbers of animals killed one year post-construction. The wall which kept the animals off the road is a one meter high concrete wall with a 6 inch (15.24 cm) lip that faces toward the wild lands away from the road. The concrete is composed of a very smooth mix, so it would be difficult for animals to climb up. There are 8 box culverts along 2 miles of a four lane divided highway. The culverts are approximately 8 feet by 8 feet (2.4x2.4 m), but with natural sedimentation in the culverts, the heights have decreased somewhat over time. At all times there are at least two box culverts with running water, and two culverts at the edges of the wet prairie that are dry. The remaining culverts vary in water depth according to conditions. The greatest weakness of this system at this time is the lack of regular maintenance to clear vegetation growing near the concrete wall. Because plants can grow up and over the wall, tree frogs and other climbing species have been able to access the roadway in this manner. A United States Geological Survey (USGS) website is dedicated to the project (United States Geological Survey 2011).

*Figure 9. Paynes Prairie Ecopassage and amphibian and reptile wall, shortly after construction © P. Cramer*

### Turtles, Tortoises, Snakes and Lizards

Many of the considerations for amphibians are identical for reptiles. The Paynes Prairie ecopassages mentioned above for amphibians have worked for lizards, alligators and snakes, but no turtles were recorded using the culverts. However, in a study of painted turtle movement Jackson and Marchand (1998) found that a 2'x2'x20'<sup>1</sup> (6x6x37 m) tunnel made of wood with 131 feet (40 m) of drift fence at both ends was successfully used by painted turtles, though no road was involved in this study. In this study, the authors caution that clear lines of sight along the drift fencing as well as at the tunnel entrances were an important variable for successful through-passage.

The more recent Lake Jackson crossings and ecopassages along Lake Jackson north of Tallahassee, Florida were installed in 2010. Prior to the installation of the wall and culverts for turtle movement, Aresco (2005) was able to temporarily reduce the high mortality of moving turtles with a drift fence to an existing culvert, and conducted monitoring of the stretch of road for 44 months. A website (Aresco 2011) gives a thorough review of the entire process of identifying a deadly stretch of road for turtles, and raising public awareness and agency support, and finally a mitigation system that includes culverts and a concrete wall like those along Paynes Prairie, Florida (see Box 1).

Overall, research indicates that reptilian species preferences for crossing types and placement are varied among species (Jochimsen et al. 2004, Little et al. 2002), underscoring the importance of local research on the target species of interest to inform the design of mitigation solutions (Woltz et al. 2008). In Portland Oregon, the Port of Portland Authority built turtle culverts for painted turtles, which, although not scientifically studied, appear to work (Figs. 10 & 11).

Figure 11. Turtle culvert, wall, and grate ©Port of Portland

<sup>1</sup> All structure dimensions in this document use the format: Height-by-Span-by Length; or if structure length is not being discussed, simply: Height-by-Span.

For further reference, see Jochimsen et al.(2004), which provides an overview of how various structural and ecosystem characteristics effect structure effectiveness at moving amphibians and reptiles. In addition, the Minnesota Department of Natural Resources recently updated a publication on designs and practices for the repair and reconstruction of culverts, bridges, and storm water outfalls (Leete 2010). The document is particularly useful in the design of wildlife benches and curbs for animals of all sizes and shapes, and includes recommendations for using biodegradable materials to replace the use of nylon mesh for erosion control, which is known to trap small animals, such as snakes, frogs, toads, turtles, and ducklings.

### **2.2.1-2. Moderate Mobility Small Fauna**

Moderate Mobility Small Fauna are small animals such as ground squirrels, rabbits, voles, raccoons, snakes, badgers, marmots and weasels that are fairly adaptable to a variety of structure types and sizes (Fig. 12). Members of this guild are typically preyed upon by larger species and, therefore, require protective cover through a structure or, at minimum, at the approaches to a structure (Foresman 2004). Such cover may be vegetative, wood debris, rock, or even artificial cover. While some members of this guild may require a natural substrate through a culvert, others may be tolerant of an artificial surface. Most of the species in this guild prefer a non-submerged pathway through a crossing structure. If there is any flow of water through a structure, passage can be greatly increased with wildlife shelves. Twelve species of mammals that are members of the carnivore and rodent families have been documented using artificial benches created by placing shelves in these culverts (Foresman 2004).

Traffic volume and traffic noise at crossing sites can have mixed effects on these species. Clevenger et al. (2001) found that as traffic volume increased, marten, weasel, snowshoe hare, and red squirrel use of wildlife crossing culverts increased. This could be due to the fact the animals could not find breaks in the traffic that would allow them to cross the road at-grade.

#### ***Specific Considerations***

##### Rodents

Foresman (2004) documented heavy use of culverts by rodents in Montana along U.S. Highway 93. Deer mice, meadow voles, red squirrel, muskrat, ground squirrel, shrews, yellow-bellied marmot, mountain cottontail, wood rat, porcupine, and fox squirrel were photographed in corrugated steel culverts ranging from 3-12 feet (0.9 m to 3.75 m) in diameter. In Vermont, Bellis

*Figure 12. Mountain cottontail using a pipe culvert in Colorado under I-70 © Center for Native Ecosystems, ECO-resolutions, LLC & CDOT*

(2008) live-trapped small mammals on both sides of two wildlife bridge underpasses. In two summers of trapping the only animals he could document using the crossings were deer mice species ( $n=13$ ). Voles, chipmunks, jumping mice, red squirrels, weasels, and ermine were all captured on one side of the road but never recaptured on the opposite side. These structures had recently been constructed and there was little natural vegetation within 50 feet (15.2 m) of the bridges. Bellis noted in his thesis work conducted by McDonald and St. Clair (2004) that found that small mammals, including three species also included in Bellis' Vermont study, had much higher success moving through smaller than larger crossing structures, which they attributed to greater overhead cover in the smaller structures. McDonald and St. Clair (2004) also mention that a lack of natural vegetation at crossing structure limited use among small mammals.

### Small Carnivores

Clevenger et al. (2001) found that weasels, *Mustela ermine* and *M. frenata*, preferred culverts that are higher, but culvert use was negatively correlated with greater culvert openness, apparently preferring high and narrow culverts. In the same Banff study, pine martens preferred culverts with low clearance and high openness ratios, meaning they preferred short and wide culverts. Weasels' use of culverts was also positively correlated with the amount of vegetative cover. Badgers have been recorded using culverts, especially in British Columbia (Klafki 2002, Newhouse and Kinley 2002), which mimic their natural burrows on the landscape (Fig. 13).

Overall, crossings that would promote movement of Moderate Mobility Small Fauna need to have vegetation right up to the crossing structure entrance; be small in size relative to other wildlife crossings; be free of water year round or a shelf structure placed to facilitate small and meso mammal movement (Fig. 14); include a tube built in below the shelf for voles; and be less than 300 feet (91.4 m) in length. All the culverts in the studies mentioned are 200 feet (61 m) or less in length as the animal traverses under the road.

### 2.2.1-3. Adaptive High Mobility Fauna

This guild includes medium-sized mammals that are naturally accustomed to enclosed spaces for denning and are tolerant, to a limited degree, of a more enclosed situation in an underpass. Members of this guild include black bear, bobcat, coyote, and Canada lynx. Adaptive High Mobility Fauna may adapt to a variety of structure types, so long as a minimum size requirement is met, proportional to the size of the animal.

#### *Specific Considerations*

##### Black Bear

Black bear have demonstrated an ability to use wildlife crossings in Florida (Foster and Humphrey 1995), North Carolina (McCollister and van Manen 2010), Vermont, Colorado (Singer et al. 2011), Utah (Cramer 2011), Montana (Foresman 2004, and Cramer et al. 2011), Washington (this study), and Alberta, Canada (Clevenger and Waltho 2005). Overall, scientists report black bear will use bridge wildlife underpasses and culverts (McCollister and van Manen 2010, Clevenger and Waltho 2005, Cramer et al. 2011, Singer et al. 2011). Clevenger and Waltho (2005) found black bear tended to use crossing structures that were constricted in space. In Montana, black bear have been photographed using a variety of structures. While Foresman (2004) photographed a black bear using a culvert 3.1 feet (0.95 m) in height, Dr. Cramer's current study on the same stretch of US 93 has revealed black bear using bridge crossings more often than culvert crossings. In Washington, the authors of this report documented 30 black bear passages through a pair of 12'x29'x120-144' (3.7x8.8x37-44 m) arch culverts under I-90 (Fig. 15). Only one of the 31 bear approaches resulted in a repel action. It appears the black bear in the North Bend area of Washington have adapted to this culvert. From the wide geographic span of photos of black bear using structures, it is apparent that they are a highly adaptable species and will use structures they can fit through and feel safe entering. From the data collected in the habitat area around the North Bend, Washington culvert, it also appears that vegetative cover is important to Washington black bears.

*Figure 15. Black bear cubs passing through culvert behind mom, under I-90 Washington © P. Cramer, J. Kintsch & WSDOT*

## Coyote

The coyote is a wide ranging habitat generalist that is known to be quite tolerant of human activity, and is one of the most adaptable and widespread carnivores in North America (Fitzgerald et al.1994). Coyotes almost certainly use culverts and bridges in every state and province in the U.S. and Canada. Coyotes are tolerant of smaller spaces, such as drainage culverts, and can also adapt to bridge crossings. They are also known to cross at-grade over roads. Clevenger et al. (2001) and Foresman (2004) documented multiple coyote passages in culverts ranging from 3 feet (~1 m) up to 12 feet (3.7 m) high. Alternatively, Haas (2000) found coyote use of underpasses in California increased with underpass openness, and that fencing and roadway dividers (shoulder and median barriers) were most effective in encouraging coyote use of underpasses. Lyren (2000) found the same population of coyotes experienced significantly higher mortality by vehicles in areas with no wildlife fencing as compared to areas with wildlife fencing. The volume of traffic appears to also affect coyote use of structures. Lyren (2000) studied the same underpasses Haas (2000) studied in California and found the frequency of underpass use by coyotes appeared to be suppressed by traffic volume. Clevenger et al. (2001) also found that traffic volume was the most important predictive factor in coyote use of culverts in Alberta, with their use negatively correlated with traffic. These findings may indicate an aversion to traffic noise and possible avoidance of human activity (due to persecution).

In Washington, coyotes were photographed in this study at both bridge and culvert structures (Fig. 16). At a large culvert under I-90 near North Bend, coyotes were photographed at the entrance 19 times. They appeared to repel from the culvert on three occasions, and paralleled the structure at least four times. This is one of the highest volume roads in Washington and it is not known if the traffic volume affected the coyotes' use of this and other monitored structures.

Figure 16. Coyote using culvert under I-90, Washington © P. Cramer, J. Kintsch & WSDOT

In general, structures for coyote passage can be quite variable, but coyotes are a wary predator and sometimes behave like a prey species – in part due to the continued hunting pressures from humans in every state – and may be hesitant to use crossing structures. The presence of native vegetation cover at crossing structure entrances (positive correlation), human activity (probable negative correlation), traffic volumes/noise (negative correlation), and the presence of guide fencing (positive correlation) may all affect a coyote's willingness to use a crossing structure.

## Bobcats

Bobcats have been documented using structures in Montana (Cramer et al. 2011, and a study underway on US 93 North of Missoula by the Salish Kootenai Tribe and Western Transportation Institute), Colorado (Singer et al. 2011), California (Haas 2000, Lyren 2000, Ng et al. 2004), Florida (Foster and Humphrey 1995, Dodd et al. 2004), Vermont (Bellis 2008) and in Washington in this study, among others. A common theme among bobcat and wildlife crossing studies was that bobcats were documented with a preference for crossing roads at-grade, even in places where there are wildlife crossing culverts and bridges present (Bellis 2008, Cain et al. 2003, Haas 2000, Lyren 2000, Ng et al. 2004), often becoming victims of vehicular collisions. Cain et al. (2003) also found that bobcats crossed roads most frequently in areas where distance between dense vegetation was shortest. When they do use structures, they appear to prefer larger structures over more confined culverts, although monitoring in Colorado captured photographs of bobcats using pipe culverts as small as 7.4 feet (2.25 m) in diameter, including one partially sediment-filled pipe, and as large as an open span bridge (Fig. 17; Singer et al. 2011). Cain et al. (2003) found bobcat exhibited a preference for structures with high openness ratios. In Florida Foster and Humphrey (1995) recorded some of the first monitoring pictures of bobcats, which were under pairs of bridges on I-75. In this Washington study, bobcats were recorded only at the large arch culvert under I-90 near North Bend. There were three bobcat observations and all appeared to pass through the culvert. In Washington, bobcats may be more prone to using crossing in areas with abundant natural vegetation cover on both sides of the road – as is present at North Bend crossing – and with low levels of human activity (Fig. 18).

*Figure 17.* Bobcat using pipe culvert under I-70, Colorado © Center for Native Ecosystems, ECO-resolutions, LLC & CDOT.

*Figure 18.* Bobcat using large arch culvert under I-90, Washington © P. Cramer, J. Kintsch & WSDOT.

## Lynx

Low population densities, large home ranges and wide-ranging movements across the landscape have made lynx particularly difficult study subjects; consequently, few studies have documented lynx use of crossing structures. Over the course of three years of monitoring at seven different sites across Colorado, researchers did not document a single lynx using the structures, which included two pipe culverts and five box culverts (Crooks et al. 2008). Lynx have been documented using wildlife underpasses and overpasses in Banff, Canada, but lynx are not common around Banff and their use of the structures has been only rarely captured. As of yet, researchers cannot confirm whether lynx will readily use crossing structures in the western United States (Huijser and Paul 2008).

### **2.2.1-4. High Openness High Mobility Carnivores**

The carnivores of this guild, including grizzly bear, wolf and puma, prefer large structures with good visibility. Because of their larger body sizes, members of this guild have a larger minimum structure size requirement than Adaptive High Mobility Fauna such as black bear and coyotes. Species in this group tend to prefer more open structures than Adaptive High Mobility Fauna, but are more tolerant of structures longer than 100 feet (30.5 m) or enclosed structures than members of the Very High Openness Fauna Guild, such as elk.

Few studies have analyzed how the group of carnivores encompassed by this guild use wildlife crossings as a whole. Clevenger and Waltho (2000) analyzed carnivore movement through 11 wildlife underpasses in Banff National Park in Alberta, Canada for 35 months and were able to make some generalizations. They found that grizzly bear, black bear, wolf, and puma use of crossings was more influenced by human activities than by structure variables. The most significant attribute influencing these species' use of the wildlife crossings was underpass distance to town site (positively correlated), followed by human activities such as hiking and human use of the site and horseback riding (negatively correlated). They found the landscape and structure variables were the least significant attributes affecting how the carnivores used the structures. Individual species preferences have been analyzed in more detail in other studies, as described below.

### ***Specific Considerations***

#### Puma (Mountain Lion)

Pumas are habitat generalists, but as highly specialized ambush predators they require good cover or complex terrain for concealment (Sweaner et al.2000). Exurban development and recreational activity in puma habitat in recent decades has led to an increase in human conflicts with this species. Beier (1995) found that while pumas avoided substantially developed areas and the associated noise, lighting, and presence of domestic dogs, they readily used areas with heavily used recreational trails.

Gloyne and Clevenger (2001) reported on puma use of 22 crossing structures in Banff National Park in Alberta. They found a significant positive correlation between passages made by puma through the structures and the passages made by mule deer and white-tailed deer. Contrary to the Clevenger and Waltho (2000) publication just one year earlier for the same study site, they found no correlation between puma and human use of the wildlife crossings. Puma's use of open span bridged underpasses was more than expected. Bridge underpasses spanning creek drainages were used in proportion to their availability, while all other crossing types were used significantly less than expected. The crossings with the highest number of puma passages were those situated close to high quality puma habitat. The general take home message from this study was that puma tended to use underpasses more than overpass structures. Clevenger and Waltho (2005) in a later study of the Banff Crossing structures found puma favored more constricted spaces for crossings. The analysis in this study also found that distance to cover was the most important landscape attribute for successful puma usage of crossing structures, where the greater the distance to cover, the lower the likelihood of successful passage.

Figure 19. Puma (mountain lion) using a box culvert under I-70 in Utah © P. Cramer

Studies in Utah (Cramer 2011) and Montana (Cramer et al. 2011) have recorded puma presence approximately a dozen times. They have shown to be highly adaptable and have been photographed crossing at-grade over U.S. 93 in Montana, and under Interstates in Utah using box culverts (Fig. 19) and bridges and repeatedly over an interstate on a narrow wildlife overpass. Although there is not enough data at this time for statistical analyses in these studies, it appears puma prefer to cross roads in areas with little human development.

#### Other High Openness High Mobility Carnivores

There are few studies that document wolf or grizzly bear use of wildlife passages. Clevenger and Waltho (2005) found grizzly bear and wolf tended to use crossings that were high, wide, and short in length. Given their hesitancy to use crossings, in large part due to their cautious nature with humans, this study is the only one that defines these species preferences and would be the best recommendation for crossing structures that pass these species at this time.

### **2.2.1-5. Adaptive Ungulates**

All ungulates in North America have been recorded using wildlife crossing structures. However, several of these species are significantly more adaptable to a variety of wildlife crossing structures than others – these are the Adaptive Ungulates. This guild includes white-tailed deer, mule deer, moose, and mountain goat. These are species that have minimum requirements for suitable crossing structures, but are not as hesitant to enter the enclosed spaces of culverts or even bridges, as are species in the guild Very High Openness Fauna.

#### ***Specific Considerations***

##### Mule deer

Mule deer (including black-tailed deer, a subspecies of mule deer) is the primary deer species of interest with regards to wildlife-road conflicts in Washington, and is the species this report will focus on most intensely. White-tailed deer are also present in Washington, particularly in the eastern portion of the state. Of the 100-plus wildlife passages nationwide that have been specifically designed for mule deer, nearly all have successfully passed mule deer (Bissonette and Cramer 2008). Mule deer and white-tailed deer are adaptive species and over time can learn to use bridges and culverts as passageways, particularly if eight-foot high guide fencing is present. White-tailed deer have proven to be very adaptive to transportation structures across the U.S. and the preferences for mule deer below can generally apply to them as well.

##### Mule Deer and Culverts

The first mule deer wildlife passage study was in Colorado at a box culvert under Interstate 70 (Reed et al. 1975). This 10'x10'x100' (3x3x30.5 m) box culvert passes some mule deer, but the long, narrow culvert may have a high repel rate (Singer et al. 2011) and in the first years after the culvert was built only a portion of the herd used the culvert in their seasonal migration route, leaving many animals unable to reach their wintering grounds. Subsequent studies (Ford 1980, Gordon et al. 2003, Gordon and Anderson 2003, Rosa 2006) demonstrated that mule deer were willing to use a range of culvert shapes and sizes. Gordon and Anderson (2003) implemented a design in Wyoming where the dimensions of a concrete box culvert under a two-lane road could be manipulated to study the point at which more deer were repelled away from the culvert that used it. The smallest functional dimension for mule deer in this study was 12'x20' (3.7x6 m) under a two lane road where the culvert was 60 feet (18 m) in length. As a result, these dimensions have become the minimum standard for the design of crossing structures for large herds of mule deer rather than just occasional individual animals. Ongoing monitoring of six new similarly-sized culverts connected with wildlife exclusion fencing along the same Wyoming roadway have documented over 13,000 successful mule deer crossings along this migration corridor between October 1 through December 31, 2010 (Sawyer and LeBeau 2011).

Ongoing research in Utah (Cramer 2011) is documenting successful as well as attempted passage at three differently-sized corrugated steel plate culverts (all designed as wildlife crossings), eight concrete box culverts (one designed as a wildlife crossing), as well as three bridges designed specifically for wildlife and four additional existing bridges. While the study is not complete, it appears that a sense of structure openness for culverts, especially, is a very important characteristic for mule deer. The study further demonstrates that longer culverts (greater than 120 feet long [36.6 m]) have higher repel rates (i.e., which are when animals approach a structure and then turn away) than the shorter culverts (ranging in length from 65 to 120 feet long [19.8-36.6 m]). The long culverts pass beneath four lane highways, while the shorter culverts path beneath two-lane roads or two lanes of highway with an open median. Even along interstates, it appears that paired culverts with separate structures for the opposing traffic lanes, and an open median can accommodate mule deer fairly successfully. For example, along I-15 there are two sets of corrugated steel culverts that are shorter (65-75' long [19.8-22.9 m]) and larger (17-20' high [5.2-6 m]) than the other culverts in the study (Fig. 20). These culverts have low rates of repellence (5-6%) compared to rates of repellence of 20 to 35 percent for longer culverts. The study also demonstrated that concrete box culverts 200 feet (61 m) or longer along Interstates 70 and 15 did not function as wildlife crossings for mule deer if there was no wildlife fencing present. Further research will help determine whether deer can be encouraged to use such long structures in areas where wildlife exclusion fencing has recently been placed.

Figure 20. Mule deer moving through culvert under US 91 in Utah © P. Cramer

It appears that mule deer are willing to traverse under two lane roads through culverts that are approximate 100 feet (30.5 m) long and a variety of heights and widths, as long as the height is a minimum of 10 feet (3 m) and the width 20 feet (6 m; Sawyer and LeBeau 2011), with some varying conditions acceptable. When culverts are longer than the width of two lanes of traffic, repellence rates for mule deer increase to 10 to 50 percent of approaches.

Based on these research studies, it is recommended that culvert crossing structures be less than 120 feet (37 m) and most definitely less than 200 feet (61 m) for passing species in the

Adaptive Ungulates Guild. Minimizing culvert length as much as possible is recommended to accommodate the majority of mule deer that approach a culvert. If a culvert must traverse more than two lanes, then opening up the culvert by increasing the height and, in particular, the width of the culvert at eye-level (for a mule deer) is recommended to the extent possible. In addition, two separate culverts placed under opposing lanes of traffic with an open median between the

two culverts can create a more appealing situation for mule deer (as well as a number of other species in this and other guilds) than a single, long culvert (Fig. 21).

*Figure 21.* Black-tailed deer doe and fawns crossing under four lanes of I-90 through a pair of double box culverts, Washington © P. Cramer, J. Kintsch & WSDOT

### Mule Deer and Bridges

Bridges of all kinds and sizes have been shown to function for mule deer. Mule deer have been documented traversing under roads with two to four lanes with span bridges in Idaho (C. Class, personal communication), Utah (Cramer 2011, Rosa 2004), Wyoming (Sawyer and Rudd 2005), Arizona (Dodd et al. 2007b), California (Ford 1980), Colorado (Barnum 2003, Singer et al. 2011), Montana (Cramer et al. 2011) and Washington (this study). The rate of repellence is often not reported in studies or could not be measured. In Utah, rates of repellence at bridges that accommodate two to four lane highways ranges from 2.3 to 20% (Cramer 2011). In the Utah study the higher rates of repellence were related to multiple factors such as structure dimensions, human activity, the presence of livestock fencing tied to the structure base which is hard for young deer to negotiate, and animals still unaccustomed to a new structure during the first year of monitoring.

*Figure 22.* Mule deer using area under the Cle Elum bridge along I-90 © P. Cramer, J. Kintsch & WSDOT

The combined research suggests that any bridge that is a minimum of 10 feet (3 m) high and less than 100 feet long (30.5 m) as the animal traverses under the road has had success in passing hundreds of animals. There are few to no studies of mule deer using bridges that are over 100 feet in length under the lanes of traffic. This is because often, when there are greater than two lanes, opposing traffic is accommodated on two separate bridges or culverts with an open median. In Utah, Utah DOT has been able to accommodate four and five lanes of traffic on bridges less than 100 feet in length as the animals traverse under the road. In

Washington, the Cle Elum River Bridge along I-90 near the WSDOT Bullfrog Facility (milepost 79) is a perfect example of two low height (less than 10 feet [3 m] at the spots where mule deer cross under) bridges accommodating two to three lanes of traffic each, with an open median are sufficient for deer to adapt to using (Fig. 22; see monitoring report, Appendix D).

### Mule Deer and Overpasses

Overpasses that have passed mule deer in the United States exist in Utah, Montana, and Nevada. Constructed in 1975, the Utah passage is the oldest wildlife overpass in North America. Each of a pair of bridges measures 210 feet (64 m) long by 22 feet (6.7 m) wide as they cross over I-15. More than 700 successful mule deer pass have been recorded over the first 18 months of monitoring (Fig. 23; Cramer 2011).

In 2009 in Montana, and 2010 in Nevada, pre-fabricated arch culverts were built around the two lanes of US 93 and dirt was filled over the culverts so wildlife could move over the traffic on wildlife overpasses approximately 100 feet (30.5 m) wide, in both states. Mule deer began using the Nevada overpass within days of completion (L. Bellis personal communication), while in Montana they were using it within weeks (P. Basting personal communication). Culvert overpasses such as these provide a cost-effective alternative (less than 2 million dollars) to wildlife bridges in areas where tunneling traffic is a viable option.

In addition to the research on different types of crossing structures, numerous studies have shown that 8-foot (2.4 m) high wildlife exclusion fencing is an important mechanism for boosting passage rates, preventing at-grade crossings, and helping animals to adapt to the crossing structures (Clevenger et al. 2002, Cramer 2011, Dodd et al. 2009). Wildlife fencing to guide deer towards a structure is recommended for all crossing structures, regardless of type.

Figure 23. Mule deer using overpass over I-15, Utah  
© P. Cramer

### Moose

Moose exhibit an amazing ability to adapt to small structures. Given their restricted range in the United States, few states have experience in accommodating moose in underpasses. In Utah, moose have been documented using 10'x17' x165' (3x5x50 m) corrugated steel culverts in the northern mountains (Fig. 24; Cramer 2011). Sawyer and LeBeau (2011) have similarly reported moose use of culverts measuring 10'x20'x60' (3x6x18 m) in Wyoming. While this is not the recommended size of structures built for moose, populations have adapted to culverts that have been in place for years. It is believed moose will pass readily under bridges, though

Figure 24. Moose using culvert under US 91 in Utah  
© P. Cramer

there is little documented evidence of such movements and few monitoring studies have targeted or included the study of moose passage. An exception is an Alaska study, which documented moose movement under a specifically designed bridge crossing with a minimum passage height of 10.5 feet (3.2 m) along the length of the bridge and 9-foot (2.7 m) high guide fencing (McDonald 1991).

### Mountain Goats

Mountain goats have shown a willingness to pass under bridges in Montana, just outside of Glacier National Park (Singer and Doherty 1985). This study is the only study known to the authors that documents mountain goat movements through structures explicitly built for them. There is no known research or anecdotal information documenting mountain goats passage through culverts, but there is little to suggest that herds of mountain goats would adapt to moving through culverts.

### **2.2.1-6. Very High Openness Fauna**

Unlike the Adaptive Ungulates Guild, members of the Very High Openness Fauna Guild are particularly wary of predators and require very wide vistas and clear lines of sight through a crossing structure. They tend to prefer a moderate amount of cover at the structure approaches or even inside the structure; however such cover must not infringe upon their ability to detect or escape from potential predators. While largely composed of ungulate species, including elk, bighorn sheep and pronghorn, other predator-wary species, such as grouse, are also included in this guild.

### ***Specific Considerations***

#### Elk

Elk have proven to be very cautious with regards to their willingness to pass through bridges or culverts. In over 35 years of monitoring wildlife crossings in studies across the United States, elk have consistently shown themselves to be

Figure 25. Elk repelling from a long box culvert under I-70 in Utah © P. Cramer

extremely wary of using culverts of all shapes and sizes as crossings (Fig. 25). Regular use of box culverts by elk (a minimum of dozens of passages per year) has been documented at only one location in the United States, along US Highway 30 through Nugget Canyon in Wyoming (Sawyer and Le Beau 2011). Elk use of box culverts at other locations has been largely incidental, with less than five animals per occurrence (e.g., Singer et al. 2011). Prescriptions for wildlife crossings for elk should always involve a bridge. Elk have shown a willingness to use bridged wildlife crossings in Arizona (Dodd et al.

2007a), Utah (Cramer 2011, Rosa 2006), Wyoming (Sawyer and Rudd 2005) Idaho (C. Class personal communication), Colorado (Singer et al. 2011) and Washington (this study). In monitoring conducted for this study, elk showed a willingness to move under paired bridges accommodating I-90 at the Cle Elum and Snoqualmie Rivers. The Cle Elum Bridge is 11 feet (3.35 m) high at the locations elk were photographed grazing under the bridge. The Snoqualmie River bridge is 6.8 feet (2 m) high where elk were photographed traversing under the bridge. In this study, elk exhibited a preference for structures that are wide (over 65 feet [19.8 m]) across from side to side, giving a feeling of openness despite the seemingly low height of the structure. In Arizona, Dodd et al. (2007) found that the openness of the area under the bridge is an important factor influencing elk use of structures. This feeling of openness can be enhanced by angled natural substrate support slopes, as opposed to vertical walls. In the Arizona study, a pair of bridges a few hundred feet apart and almost identical in construction except for the abutment slopes had dramatically different elk usage rates. The structure with concrete walled sides produced significantly higher rates of repulsion than the adjacent structure with sloped earthen sides. Dodd et al. (2007) suggest all bridged wildlife crossings include natural 2:1 slopes under the bridges rather than concrete materials.

Elk appear to be highly willing to use two overpass structures in Banff National Park in Alberta, Canada, where monitoring has documented elk passage numbers in the hundreds to thousands (Clevenger and Waltho 2005). Elsewhere, elk have not been documented in large numbers using overpasses, though, notably, of the handful of wildlife overpasses located in North America, only a few are located in elk habitat. In Utah, elk have been documented using the state's only overpass on only 12 occasions in two years. This overpass is composed of two bridges, each just 21 feet (6.4 m) wide and 200 feet (61 m) long, with a natural median above the level of traffic. All of these passes were made by bull elk. No females have been documented using this structure in over two years of monitoring, even though it has been in

place for over 30 years and has ample tree cover at the entrances and in the median. The limiting factor may well be the narrow nature of the overpass.

An overarching guideline for evaluating existing structures for elk passage is to keep structures as open as possible (Fig. 26). The span of a structure as an elk crosses needs to be much wider than it is tall, as exhibited by the bridges structures along I-90 in this Washington study.

Fencing elk to existing culverts may force individual elk through those culverts, but repeatedly across the western states, herds of elk have refused to use such structures. Bridges are the preferred option for elk passage.

### Pronghorn

Pronghorn are notoriously wary animals and are perhaps the most difficult large mammal for which to design functional wildlife crossings. In a review of pronghorn movements near roads, Sawyer and Rudd (2005) concluded that either very high

and wide bridges or overpasses are suitable structures for pronghorn passage. Little research has been conducted on the crossing features influencing pronghorn passage. According to Sawyer and LeBeau (2011), "U.S. Highway 30 in Nugget Canyon in Wyoming may be the only place where pronghorn have been documented using crossing structures (approximately 12 occurrences)". In this herd, it appears pronghorn learned to use the passage by following mule deer through the structure. Pronghorn overpasses are planned for the Trappers' Point area along US 189 near Pinedale, Wyoming.

### Bighorn Sheep

Bighorn sheep have been studied only in Arizona to ascertain their preferences for crossings. Bristow and Crabb (2008) used radio collars and monitoring cameras to evaluate the effectiveness of three existing bridged underpasses for movement of desert bighorn sheep along Arizona's SR 68. In 25 successful crossing events, only rams used the structures. No marked ewes used the underpasses or crossed over the road at grade. In a separate study along US 93 in Arizona, several bighorn rams were documented using bridged underpasses and ewes and rams crossed across the road at grade (McKinney and Smith 2006). The authors of this study determined that the overpasses were necessary for population-level movement. In November of 2010, three bighorn overpasses, two measuring 50 feet (15 m) wide and one measuring 100 feet (30.5 m) by 202 feet (61.6 m) long were completed over US 93. These overpasses were built much in the spirit of the Utah overpass across I-15;

Figure 26. E Bull elk moving under arched wildlife crossings under I-70, Utah © P. Cramer

they are simple bridges over a four-lane highway. Within days of installing the monitoring cameras, Arizona Game and Fish biologists documented both male and female sheep moving over the overpass<sup>2</sup>.

Based on the monitoring results from Arizona, anecdotal information from other locations, an understanding of sheep's predator avoidance strategies, and the apparent reluctance of ewes to use bridged underpasses, overpasses are the recommended structure type for passing multiple members of both sexes of a bighorn sheep population.

### 2.2.1-7. Arboreal Fauna

Species in this guild move primarily through the canopy rather than on the ground surface, such as flying squirrels, arboreal voles and some bats. The best mechanism for providing safe passages for species in this guild is to construct a canopy-level structure across the roadway, for example, a rope or metal bridge (Fig. 27). A second method that is still under investigation is the placement of tall poles alongside a two-lane road to assist gliders over the road and flow of traffic. In North Carolina, several pairs of these tall poles have been placed along two lane roads with trees on both sides of the road. There are platforms toward the top of these poles that are meant as "launching" pads for the flying squirrels in the area. Cameras mounted on these platforms have recorded successful flying squirrel passage between poles (A. Burroughs NCDOT, personal communication). Researchers in North Carolina are investigating this method further and will make the results public at some point in the future.

### **2.2.1-8. Aerial Fauna**

Aerial Fauna are animals that move primarily by flying, such as songbirds, raptors, bats, and flying insects, including butterflies. As animals in this group are capable of flying over a roadway, the primary concern with regards to connectivity across roads is to divert them from flying into the path of traffic. Several mitigation methods can help minimize collisions and also the effects of habitat fragmentation caused by road infrastructure.

Crossing structures can assist flying fauna to fly below or over the flow of roadway traffic. Large structures that cross high above natural areas allow flying creatures the ability to maintain flight underneath the road. Such structures include causeways, viaducts and expanded bridges. In Europe, vegetated overpasses have also been shown to provide safe crossings for woodland bird species (Jacobson 2005). In this study there were significantly more bird flights over vegetated overpasses compared to passes directly over the road, and in some cases the birds included the wildlife overpasses within their territories.

Directing animals to fly high above or away from the flow of traffic is another alternative. Where bridges cross over waterways or near aquatic areas, birds may use the airflow at the bridge to swoop in and gain lift. This behavior has been documented in areas along the coasts of Texas and Florida. The Departments of Transportation in these states have installed either aluminum fence poles (Texas) or poly vinyl chloride (pvc) pipes (Florida) on such bridges to create the appearance of a larger barrier thereby causing the birds to fly higher over the bridge as well as the traffic (Jacobson 2005).

Predatory birds such as owls are typically killed along roadways when they find a source of rodents within the right-of-way. In Idaho and Oregon along I-84, owl spring migrations occur at the same time farmers are plowing their fields, thus driving out local rodents toward the interstate right of way for cover and forage. While no solutions have been initiated as of yet, it appears the problem could be partially mitigated by keeping rodents out of the right of way, or by preventing owls from accessing the prey through the placement of low fences, or by placing materials that flap in the wind to discourage the owls from approaching the right of way. Another opportunity exists in areas where enough water is present to support the growth of bushes in the median, such as sage brush in this area of Idaho. This would make aerial attacks more difficult from a distance across the lanes of traffic.

In Arizona, the first recorded bird crossing was constructed in Tucson. The burrowing owls nesting along the road were in danger of flying over the road barriers and into traffic. A median area that acted as a planter was placed with fast growing trees and shrubs. This acted as a diversion device to alter the flight of the owls up and over traffic (Fig. 28). Unfortunately, habitat destruction nearby forced the relocation of these birds.

*Figure 28.* Rick Ellis, Pima County Planner in Arizona at an owl crossing, where trees were planted to divert flying owls over traffic flow © P. Cramer

These Species Movement Guilds are meant to better classify an animal of concern near a transportation corridor. Interested biologists may not know if a particular species has been studied for their response to mitigation. By placing that species within its respective Species Movement Guild, generalizations can be made as to which mitigation solutions may work for that species. The overview above represents the best compilation of the current state of the science of wildlife and transportation in the United States and Canada.

### **2.3. Structure Functional Classes**

The term ‘wildlife underpasses’ connotes many different structures from the smallest culverts that may pass a salamander, to the space under a highway viaduct, tens to hundreds of feet above the landscape. This classification of transportation infrastructure into defined Structure Functional Classes, provides a definitive set of conditions for four different underpasses, the overpass, and two unusual designs for passages (Table 2). The critical dimensions for breaks among the four classes are based on heights and widths of structures, which are dictated by engineering design constraints and wildlife characteristics that define individual species’ willingness to move through a structure. These classifications are supported with the information below. This classification of structure types can help transportation planners, biologists and engineers to relate wildlife passage needs to a specific structure type or types with a common vocabulary. This classification was first proposed in the National Academies research ‘Evaluation of the Use and Effectiveness of Wildlife Crossings’ (Bissonette and Cramer 2008) and the accompanying website (Bissonette and Cramer 2006) and has been subsequently updated and modified for this research.

**TABLE 2:** Structure Functional Classes, viewed from a species perspective. Generally, species that use small structures will use larger structures if appropriate cover and other features are provided, but most species cannot use smaller classes. This table is for terminology only and is not intended to be used for structure design. It can be used for generalized discussions early in planning process. It is not intended to be prescriptive since each site requires site-specific planning by qualified biologists and engineers. These structure classes were developed by the authors in collaboration with Sandra Jacobson, U.S.D.A. Forest Service.

<b>Crossing Structure Category</b>	<b>Function</b>	<b>Approximate Dimension Range (Span x Rise)</b>	<b>Passage Examples</b>	<b>Species Examples</b>	<b>Behavioral Attributes</b>	<b>Species Movement Guilds (Potential)</b>
Class 1: Small Underpass	Provides enclosed protection for small animals that require cover.	Metal pipe culverts or small box culverts 1.5 m (5') span or less	Small bridges, dry culverts, and ephemerally flooded drainage culverts. Continually flooded drainage structures have limited functionality for terrestrial species but may function for some aquatics.	Amphibians, reptiles, small mammals and some medium-sized mammals (badger, fox, bobcat). Aquatic species include fish, aquatic amphibians, and invertebrates.	Small animals that prefer cover or do not mind confinement.	Low Mobility Fauna, Mobile Small Fauna, Highly Mobile Adaptive Fauna
Class 2: Medium Underpass	Provides some cover yet more openness than Class 1 structures for animals smaller than deer. If water is conveyed, allows for stream simulation including unwetted natural banks.	Underpasses larger than 1.5 m (5') span, to 2.4 m (8') span x 2.4 m (8') rise	Box culverts, arch pipes and other culvert shapes, small bridges.	Coyote, bobcat, ocelot, lynx and some large carnivores (black bear, puma); alligator.	Medium sized mammals that require some cover and some openness to see through passage.	Low Mobility Fauna, Mobile Small Fauna, Highly Mobile Adaptive Fauna, Adaptive Ungulates
Class 3: Large Underpass	Provides an approximate minimum for ungulates, especially deer, and other species that require visibility, maneuverability, and moderated noise. May allow some natural processes including vegetation growth and stream processes.	Underpasses with minimum dimensions: 6.1 m (20') span x 2.4 m (8') rise, or 3.1 m (10') span x 3.1 m (10') rise, and open span bridges	Box culverts, large arch pipes, bridges including open span bridges. Multiple chambered structures are considered as individual units.	Ungulates use structures in approximate proportion to their size (ie, deer can use smaller structures than elk or moose) although pronghorn require larger structures (minimum 18.3 m span x 5.5 m rise). Large carnivores (wolf, grizzly bear, black bear, puma).	Larger mammals that require structures of a minimum size for passage.	Low Mobility Fauna, Mobile Small Fauna, Highly Mobile Adaptive Fauna, High Openness Mobile Fauna, Adaptive Ungulates

<b>Crossing Structure Category</b>	<b>Function</b>	<b>Approximate Dimension Range (Span x Rise)</b>	<b>Passage Examples</b>	<b>Species Examples</b>	<b>Behavioral Attributes</b>	<b>Species Movement Guilds (Potential)</b>
Class 4: Extensive Bridge (includes Viaducts)	Allows ecosystem processes to permeate highway such as wetland water flow, vegetation growth, and entire floodplains. Provides excellent horizontal visibility for animals requiring openness.	Bridge extending over several spans. Designed for each site so dimensions vary. May allow more sunlight under structure than other types.	Viaducts are long bridges elevated over the landscape in a series of smaller spans, often connecting points of equal height. Typically over wetlands, steep terrain.	Most species including wetland species, birds, pronghorn.	Viaducts are particularly good for wary species including carnivores that may not approach other structures, or low mobility species such as mollusks that require vegetation throughout the structure.	Low Mobility Fauna, Mobile Small Fauna, Highly Mobile Adaptive Fauna, High Openness Mobile Fauna, Adaptive Ungulates, Arboreal Fauna, Aerial Fauna
Class 5: Wildlife Overpass	Provides an open top and expansive visibility of the horizon for animals preferring unenclosed spaces. Allows full sunlight and precipitation for vegetation growth. May allow small, sunlit water features.	Overpass structure for wildlife to pass over roadway, as small as 6.7 m (22') wide, but preferably at least 50 m (164') wide.	Overpasses with soil and plant growth.	All ungulates (pronghorn not proven yet), carnivores (bear, puma, forest carnivores). Songbirds and insects including butterflies.	Any species that requires natural habitat, sunlight or ambient conditions for movement.	Low Mobility Fauna, Mobile Small Fauna, Highly Mobile Adaptive Fauna, High Openness Mobile Fauna, Adaptive Ungulates, Arboreal Fauna, Aerial Fauna
Class 6: Specialized Culvert	Allows outside environmental conditions to occur within the entire structure, including light, temperature and moisture.	Current designs are small culverts less than .5 m (24") span but could be larger structures.	Trench drains and slotted culverts.	Reptiles and amphibians	Reptiles and amphibians that require ambient conditions to survive and disperse, or to orientate during movements.	Low Mobility Fauna
Class 7: Canopy Bridge	Provides an arboreal passage for animals that typically do not descend below tree canopy to ground.	Adequate to cross all traffic lanes. May be connected to trees in the median.	Treetop rope bridges, or modified wire or metal structures.	Squirrels, arboreal rodents, opossum. Potential for insects and plants.	Species that move through the canopy rather than on the ground surface.	Arboreal Fauna

Figure 29. Example of a Class 1 Small Culvert, I-70  
CO © J. Kintsch

Figure 30. Example of a Class 2 Medium Culvert,  
I-90 WA © J. Kintsch & P. Cramer

### Class 1: Small Underpasses

Small passages made of metal or concrete pipes and culverts up to 5 feet (1.5 m) in diameter are typically (but not always) preferred by smaller mammals, amphibians and reptiles, and some medium sized animals such as badger, fox, and bobcat (Fig. 29). These species do not hesitate to enter confined spaces and may need cover and other conditions, such as moisture, that are more typically found in smaller spaces as opposed to larger, more open passages. Such conditions can be replicated in a larger passageway by maintaining woody or vegetative cover through the passage or by laying a small pipe through the larger culvert to accommodate small animal passage. Culverts that accommodate water typically fall into this category. Some species require the moisture present with water courses, such as amphibians. Other species need more dry conditions. It is recommended that even these smaller structures be designed or enhanced to allow some terrestrial movement by installing raised shelves along the sides of these aquatic passages.

### Class 2: Medium Underpasses

Medium passages are underpasses that are larger than 5 feet (1.5 m) in span and up to 8 feet (2.4 m) in span, with an 8 feet (2.4 m) rise (Fig. 30). Height is used as the definitive measure at this level because the majority of existing passages in this size class are culverts where the height is equivalent or similar to the width or span. The definitive height of 8 feet (2.4 m) was used as the upper limit of the height of a crossing this size based on data gathered in the United States and Canada that included the dimensions of 128 existing wildlife crossings (Bissonette and Cramer 2008). Plotting the height of crossings by the number of crossings with that height, the data exhibited a break in groupings between the heights of 8 and 10 feet (2.4 and 3 m; Fig. 31). Eight feet (2.4 m) is also calculated as the upper size limit for medium-sized passages because the majority of mule deer determined to use underpasses in the previously mentioned studies used crossings greater than 8 feet high. By this definition, a 8'x8' standard box culvert (2.4x2.4 m) is the upper limit for

a medium underpass because deer typically do not prefer these passages, fully understanding that, in some instances, deer will use these smaller passages

Also included in this class are small bridges up to 8 feet (2.4 m) high. While still classified as medium underpasses, these bridges are much wider than a culvert of the same height and span, and provide a greater appearance of openness. Medium underpasses are typically used by medium sized animals such as coyotes, bobcat, lynx, black bear, and puma, and smaller low mobility and moderately mobile fauna such as snakes, turtles, marmots, otter, beaver, and some ground birds.

Figure 31. Height of 128 known wildlife crossings plotted versus the number of wildlife crossing structures at that height. These wildlife crossing dimensions were taken from survey participants in the National Cooperative Highway Research Program study, 'Evaluation of the use and effectiveness of wildlife crossings' (Bissonette and Cramer 2008). All crossings included in this graph were specifically built for wildlife.

**Class 3: Large Underpasses**

The minimum dimensions for large underpasses are defined, in part, as passages that can regularly pass deer species (both mule and white-tailed). These passages are defined as having a minimum of a 10 feet (3 m) span by 10 feet (3 m) rise – typically culverts – up to a 20 feet (6.1 m) span by an 8 feet (2.4 m) rise. These values are a reflection of the typical size of prefabricated culverts such as 10 by 10

Figure 32. Example of a Class 3 Large Underpass arch culvert being used by mule deer under I-90 Washington © P. Cramer, J. Kintsch & WSDOT

Figure 33. Example of a Class 3 Large Underpass bridge structure being used by black-tailed deer, SR 6, Washington © P. Cramer, J. Kintsch & WSDOT

feet (3x3 m) culverts, as well as larger arch culverts (Fig. 32). This class also includes all types of bridges, from those that are open span to those with multiple chambers where the individual units fall in this size range (Fig. 33). The smallest passage that has been monitored and verified used by deer is a 10 by 10 feet (3x3 m) culvert in Dowd Junction, Colorado (Reed et al. 1975). Donaldson (2005, 2006) documented limited use of a smaller culvert (10x6 ft [3x1.8 m]) by white-tailed deer in the eastern U.S., but recommends passage height be at least 12 feet (3.7 m). Gordon and Anderson (2003) recommend the minimum dimensions for a deer passage in their study area in Wyoming be at least 8 feet (2.4 m) high and 20 feet (6.1 m) wide. Based on these results and recommendations, the minimum size for a Large Underpass was determined to be either a 8'x20' (2.4x6.1 m) culvert; a 10'x10' (3x3 m) culvert; or a bridge at least 8 feet high and 32.8 feet wide (2.4x10 m). The latter is similar to the 8'x43' (2.4x13.1 m) bridges under Florida's I-75, which are used by white-tailed deer (Foster and Humphrey 1995). Also included in this class are larger structures, such as span bridges, which are typically larger than these dimensions, with spans over 43 feet (13 m). The added width provides greater openness to a passage. These types of passages have been documented passing all kinds of species from Low Mobility Small Fauna, such as frogs, to Very High Openness Fauna, such as elk.

#### Class 4: Extensive Bridges - Viaducts

These passages are areas where the roadbed is elevated high above the landscape over great distances, such that wildlife and ecosystem process can function naturally in the landscape beneath the viaduct. These structures span hundreds of yards (meters) and are typically at least 15 feet (4.6 m) above the ground surface. Most species of wildlife can use these areas, including wetland and riparian species as well as flying animals (Fig. 34).

Figure 35. Example of a Class 5 Wildlife Overpass, NV © L. Bellis, Nevada DOT

Figure 36. Mule Deer on top of Nevada overpass © L. Bellis, Nevada DOT

### Class 5: Wildlife Overpasses

Wildlife overpasses have been frequently used in Europe as an effective means for re-connecting habitats over roadways (Bank et al. 2002) and are increasingly being constructed in North America (Figs. 35 & 36). Currently there are only ten overpasses for wildlife in North America, ranging from a 22 feet (6.7 m) wide crossing built for mule deer in Utah; to a 50 feet (15.2 m) bighorn sheep overpasses in Arizona; to 164 feet (50 m) wide overpasses across the Trans-Canada Highway in Banff National Park. Ongoing studies of the two Banff overpasses offer some of the most comprehensive research to date on designing these types of structures. Monitoring has documented use by almost every large and meso-mammal species in the Park, from grizzly bear to elk to lynx (Clevenger and Waltho 2000, 2005; Clevenger et al. 2001). The open design and presence of natural vegetative cover literally extends habitat over the highway, facilitating its use by large carnivores and ungulates as well as small mammals, amphibians, and insects.

Two important design considerations that affect the effectiveness of a wildlife bridge are the width of the structure (Keller 1999; Pfister et al. 2002), and the presence of flat, clear lines of sight across the structure to habitat on the opposite side of the road (Clevenger et al. 2002). Pfister et al. (1997) observed that wildlife behavior was more natural on wider structures, and concluded that structures at least 197 feet (60 m) wide were more effective than those narrower than 164 feet (50 m). A parabolic design, where the structure ends are wider than the middle portion are believed to provide the most effective design for wildlife bridges (Clevenger et al. 2002). With this design, Clevenger et al. (2002) recommends that the narrowest portion of the structure should be approximately 230 feet (70 m) wide and extend out to 295 feet (90 m) at the ends to allow animals approaching from the side a better line of sight across the structure. A straight-line parabolic design is typically more cost-effective than a true hourglass design and provides the same benefits. In both Europe and North America, 164 feet (50 m) is regarded as the absolute minimum width for a multi-species overpass, and 197-230 feet (60-70 m) or more is a generally recommended, depending on other site-specific and engineering considerations (Keller 1999; Clevenger et al. 2002; Pfister et al. 2002). Current research projects in Utah, Arizona, Nevada, and Montana are finding that overpasses with much more narrow widths (less than or equal to 150 feet [45.7 m]) are passing individual species – including mule deer in Nevada and Utah; white-tailed deer in Montana; and bighorn sheep in Arizona – in numbers that are measured by the dozens to hundreds of passes per year. A more thorough review of overpasses in the western United States in the coming years is a necessary action to make better recommendations for the design of future overpasses.

Overpasses have also been built over above ground pipelines, with anecdotal evidence of caribou, moose, black bear and coyote use.

## **2.4. Monitoring Approach**

### **2.4.1. Purpose and Methods**

A field research component of this research was conducted in conjunction with the development of the Passage Assessment System (PAS). Little monitoring had been previously conducted to assess how wildlife in Washington use existing bridges and culverts; this field component was carried out to better inform the knowledgebase specific to the use of transportation infrastructure by wildlife in Washington. This component of the research project helped in refining the PAS and the accompanying Species Movement Guilds and Structural Functional Classes.

In April 2010 motion-triggered trail cameras were placed at six sites across Washington. These sites were selected to best represent different geographic areas, roads with variable number of lanes and different traffic volumes, and different types of structures. Due to funding limitations, sites greater than 200 miles from

Seattle were not selected. In June 2010, six additional cameras were placed at three additional sites. Three sites in the southwestern region of Washington were monitored: a box culvert at Mosquito Creek under US 101; a bridge over the Bone River on US 101; and a bridge over the Willapa River on SR 6. Three sites in central Washington were monitored: a corrugated steel wildlife crossing culvert under I-90 near North Bend; a double concrete box culvert under I-90 near Roslyn; and the Cle Elum River Bridge near Cle Elum. Two of the sites that had cameras placed during April, at North Bend, were pulled due to vandalism that resulted in the theft of two cameras. These sites were at the Snoqualmie trail bridges, and the South Fork Snoqualmie River bridges. They were not monitored longer than several days.

At each site, a camera was positioned at each end of the structure to best monitor all animal approaches and passes through the structures. The cameras were placed inside metal utility boxes and locked to bicycle cables which were embedded in 60 to 120 pounds of concrete on the inside bottom of the utility box. Cameras were checked every two weeks to change the batteries and retrieve photographic data. Data were entered into Excel spreadsheets for analysis. Monitoring activities continued until October 2010. The majority of these cameras are still in use by WSDOT at the writing of this report.

## **2.4.2. Overall Results**

A complete summary of the monitoring results is presented in Appendix D 'Structure Evaluations, Monitoring Results and Recommendations'. The monitoring summaries provide an overview of the data, including the number of deer and elk at the site; whether the animals used the structure or were repelled; seasonal use of the structure by deer; and tallies of all species detected at the site. For each site, six sample pictures of the camera data are displayed to demonstrate wildlife activity at the site. Monitoring information can help WSDOT determine which species will use certain structures more readily than others. The summaries also help support and clarify conclusions drawn during the site evaluations and refine the recommendations provided to enhance the structures for wildlife passage.

Of particular note from the study results is the documented elk use of two large bridged structures under I-90, one at the South Fork Snoqualmie River near milepost 33, the other at the Cle Elum River near milepost 79. Research throughout the western United States has documented the species' reluctance to pass through confined spaces such as culverts or small, restricted bridges. However, photographic evidence compiled through this research project showed elk movements under bridges that were wide, but less than 10 feet (3 m) high. This new insight that elk may be willing to use low bridges so long as they are sufficiently wide helped inform the requirements quoted for elk in the Species Movement Guilds description (Chapter 2.2.1.1-6) and may help WSDOT and other agencies to better design cost-effective bridges suitable for elk.

A very interesting site included in this study was near North Bend, where a pair of corrugated steel culverts crosses under I-90 (milepost 29). These culverts are located in a thickly vegetated area. Judging from the characteristics of the structure itself and the fact the small stream through this crossing was placed underground for half of the crossing; it appears that these culverts were designed specifically for wildlife passage. If wildlife were not considered, the stream could have been shunted underground for the entire length of the passage. In the WSDOT Bridge Engineering Information System records this structure is listed as being built in 1976 and is listed as a game crossing. The structure is tied into an extensive segment of 8-foot (2.4 m) high wildlife fencing. This culvert appears to be among the most successful black bear crossings in the western U.S., as demonstrated by 31 black bear observations during 5 months of study. In comparison, study sites in two states combined (Montana and Utah) have tallied less than 12 successful black bear crossings over the course of two years. While the passage is very successful for black bear, only three bobcats approached and crossed through the structure, and seven of 19 approaches by coyotes were repelled. Our camera technician on several occasions could smell the bear presence in the culverts when she came to check the cameras. This may explain the low numbers of deer using it. It may also support the idea that in an area of high species diversity, multiple crossings may be necessary for prey, predator and even competitor species. A site visit in April 2011 by Dr. Cramer revealed multiple piles of elk fecal pellets on both sides of the highway at this site. This data further supports the idea that multiple species of prey and predators may be at this site, but only a select group (the predators) is predominately using the culvert.

Site visits in 2011 allowed for further examination of wildlife in the areas near the crossings. During site visits in April 2011, Dr. Cramer conducted vegetation and fecal pellet counts along transects that included 25 location points in a grid pattern on each side of the highway at sites where cameras were placed. Preliminary results of pellet counts revealed that the cameras that face the crossings are only capturing a portion of the animals located in the vicinity of the crossings. This was exemplified most strongly at the Mosquito Creek culvert (US 101, milepost 76.5), as well as the large corrugated steel culverts near North Bend (I-90, milepost 29). Only one elk was photographed at the west entrance to the Mosquito Creek culvert, yet there were dozens of piles of fresh elk pellets on that side of the highway in the vicinity of the culvert entrance. The monitoring transects for fecal pellets at the large culverts at North Bend also revealed dozens of elk fecal pellet piles on both sides of the highway. This added information lends further evidence to the theory that elk prefer not to use culverts. These site visits also revealed mule and black-tailed deer use of areas near the crossings. The data have not been analyzed sufficiently at this point to glean trends in the presence of deer and other species photographed in front of the cameras and the correlation to the fecal pellet groups found in these transects.

Deer in the study exhibited a willingness to pass through culverts smaller than the researchers predicted they would. Photographic data from the Mosquito Creek

culvert under US 101, and the double box culvert under I-90 at Tucker Creek (milepost 73) showed a surprising amount of black-tailed deer using the US 101 culvert, and mule deer using the I-90 box culvert. These data had the researchers and WSDOT biologists re-thinking the culvert size limits that deer will navigate through. The Mosquito Creek culvert is only seven feet (2.1 m) high, just under 16 feet (4.9 m) wide in span, and 138 feet (42 m) long. The I-90 double box culverts at Tucker Creek are less than five feet (1.5 m) high, nine feet (2.7 m) in span, and 58 feet (17.7 m) long for each of the two culverts under opposing lanes of traffic. These culvert heights are typically considered too small for more than occasional mule deer passage. While the Mosquito Creek passage mainly passed females with young, and only passed one male, making it very limited as a passage for the deer population, the Tucker Creek culverts under I-90 passed females and young as well as 28 passages of male deer. The data from these cameras continues to inform our ideas of how deer will adapt to structures and suggest a need for additional research into the factors that affect passage use, such as traffic volumes, local adaptation, and habitat drivers, among others.

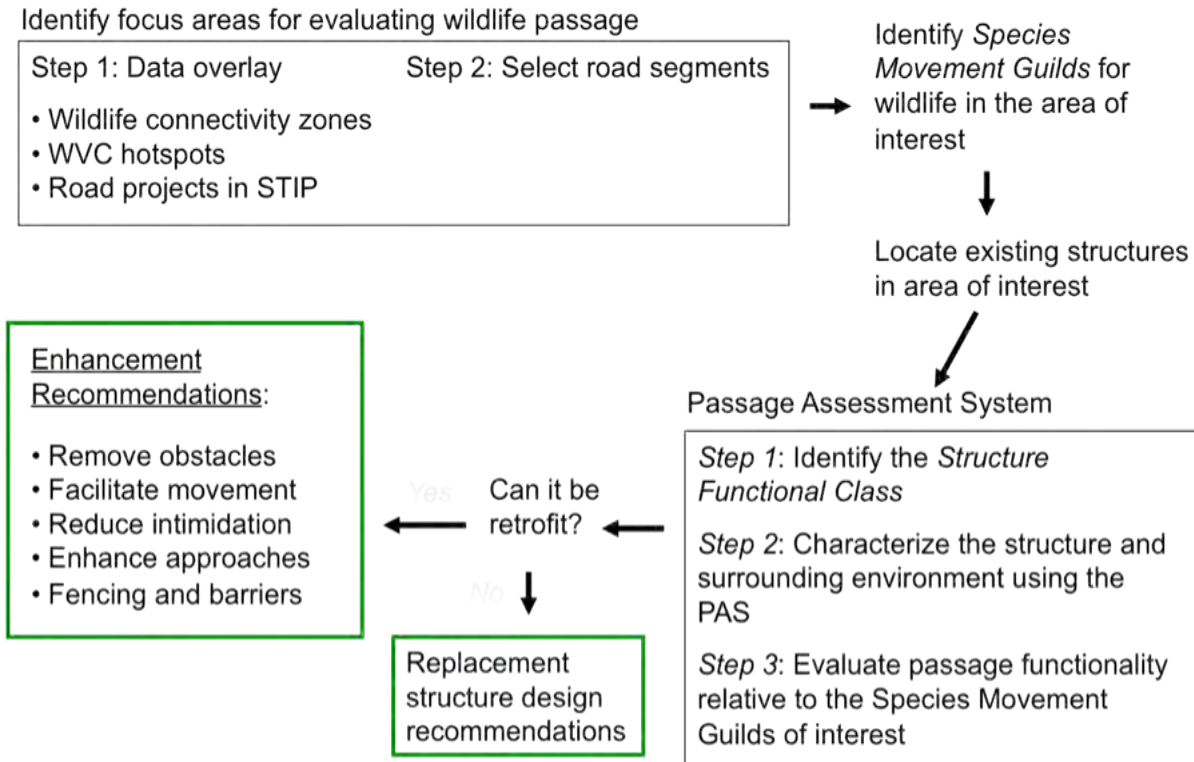

## **2.5. Passage Assessment System**

The Passage Assessment System (PAS) guides practitioners through a series of targeted questions designed to characterize a bridge or culvert relative to its potential to function as a wildlife passage. The PAS is one of several complementary tools to assist WSDOT in identifying important connectivity areas and design mitigation solutions to improve or restore permeability for native wildlife. While the Washington Wildlife Habitat Connectivity Analysis (WHCWG 2010) offers a broad-scale perspective of connectivity across the state, the PAS allows WSDOT biologists to assess permeability at the site scale, for example along targeted stretches of roadway identified as bisecting these landscape connections.

The PAS is intended as an evaluation tool to ensure that biologists ask the right questions in the field and fully document the conditions that may affect passage functionality for the diversity of target species. Upon completion, the biologists will have a complete passage assessment including preliminary ideas for improving the structure, which can be further refined during the project planning and design processes. The PAS provides an effective mechanism for determining which structures are suitable for enhancements to improve their functionality as wildlife passages or, if no such enhancements are appropriate, identify structure replacement needs for improved highway permeability for wildlife. In this way, the PAS can inform project plans and budgets at the earliest stages of the transportation planning and design process. Figure 37 depicts the major steps in identifying and evaluating existing structures for their potential to pass targeted wildlife species.

To begin the assessment process, it is necessary to first select the roadway segments of interests before conducting the PAS in the field. These may be areas that are

## Major Steps in Identifying the Potential of Existing Structures for Wildlife Passage Based on Species Movement Guilds

*Figure 37.* Flowchart identifying the major steps in evaluating the potential for an existing structure to pass native wildlife. In determining where to focus limited dollars, this process may be used at multiple locations along a given stretch of roadway to evaluate each potential safe passage opportunities (culverts, bridges and overpasses) and thereby identify which species guilds are well served by the existing conditions versus those that are underserved in the geographic area of interest.

identified connectivity zones; areas with high levels of animal-vehicle collisions, as determined from carcass removal data; areas that are slated for upcoming projects in short-term (3-5 year) planning or longer term (5-15 year) corridor planning; or, preferably, a combination of the above. A list of existing structures that fall in the roadway segments of interest can then be compiled from WSDOT's structures inventory. The locations identified on this list are where DOT biologists will use the PAS to evaluate existing structures for their functionality to pass target wildlife. Structures that are too old or are unsafe need not be evaluated, as they must be replaced; wildlife permeability considerations should then inform the design of the new structure. Other conditions that may affect whether a structure should be enhanced that are not considered in the PAS include land use and protected status of the lands on either side of a structure; the age or safety of a structure; or situations where an enhancement is not cost-effective relative to the replacement schedule.

The final step before taking the PAS into the field is to identify the species of interest whose habitat is bisected or adjacent to the roadway, and for which movement from one side of the road to the other may be of concern. In general, target species include those that are of danger in animal-vehicle collisions, such as deer, elk and moose; species of concern such as forest carnivores and threatened and endangered species; and other species that are sensitive to the barrier effect of roads. The Wildlife Habitat Linkages identified 16 focal species for the connectivity analysis. These species, if they occur in the geographic area of interest, should be included as target species. Appendix A identifies target species and associated Species Movement Guilds for each ecoregion in the state.

The assessment questions that compose the PAS were derived from a similar assessment system used in Colorado (Kintsch et al. 2011) and were further refined through a field test in Florida conducted by one of the researchers (Cramer). Following an additional series of refinements in collaboration with WSDOT, the researchers conducted a one-week field test, visiting 17 sites in southern and central Washington, including sites representing multiple bioregions and a range of structure types (pipe culverts, box culverts, arch culverts, small bridge underpasses and large bridge underpasses) as well as road types (from two to six lanes, including both divided and undivided highways). See Appendix D for complete site summaries. Final refinements to the PAS were made based on monitoring results and feedback an April 2011 workshop where the PAS was presented to WSDOT biologists from across the state.

The PAS is composed of three sections: General Questions, Undivided Highway, and Divided Highway, as well as a User's Guide provided for additional reference. For each structure that is being evaluated the user will complete 1) the General Assessment Questions, and 2) either the Divided or Undivided Highway Assessment Questions, depending on whether the structure of interest is located on a divided or undivided highway. Each of the questions in all three sections is fully clarified in the User's Guide. The complete PAS is available in hardcopy format in Appendix B of this

report, or a digital copy is available from the Fish and Wildlife page of WSDOT's intranet. It is recommended that two biologists conduct the PAS together to capture a more comprehensive picture of a structure's passage characteristics.

The General Assessment Questions record basic information about the site, including a milepost, GPS point, a unique location code, the Species Movement Guilds present at that site (Chapter 2.2), the Structure Functional Class Type (Chapter 2.3), and whether the highway is divided or undivided. The answer to this last question – divided or undivided highway – will determine which form the user completes next, either the Divided or Undivided Highway Assessment Questions. While the questions posed are the same for a divided or undivided highway, they must be posed independently for each structure at a divided highway site.

At the start of the form the user is asked to respond to a set of preliminary questions. These are a collection of targeted questions designed to determine if there is a 'fatal flaw' with the structure relative to the Species Movement Guild(s) of interest. Each question should be considered relative to the Species Movement Guilds indicated. If a fatal flaw is identified, then the user need not complete the remaining PAS questions as the fatal flaw renders the structure unsuitable for enhancement; a newly designed and constructed structure is required to pass wildlife at that location. Fatal flaws may be specific to some or all guilds and include situations where a culvert is too long for the target species to pass through or where there is a lack of visibility from one end of a structure to the other.

If no fatal flaws are identified, the user then continues with the remaining questions, which are divided into distinct sections to guide the evaluation process. Some questions are repeated to capture conditions on both sides of a structure. The assessment questions include:

- Basic questions about the structure size and shape;
- Number of traffic lanes;
- Presence of parallel infrastructure, such as railroads, frontage roads or recreational paths;
- Questions about the inlet and outlet including specific inlet or outlet features (such as an apron or a perched outlet), the presence of obstructions (such as riprap or debris), vegetation cover, and the predominant land use within the immediate vicinity;
- Questions about the inside of the structure including visibility, water flow, presence of a dry pathway, substrate, noise, vegetative cover, skylights, obstructions, and the presence of a road or trail through the structure;
- Questions about fencing and walls associated with the structure including the type, height and condition of any fencing or walls, and presence of any escape mechanisms such as jump outs or one-way gates;
- Evidence of wildlife use;
- Evidence of human activity.

Throughout the PAS, users are encouraged to take a number of photos from multiple directions to fully capture a visual record of the structure and its attributes.

Finally, the user is instructed to document their general impressions regarding the functionality of the structure for each of the Species Movement Guilds of interest. For each guild, the user is instructed to rank the structure such that an A rank means that animals could pass through the structure as is or with small modifications; a C rank means that the structure could be functional with modest modification; and an F rank means that the structure cannot be enhanced to function as a wildlife passage. This section is a subjective assessment and responses should be based on the user's overall impression having completed the full PAS. Users are then asked which features could be changed to make the structure more functional for any Species Movement Guild of interest given an A or C rank. This question offers an opportunity for the user to suggest potential improvements. These may be amended and refined later, but this evaluation is helpful for capturing preliminary ideas and impressions while still in the field.

While users should answer all questions in the PAS, regardless of which Species Movement Guilds need passage at a given site, when determining whether or not a structure can be enhanced to improve functionality, if the only target species is a toad, for example, then the structure does not need to be evaluated for bears, and vice versa. However, at many sites there is a suite of species – and therefore, guilds – requiring safe passage.

Notably, the time of year at which the passage assessment is conducted can greatly alter perspectives on the functionality of that structure for a given Species Movement Guild, largely, because of differences in water flow through the seasons. In some areas, users may need to visit a site two or more times throughout the year to develop a more complete picture of how passage is affected by changing water levels. If the users can only visit a site once, the visit should ideally occur at a time when water levels are near their highest, and special consideration should be given to how either higher or lower water levels might affect passage through the structure. The length of time that high water flows may affect terrestrial passage should also be considered – if submersion occurs for less than a month or during a season when the target wildlife are not active, there may not be a conflict with wildlife passage. In addition, multiple visits throughout the year can also capture information about how vegetation growth may affect passage or visibility, as well as provide opportunities to detect signs of animal activity at different times of year.

Upon completing the PAS the user will be equipped to answer the question: 'can this structure be improved to accommodate passage for the target species present in this area?' It is possible, in some cases that a given structure may be enhanced to accommodate one or several of the target species, but cannot be suitably enhanced for all target species. The user is encouraged to consider the range of possible enhancements and how they could be implemented at each site being assessed. Chapter 2.5.2 provides guidance for identifying suitable enhancement options once

it has been determined that a structure may be enhanced to improve permeability for the target species.

### **2.5.1. Refining the Passage Assessment System for Local Conditions**

The PAS was developed and designed for Washington’s DOT, however the assessment process is applicable regardless of geography. Once the species present in a given region have been classified according to the Species Movement Guilds, the PAS can be applied to that region. Some evaluation thresholds may need to be adjusted based on local conditions – such as a wildlife population that has adapted to human activity – or as new research becomes available, providing a more refined understanding of the factors affecting species’ use of structures.

The PAS was developed for the purpose of assessing highway infrastructure located in non-urban environments. This evaluation system may also be applied to structures located in urban environments, however, users should be aware that urban wildlife are more adapted to human activity and infrastructure than their non-urban counterparts and may, therefore, have different tolerances for which the user will need to account when developing enhancement solutions.

### **2.5.2. Passage Enhancement Toolbox**

Having determined that a structure *can* be enhanced for wildlife passage, biologists are then confronted with the question of *how* to enhance the structure to facilitate passage. Given the unique characteristics of every structure and the specific permeability objectives at each site, there is no simple answer to this question, however a number of commonly encountered situations are addressed in the Passage Enhancement Toolbox (Appendix C). The toolbox addresses a number of situations and provides examples of each. Enhancement options are organized into six categories:

- Remove obstacles to wildlife passage
- Facilitate movement and create pathways
- Reduce intimidation
- Enhance structure approaches
- Fencing and barriers
- Add or adjust structural features

Some enhancements require investments in maintenance, for example, removing sediment from a culvert or repairing holes in wildlife fencing; others require new investments, such as installing new fencing or guide walls, or constructing a new pathway through a structure. The toolbox is a living document that should be updated as revised as new techniques are tried and tested, providing an ever-

expanding array of enhancement options for DOTs to draw from. These enhancements can be further refined and customized to site-specific conditions during the DOTs project design processes, prior to implementation.

## **CHAPTER 3. CONCLUSIONS AND RECOMMENDATIONS**

### **3.1. Conclusions**

The PAS is an effective tool for evaluating the permeability of existing structures in WSDOT's transportation network. Using the PAS in conjunction with the Washington Wildlife Habitat Connectivity Analysis (WHCWG 2010) will allow biologists to conduct site-specific assessments within targeted high priority connectivity zones and in upcoming project areas as identified in the Statewide Transportation Improvement Program (STIP).

The PAS and all the supporting information that went into its development represents a first-time compilation of research results and theories on wildlife crossings across North America. The refinement of the Species Movement Guilds for this research allows any user of the information to categorize a species of interest to better understand how this species or similar species have been found move and behave with respect to roads and wildlife crossings. This allows for a fast, efficient classification of wildlife based on generalizations of movement behavior for broader categories of wildlife, regardless of known research on the specific species. The Structural Functional Classes, which were also refined for this research, can similarly be applied to all transportation culverts and bridges across North America. With the publication of this research in several different arenas, these classes are positioned to become the standard categorization for the science of transportation ecology. The development of the Passage Enhancement Toolbox is another resource that can be used by multiple users in North America and can be used as a reference for many different ways to mitigate and enhance existing structures along transportation corridors, regardless of locale. Overall, the information gathered in the development of the PAS – in addition to the PAS itself – will benefit the science and practice of transportation ecology as a whole.

The PAS was first introduced to group of WSDOT biologists in April 2011; additional experience using the PAS in the field will hone the biologists' skills in conducting and interpreting passage evaluations as a part of WSDOT's overall efforts to address permeability for wildlife and mitigate the impacts of the transportation network on connectivity for both terrestrial and aquatic wildlife. The PAS should be considered a living document as new research reveals how passage characteristics affect permeability for different types of species.

## 3.2. Next Steps and Recommendations

There are a number of ways in which the PAS may be enhanced over time to facilitate the assessment process and guide the design of appropriate mitigation enhancements. In addition to being available as hard copy data forms for use in the fields, the PAS is also ready to be programmed into handheld GPS-data collection units. Two such units are currently being beta-tested by the USDA Forest Service (contact: S. Jacobson). These and other units are scheduled to be tested in conjunction with a University of California at Davis and Caltrans research project in the summer of 2011. These units provide a streamlined mechanism for collecting and compiling field data. Both the hard copy forms and the programmable units may be easily updated and refined as needed. Continued use of the PAS by WSDOT, CALTRANS and other DOTs will help to inform any such updates.

Ongoing and new monitoring studies that help deepen our understanding of wildlife responses to crossing structures may also further inform and refine the PAS over time. With the deployment of field research cameras across Washington, WSDOT will be better equipped to record species' responses to transportation infrastructure and traffic. These data will greatly assist WSDOT in developing wildlife crossing structures and enhancements to existing structures that will promote permeability of roads for all wildlife. As the knowledgebase of what works and doesn't work for different species evolves, DOTs will be increasingly equipped to design effective crossing structures and improve the functionality of existing structures. Targeted monitoring where permeability enhancements have been implemented will create a positive feedback loop for maximizing the effectiveness of future improvements.

WSDOT is also advised to continue updating the Passage Enhancement Toolbox as new strategies are developed and tested in different situations. A complementary effort would be the compilation of engineering designs for each of these enhancement options so that WSDOT is equipped with a ready-to-go suite of designs from which engineers can draw upon when integrating permeability enhancements into transportation projects.

	Elk	<i>Cervus elaphus</i>		X	X	X	X
	Greater Sage Grouse	<i>Centrocercus urophasianus</i>	X				
	Pronghorn	<i>Antilocapra americana</i>					
	Sharp-tailed Grouse	<i>Tympanuchus phasianellus</i>	Y				
	White-tailed Ptarmigan	<i>Lagopus leucurus</i>			X	X	
	Woodland Caribou	<i>Rangifer tarandus</i>			X	X (limited)	
<b>Arboreal Fauna</b>	Northern Flying Squirrel	<i>Glaucomys sabrinus</i>		X			X
<b>Aerial Fauna</b>	Fringed Myotis	<i>Myotis thysanodes</i>					X
	Long-legged Myotis	<i>Myotis volans</i>					Y
	Northern Spotted Owl	<i>Strix occidentalis</i>		X			X
	Short-eared Owl	<i>Asio flammeus</i>	Y (limited)				
	Silver-haired Bat	<i>Lasiurus noctivagans</i>				X	
	Townsend's Big-eared Bat	<i>Plecotus townsendii</i>				X	

APPENDIX B: PASSAGE ASSESSMENT SYSTEM

**PASSAGE ASSESSMENT SYSTEM: GENERAL QUESTIONS**

*Please complete this form for each structure visited*

Date:

Location ID:

Location Code:

Route #:

Milepost:

GPS ID:

GPS Latitude:

GPS Longitude:

**Structure Functional Class:** Class 1: small underpass      Class 2: medium underpass      Class 3: large underpass  
Class 4: extensive bridge      Class 5: wildlife overpass      Class 6: specialized culvert  
Class 7: canopy bridge

**Species Movement Guild (select all that apply):** Low Mobility Small      Moderate Mobility Small      Adaptive High Mobility Fauna      High Openness High Mobility Fauna      Adaptive Ungulates  
Very High Openness Fauna      Arboreal Fauna      Aerial Fauna

**Briefly describe the general environmental conditions at the time of the assessment (e.g., water levels, vegetation):**

**Bridge Number:**

**Divided or Undivided:** Divided      Undivided

**Highway Direction:** East/West      North/South

**Roadway Photos Numbers:** 1:      2:      3:      4:

## PASSAGE ASSESSMENT SYSTEM: DIVIDED HIGHWAY

**Special Note About Divided Highways with One Long Structure:** This form is designed for divided highways with two separate structures cross under or over opposing traffic lanes, although it may also be use where one long structure crossing the entire roadway, including the median. In this case, users need not complete the sections of the Assessment that correspond to the median side inlet/outlet, which are not present when there is just one long culvert. Users should complete the Median section of the assessment regardless.

### Preliminary Questions (i.e., fatal flaws)

Assess each of the following questions relative to the species guild of interest to determine whether the structure is fatally flawed for members of the Species Movement Guilds indicated:

<b>Is the structure longer than 300 feet? Consider each structure under a divided highway separately. (fatal flaw for Adaptive Ungulates and Very High Openness Fauna)</b>	No (continue)	Yes (structure is not suitable for enhancement)
<b>Is the culvert slope &gt; 30 degrees and 100' or longer? (fatal flaw for all Species Movement Guilds)</b>	No (continue)	Yes (structure is not suitable for enhancement)
<b>Is there extensive development/pavement in the immediate vicinity of one or both sides of the structure? (fatal flaw for all Species Movement Guilds)</b>	No (continue)	Yes (structure is not suitable for enhancement)
<b>Can you see through the structure to the other (for divided highways, consider each structure individually)? (if no, fatal flaw for Adaptive Ungulates, Very High Openness Fauna and High Openness High Mobility Carnivores)</b>	Yes (continue)	No (structure is not suitable for enhancement)

### West/North Structure

<b>What is the shape of the structure?</b>	Round Pipe	Squash Pipe	Box Culvert	Arch Culvert
	Bridge Underpass - sloped	Bridge Underpass - straight	Bridge Overpass	Other (text)
<b>What is the structure material?</b>	Concrete	Metal	Plastic/Fiberglass	Other (text)
<b>[If Shape = Box] Are there multiple chambers?</b>	No	Yes - Describe:		
**If Yes, select the most appropriate chamber for terrestrial passage to answer the following questions.				
<b>[If Shape = Bridge Underpass] Is this a single span or multispans structure?</b>	Single span		Multispans (1 or more supports)	
**If Multispans, select the most appropriate chamber for terrestrial passage to answer the following questions.				
<b>[If Shape = Bridge Underpass] What is the material of the abutments on the West/North side?</b>	Concrete	Concrete/Soil	Soil	Riprap
	Gabian Wall	Other (txt)		
-What is the slope ratio? (horizontal:vertical)	0:1	1:1	2:1	
<b>[If Shape = Bridge Underpass] What is the material of the abutments on the East/South side?</b>	Concrete	Concrete/Soil	Soil	Riprap
	Gabian Wall	Other (txt)		
-What is the slope ratio? (horizontal:vertical)	0:1	1:1	2:1	

**Road Attributes**

Number of lanes of road: \_\_\_\_\_

Is there parallel infrastructure such as railroads, recreational paths, frontage roads, etc?      No      Yes - Describe:

**Notes:**

**INLET SIDE (West/North Structure)**

Photo Number 1: 2: 3: 4:  
 Is there an apron at the inlet? No Yes, metal Yes, concrete  
 Does the culvert have wing walls? No Yes

**Structure Approximate Dimensions (functional dimensions if partial)**

Are the distances measured for the whole structure or for a single chamber of a multispan structure? Whole Structure Single Chamber  
 For each measurement, indicate 'actual' or 'estimated' measurement with an 'x' in the appropriate column. Actual Estimated  
 -Height/Rise (feet) – can be marked as graduated \_\_\_\_\_  
 -Width/Span (feet) – distance from side to side for animal crossing over/under road \_\_\_\_\_  
 -Length (feet) – distance through the structure for animal crossing over/under road \_\_\_\_\_

**Obstructions**

Is the immediate entrance blocked? None Cattle Fence Boulders humans would have to climb over  
 Rocks/Riprap (> volleyball size) Rocks/Riprap (> baseball size) Some rocks, not continuous  
 Thick Vegetation Gate Other:  
 Are there structures that block the entrance within 25 feet? No Cattle Fence Small Mesh Fence  
 Boulder Field Stream Flow High/Steep Cut or Fill Slope

**Fill Slope**

Is the structure located in a fill slope? No Yes, < 20' high Yes, > 20' high  
 -If yes, how is the structure situated in the slope? At the base Midway on fill slope Near top of fill slope

**Approach Vegetation & Cover**

Is there vegetation/cover within 25' of the inlet? No Yes, partially Yes, completely  
 -If yes, select predominant type: Grasses Bushes Bushes/Trees  
 Is there vegetation/cover within 25-50' of the inlet? No Yes, partially Yes, completely  
 -If yes, select predominant type: Grasses Bushes Bushes/Trees

**Land Use Within 100 feet of inlet:**

Predominant land use: Forest Prairie/Grassland Agriculture Wetlands  
 Shrub/Steppe Mixed: Human/Natural Residential Commercial Other:

**Noise**

What does passing traffic sound like at the entrance to the structure?  
 Silent Low Rumble Loud and Jarring

**Road Attributes**

How wide is zone of maintained vegetation (allowing extra visibility along the road shoulder)?  
 0' 0-6' 6-30' Undetermined  
 Is there a guard rail or jersey wall above the structure? No Yes, structure only Yes, extensive

**Notes:**

**OUTLET SIDE (West/North Structure)**

<b>Photo Number</b>	1:	2:	3:	4:
<b>Is there an apron at the outlet?</b>	No		Yes, metal	Yes, concrete
<b>Is the outlet perched?</b>	No		Yes, < 0.5 feet	Yes, > 0.5 feet
<b>Does the culvert have wing walls?</b>	No		Yes	

**Structure Approximate Dimensions (functional dimensions if partial)**

Are the distances measured for the whole structure or for a single chamber of a multispan structure? Whole Structure Single Chamber

For each measurement, indicate 'actual' or 'estimated' measurement with an 'x' in the appropriate column. Actual Estimated

-Height/Rise (feet) – can be marked as graduated				
-Width/Span (feet) – across or span of bridge/culvert along road				
-Length (feet) – for animal crossing over/under road				

**Obstructions**

<b>Is the immediate entrance blocked?</b>	None	Cattle Fence	Boulders humans would have to climb over
	Rocks/Riprap (> volleyball size)	Rocks/Riprap (> baseball size)	Some rocks, not continuous
	Thick Vegetation	Gate	Other:
<b>Are there structures that block the entrance within 25 feet?</b>	No	Cattle Fence	Small Mesh Fence
		Boulder Field	High/Steep Cut or Fill Slope
		Stream Flow	

**Fill Slope**

<b>Is the structure located in a fill slope?</b>	No	Yes, < 20' high	Yes, > 20' high
-If yes, how is the structure situated in the slope?	At the base	Midway on fill slope	Near top of fill slope

**Approach Vegetation & Cover**

<b>Is there vegetation/cover within 25' of the outlet?</b>	No	Yes, partially	Yes, completely
-If yes, select predominant type:	Grasses	Bushes	Bushes/Trees
<b>Is there vegetation/cover within 25-50' of the outlet?</b>	No	Yes, partially	Yes, completely
-If yes, select predominant type:	Grasses	Bushes	Bushes/Trees

**Land Use Within 100 feet of outlet:**

Predominant land use:	Forest	Prairie/Grassland	Agriculture	Wetlands
	Shrub/Steppe	Mixed: Human/Natural	Residential	Commercial
				Other:

**Noise**

<b>What does passing traffic sound like at the entrance to the structure?</b>	Silent	Low Rumble	Loud and Jarring
---	--------	------------	------------------

**Road Attributes**

<b>How wide is zone of maintained vegetation (allowing extra visibility along the road shoulder)?</b>	0'	0-6'	6-30'	Undetermined
<b>Is there a guard rail or jersey wall above the structure?</b>	No	Yes, structure only	Yes, extensive	

**Notes:**

**Fencing/Walls (West/North Structure)**

<b>Photo Number</b>	1:	2:	3:	4:
<b>Is there fencing present on the West/North side of the structure?</b>	Yes	No		
<b>Select type of fencing to <i>right</i> when facing structure:</b>	Curb (not including wingwalls)		Wall (not including wingwalls)	
Chain Link	Wildlife Fence	Sediment Fence	4-Strand Wire	Other:
-If curb or wall, does it have a lip?	Yes	No		
-What is the height of fencing/wall?	None	! 6"	> 6" to ! 2'	2' to 4'
-What is the mesh size?	None	6x6"	6x6", graduating smaller to 2x3 at base	
-Is it connected to the structure?	Yes	No - small gap (! 0.5')		No - large gap (>0.5')
-Does the fencing reach all the way to ground level without gaps?	Yes	No		
-Is the fencing entrenched in the ground to prevent animals from digging under it?	Yes	No		
- Is the ROW fencing the same as the fencing that is immediately adjacent to the structure?	Yes	No		
If no, what is the ROW fencing type:	Curb (not including wingwalls)		Wall (not including wingwalls)	
Chain Link	Wildlife Fence	Sediment Fence	4-Strand Wire	Other:
-Minimum distance fence extends from structure:	! 10 feet	10-50 feet	50-100 feet	>100 feet
	~" mile	1 mile	Miles	End not visible/known
<b>Select type of fencing to <i>left</i> when facing structure:</b>	Curb (not including wingwalls)		Wall (not including wingwalls)	
Chain Link	Wildlife Fence	Sediment Fence	4-Strand Wire	Other:
-If curb or wall, does it have a lip?	Yes	No		
-What is the height of fencing/wall?	None	! 6"	> 6" to ! 2'	2' to 4'
-What is the mesh size?	None	6x6"	6x6", graduating smaller to 2x3 at base	
-Is it connected to the structure?	Yes	No - small gap (! 0.5')		No - large gap (>0.5')
-Does the fencing reach all the way to ground level without gaps?	Yes	No		
-Is the fencing entrenched in the ground to prevent animals from digging under it?	Yes	No		
- Is the ROW fencing the same as the fencing that is immediately adjacent to the structure?	Yes	No		
If no, what is the ROW fencing type:	Curb (not including wingwalls)		Wall (not including wingwalls)	
Chain Link	Wildlife Fence	Sediment Fence	4-Strand Wire	Other:
-Minimum distance fence extends from structure:	! 10 feet	101 feet	120-250 feet	# mile
	" mile	2 mile	Miles	End not visible/known
<b>What is the general condition of the fencing?</b>	Gaps and areas where fence is down		Some tacking up of fence needed	
	Vegetation needs to be cleared from fence		Fence in good working order	
<b>Is there an escape ramp(s) within a 1/2 mile of the structure in either direction?</b>	No	Yes - 1	Yes - 2 or more	
<b>Is there a one-way gate(s) within a 1/2 mile of the structure in either direction?</b>	No	Yes - 2	Yes - 2 or more	
<b>Are there uncontrolled driveways or intersections that cause breaks in the fencing within a 1/2 mile of the structure in either direction?</b>	None	1	2-5	6-10
				>10

**Notes:**

**INLET SIDE (East/South Structure)**

Photo Number 1: 2: 3: 4:

Is there an apron at the inlet? No Yes, metal Yes, concrete

Does the culvert have wing walls? No Yes

**Structure Approximate Dimensions (functional dimensions if partial)**

Are the distances measured for the whole structure or for a single chamber of a multispan structure? Whole Structure Single Chamber

For each measurement, indicate 'actual' or 'estimated' measurement with an 'x' in the appropriate column. Actual Estimated

-Height/Rise (feet) – can be marked as graduated

-Width/Span (feet) – across or span of bridge/culvert along road

-Length (feet) – for animal crossing over/under road

\_\_\_\_\_  
 \_\_\_\_\_  
 \_\_\_\_\_

**Obstructions**

Is the immediate entrance blocked? None Cattle Fence Boulders humans would have to climb over  
 Rocks/Riprap (> volleyball size) Rocks/Riprap (> baseball size) Some rocks, not continuous  
 Thick Vegetation Gate Other:

Are there structures that block the entrance within 25 feet? No Cattle Fence Small Mesh Fence  
 Boulder Field Stream Flow High/Steep Cut or Fill Slope

**Fill Slope**

Is the structure located in a fill slope? No Yes, < 20' high Yes, > 20' high  
 -If yes, how is the structure situated in the slope? At the base Midway on fill slope Near top of fill slope

**Approach Vegetation & Cover**

Is there vegetation/cover within 25' of the inlet? No Yes, partially Yes, completely  
 -If yes, select predominant type: Grasses Bushes Bushes/Trees

Is there vegetation/cover within 25-50' of the inlet? No Yes, partially Yes, completely  
 -If yes, select predominant type: Grasses Bushes Bushes/Trees

**Land Use Within 100 feet of inlet:**

Predominant land use: Forest Prairie/Grassland Agriculture Wetlands  
 Shrub/Steppe Mixed: Human/Natural Residential Commercial Other:

**Noise**

What does passing traffic sound like at the entrance to the structure? Silent Low Rumble Loud and Jarring

**Road Attributes**

How wide is zone of maintained vegetation (allowing extra visibility along the road shoulder)? 0' 0-6' 6-30' Undetermined

Is there a guard rail or jersey wall above the structure? No Yes, structure only Yes, extensive

**Notes:**

**OUTLET SIDE (East/South Structure)**

<b>Photo Number</b>	1:	2:	3:	4:
<b>Is there an apron at the outlet?</b>	No		Yes, metal	Yes, concrete
<b>Is the outlet perched?</b>	No		Yes, < 0.5 feet	Yes, > 0.5 feet
<b>Does the culvert have wing walls?</b>	No		Yes	

**Structure Approximate Dimensions (functional dimensions if partial)**

Are the distances measured for the whole structure or for a single chamber of a multispan structure? Whole Structure Single Chamber

For each measurement, indicate 'actual' or 'estimated' measurement with an 'x' in the appropriate column. Actual Estimated

-Height/Rise (feet) – can be marked as graduated				
-Width/Span (feet) – across or span of bridge/culvert along road				
-Length (feet) – for animal crossing over/under road				

**Obstructions**

<b>Is the immediate entrance blocked?</b>	None	Cattle Fence	Boulders humans would have to climb over
	Rocks/Riprap (> volleyball size)	Rocks/Riprap (> baseball size)	Some rocks, not continuous
	Thick Vegetation	Gate	Other:
<b>Are there structures that block the entrance within 25 feet?</b>	No	Cattle Fence	Small Mesh Fence
		Boulder Field	High/Steep Cut or Fill Slope
		Stream Flow	

**Fill Slope**

<b>Is the structure located in a fill slope?</b>	No	Yes, < 20' high	Yes, > 20' high
-If yes, how is the structure situated in the slope?	At the base	Midway on fill slope	Near top of fill slope

**Approach Vegetation & Cover**

<b>Is there vegetation/cover within 25' of the outlet?</b>	No	Yes, partially	Yes, completely
-If yes, select predominant type:	Grasses	Bushes	Bushes/Trees

-Does the fencing reach all the way to ground level without gaps?		Yes	No	
-Is the fencing entrenched in the ground to prevent animals from digging under it?		Yes	No	
- Is the ROW fencing the same as the fencing that is immediately adjacent to the structure?		Yes	No	
If no, what is the ROW fencing type:		Curb (not including wingwalls)		Wall (not including wingwalls)
	Chain Link	Wildlife Fence	Sediment Fence	4-Strand Wire    Other:
-Minimum distance fence extends from structure:				
	! 10 feet	101 feet	120-250 feet	# mile    " mile    2 mile    Miles    End not visible/known
<b>What is the general condition of the fencing?</b>			Gaps and areas where fence is down Vegetation needs to be cleared from fence	Some tacking up of fence needed Fence in good working order
<b>Is there an escape ramp(s) within a 1/2 mile of the structure in either direction?</b>			No	Yes - 1    Yes - 2 or more
<b>Is there a one-way gate(s) within a 1/2 mile of the structure in either direction?</b>			No	Yes - 2    Yes - 2 or more
<b>Are there uncontrolled driveways or intersectionsthat cause breaks in the fencing within a 1/2 mile of the structure in either direction?</b>	None	1	2-5	6-10    >10

**Notes:**

## Median

<b>Photo Number</b>	1:	2:	3:	4:
<b>Is there an open median?</b>	Yes	No		
[Include checkbox for each measurement below - Actual Measurements?]				
-What is the length of the median (distance between the two structures)? _____				
<b>What is the substrate of the median?</b>		Concrete/Asphalt	Mix: Man-made & Natural	Natural
<b>[if substrate = natural] Is there vegetation in the median?</b>		No	Yes, partially	Yes, completely
-If yes, select predominant type:				
		Grasses	Bushes	Bushes/Trees
<b>Is their median fencing/walls to prevent animals from accessing the highway via the median?</b>	Yes	No		
-Select type of fencing				
	Curb (not including wingwalls)	Wall (not including wingwalls)		4-Strand Wire
	Chain Link	Wildlife Fence	Sediment Fence	
<b>What is the general condition of the fencing?</b>		Gaps and areas where fence is down	Some tacking up of fence needed	
		Vegetation needs to be cleared from fence	Fence in good working order	

**Notes:**

## General

<b>Photo Number</b>	1:	2:	3:	4:
<b>Wildlife Use</b>				
<b>Are there signs of wildlife use in the structure such as tracks?</b>		Tracks	Scat	Live Animal
-If yes, describe				
<b>Are there signs of wildlife within 30 feet of the entrances?</b>		Tracks	Scat	Roadkill
-If yes, describe				
			Live Animal	None
				Other (text)
<b>Human Use</b>				
<b>Is there apparent human activity in the structure?</b>		Yes - Frequent/Daily	Yes - Occasional	No evidence Found
-What type(s) of activity? (check all that apply):				
		Camping/Occupancy	Vehicle/ATV use	Trail
		Recreation Dog	Night Use	Other:
<b>Which description best matches human activities immediately adjacent to the structure?</b>				
	Daily human activity at both entrances	Daily human activity at one entrance		
	Recreational use in a wild setting	Wild setting with infrequent human activity		Other:

**Notes:**

## Species Movement Guild Rankings

When ranking the structure, consider how changes in water levels and vegetation growth may affect passage for each Species Movement Guild.

A = This animal could make it though as is, or with small modifications

C = With modest modifications this structure could be functional

F = Can't be fixed with a retrofit

Rate this structure for **Low Mobility Small Fauna**, e.g., slow-moving animals that require a consistent environmental conditions, such as frogs or salamanders:

A                      C                      F

Comments:

Rate this structure for **Moderate Mobility Small Fauna**, e.g., small animals that are fairly adaptable, such as squirrels, skunks, raccoons, fishers and some turtles:

A                      C                      F

Comments:

Rate this structure for **Adaptive High Mobility Fauna**, e.g., fairly tolerant medium-sized animals, such as bobcat, coyote and black bear:

A                      C                      F

Comments:

Rate this structure for **High Openness High Mobility Carnivores**, e.g., larger animals that prefer larger structures, such as grizzly bear or mountain lion

A                      C                      F

Comments:

Rate this structure for **Adaptive Ungulates**, e.g., ungulates that require good visibility through a structure, such as deer, moose or mountain goats:

A                      C                      F

Rate this structure for **Very High Openness Fauna**, e.g., animals that require large structures with clear lines of sight that are less than 100' long, such as elk, pronghorn and turkey:

A                      C                      F

Comments:

**Which features could be changed to make the structure more functional for each target Species Movement Guild given an A or C rank?**

# PASSAGE ASSESSMENT SYSTEM: UNDIVIDED HIGHWAY

## Preliminary Questions (i.e., fatal flaws)

Assess each of the following questions relative to the species guild of interest to determine whether the structure is fatally flawed for members of the Species Movement Guilds indicated:

<b>Is the structure longer than 300 feet? (fatal flaw for <i>Adaptive Ungulates</i> and <i>Very High Openness Fauna</i>)</b>	No (continue)	Yes (structure is not suitable for enhancement)
<b>Is the culvert slope &gt; 30 degrees and 100' or longer? (fatal flaw for <i>all Species Movement Guilds</i>)</b>	No (continue)	Yes (structure is not suitable for enhancement)
<b>Is there extensive development/pavement in the immediate vicinity of one or both sides of the structure? (fatal flaw for <i>all Species Movement Guilds</i>)</b>	No (continue)	Yes (structure is not suitable for enhancement)
<b>Can you see through the structure to the other (for divided highways, consider each structure individually)? (if no, fatal flaw for <i>Adaptive Ungulates</i>, <i>Very High Openness Fauna</i> and <i>High Openness High Mobility Carnivores</i>)</b>	Yes (continue)	No (structure is not suitable for enhancement)

## Structure

<b>What is the shape of the structure?</b>	Round Pipe	Squash Pipe	Box Culvert	Arch Culvert
	Bridge Underpass - sloped	Bridge Underpass - straight	Bridge Overpass	Other (text)
<b>What is the structure material?</b>	Concrete	Metal	Plastic/Fiberglass	Other (text)
<b>[If Shape = Box] Are there multiple chambers?</b>	No	Yes - # of Chambers? (num)		
**If Yes, select the most appropriate chamber for terrestrial passage to answer the following questions.				
<b>[If Shape = Bridge Underpass] Is this a single span or multispans structure?</b>	Single span		Multispans (1 or more supports)	
**If Multispans, select the most appropriate chamber for terrestrial passage to answer the following questions.				
<b>[If Shape = Bridge Underpass] What is the material of the abutments on the West/North side?</b>	Concrete	Concrete/Soil	Soil	Riprap
	Gabian Wall	Other (txt)		
-What is the slope ratio? (horizontal:vertical)	0:1	1:1	2:1	
<b>[If Shape = Bridge Underpass] What is the material of the abutments on the East/South side?</b>	Concrete	Concrete/Soil	Soil	Riprap
	Gabian Wall	Other (txt)		
-What is the slope ratio? (horizontal:vertical)	0:1	1:1	2:1	

**Road Attributes**

Number of lanes of road: \_\_\_\_\_

Is there parallel infrastructure such as railroads, recreational paths, frontage roads, etc?      No      Yes - Describe:

**Notes:**

**INLET SIDE**

Photo Number 1: 2: 3: 4:

Is there an apron at the inlet? No Yes, metal Yes, concrete

Does the culvert have wing walls? No Yes

**Structure Approximate Dimensions (functional dimensions if partial)**

Are the distances measured for the whole structure or for a single chamber of a multispan structure? Whole Structure Single Chamber

For each measurement, indicate 'actual' or 'estimated' measurement with an 'x' in the appropriate column. Actual Estimated

- Height/Rise (feet) – can be marked as graduated \_\_\_\_\_
- Width/Span (feet) – across or span of bridge/culvert along road \_\_\_\_\_
- Length (feet) – for animal crossing over/under road \_\_\_\_\_

**Obstructions**

Is the immediate entrance blocked? None Cattle Fence Boulders humans would have to climb over  
 Rocks/Riprap (> volleyball size) Rocks/Riprap (> baseball size) Some rocks, not continuous  
 Thick Vegetation Gate Other:

Are there structures that block the entrance within 25 feet? No Cattle Fence Small Mesh Fence  
 Boulder Field Stream Flow High/Steep Cut or Fill Slope

**Fill Slope**

Is the structure located in a fill slope? No Yes, < 20' high Yes, > 20' high  
 -If yes, how is the structure situated in the slope? At the base Midway on fill slope Near top of fill slope

**Approach Vegetation & Cover**

Is there vegetation/cover within 25' of the inlet? No Yes, partially Yes, completely  
 -If yes, select predominant type: Grasses Bushes Bushes/Trees

Is there vegetation/cover within 25-50' of the inlet? No Yes, partially Yes, completely  
 -If yes, select predominant type: Grasses Bushes Bushes/Trees

**Land Use Within 100 feet of inlet:**

Predominant land use: Forest Prairie/Grassland Agriculture Wetlands  
 Shrub/Steppe Mixed: Human/Natural Residential Commercial Other:

**Noise**

What does passing traffic sound like at the entrance to the structure?  
 Silent Low Rumble Loud and Jarring

**Road Attributes**

How wide is zone of maintained vegetation (allowing extra visibility along the road shoulder)?  
 0' 0-6' 6-30' Undetermined

Is there a guard rail or jersey wall above the structure? No Yes, structure only Yes, extensive

**Notes:**

-Does the fencing reach all the way to ground level without gaps?	Yes	No					
-Is the fencing entrenched in the ground to prevent animals from digging under it?	Yes	No					
- Is the ROW fencing the same as the fencing that is immediately adjacent to the structure?	Yes	No					
If no, what is the ROW fencing type:	Curb (not including wingwalls)		Wall (not including wingwalls)				
	Chain Link	Wildlife Fence	Sediment Fence	4-Strand Wire	Other:		
-Minimum distance fence extends from structure:							
	! 10 feet	101 feet	120-250 feet	# mile	" mile	2 mile	Miles      End not visible/known
<b>What is the general condition of the fencing?</b>	Gaps and areas where fence is down		Some tacking up of fence needed				
	Vegetation needs to be cleared from fence		Fence in good working order				
<b>Is there an escape ramp(s) within a 1/2 mile of the structure in either direction?</b>	No	Yes - 1		Yes - 2 or more			
<b>Is there a one-way gate(s) within a 1/2 mile of the structure in either direction?</b>	No	Yes - 2		Yes - 2 or more			
<b>Are there uncontrolled driveways or intersectionsthat cause breaks in the fencing within a 1/2 mile of the structure in either direction?</b>							
	None	1	2-5	6-10	>10		

**Notes:**

## INSIDE STRUCTURE

Photo Number 1: 2: 3: 4:

### Visibility

Does the inside of the structure appear much darker than the outside lighting? High Contrast Low Contrast  
 Is there a clear line of sight from one end of the structure(s) to the other? No Obscured Yes, complete visibility

### Water Features

Is there perennial water flow through structure? No < 3' deep 3-10' deep >10' deep  
 Does there appear to be a dry natural substrate/dirt pathway through the structure during average flows?  
 None Dry Dirt Pathway Rock/Dirt Pathway Dry Rocky Pathway

Is there evidence that the dry pathway may be obliterated seasonally or during high water events?  
 No Yes Uncertain

### Substrate

What is the substrate of the floor at the bottom/center of the structure? Concrete/Asphalt Metal  
 Plastic Rocks Dry Soil Stream Bottom Other (txt)  
 -Is there a natural bottom through the length of the structure? Yes No  
 -Is there a natural bottom across the width of the structure? Yes No, > 6" No, 6" or greater

### Pathway Floor Substrate

Does the substrate through the structure appear similar to substrate outside of the structure? Yes No  
 -If No, what is the floor substrate?  
 Concrete Concrete with Steel Riprap Riprap Boulders Other (text)  
 (> baseball) (> volleyball)  
 -If Yes, what is the minimum width of the dry natural pathway all the way through the structure?  
 <2 feet 2-5 feet 5-10 feet 10-20 feet 20-50 feet Over 50 feet

### Vegetation

Is there vegetative cover and/or woody debris through the structure? None Some Logs, Down Trees  
 Some Grass/Brush Grasses Brush/Bushes/Trees

### Noise

What does passing traffic sound like from the middle of the structure?  
 Silent Low Rumble Loud and Jarring

### Other

Is there a road or trail through the structure? None Paved Road Dirt Road Railroad Paved Trail Dirt Trail  
 Are there obstructions inside the structure? None Debris Soil Baffles Gaps/Trenche Man-made Items  
 Is there a sky light in structure? No Yes

### Notes:

## Outlet Side: Fencing/Walls

Photo Number	1:	2:	3:	4:

## General

<b>Photo Number</b>	1:	2:	3:	4:	
<b>Wildlife Use</b>					
<b>Are there signs of wildlife use in the structure such as tracks?</b>	Tracks	Scat	Live Animal	None	Other (text)
-If yes, describe					
<b>Are there signs of wildlife within 30 feet of the entrances?</b>	Tracks	Scat	Roadkill	Live Animal	None
-If yes, describe					Other (text)

### Human Use

<b>Is there apparent human activity in the structure?</b>	Yes - Frequent/Daily	Yes - Occasional	No evidence Found
-What type(s) of activity? (check all that apply):	Camping/Occupancy	Vehicle/ATV use	Trail
	Recreation Dog	Night Use	Other:

**Which description best matches human activities immediately adjacent to the structure?**

Daily human activity at both entrances	Daily human activity at one entrance	
Recreational use in a wild setting	Wild setting with infrequent human activity	Other:

### Notes:

## Species Movement Guild Rankings

When ranking the structure, consider how changes in water levels and vegetation growth may affect passage for each Species Movement Guild.  
 A = This animal could make it though as is, or with small modifications  
 C = With modest modifications this structure could be functional  
 F = Can't be fixed with a retrofit

**Rate this structure for *Low Mobility Small Fauna*, e.g., slow-moving animals that require a consistent environmental conditions, such as frogs or salamanders:**

	A	C	F
Comments:			

**Rate this structure for *Moderate Mobility Small Fauna*, e.g., small animals that are fairly adaptable, such as squirrels, skunks, raccoons, fishers and some turtles:**

	A	C	F
Comments:			

Rate this structure for *Adaptive High Mobility Fauna*, e.g., fairly tolerant medium-sized animals, such as bobcat, coyote and black bear:

A                      C                      F

Comments:

Rate this structure for *High Openness High Mobility Carnivores*, e.g., larger animals that prefer larger structures, such as grizzly bear or mountain lion

A                      C                      F

Comments:

Rate this structure for *Adaptive Ungulates*, e.g., ungulates that require good visibility through a structure, such as deer, moose or mountain goats:

A                      C                      F

Comments:

Rate this structure for *Very High Openness Fauna*, e.g., animals that require large structures with clear lines of sight that are less than 100' long, such as elk, pronghorn and turkey:

A                      C                      F

Comments:

**Which features could be changed to make the structure more functional for any Species Movement Guild given an A or C rank?**

## User's Guide to Passage Assessment System

This User's Guide is a *reference document* to assist users of the Passage Assessment System. For each structure that is being evaluated, the user will complete (1) General Assessment Questions, and (2) Divided or Undivided Highway Assessment Questions, depending on whether the structure is located on a divided or undivided highway. Each of the questions in these sections are fully explained in this User's Guide.

### **MATERIALS:**

Clipboard, GPS unit, camera, 200' measuring tape

***Special Note About Seasonality and Using the PAS:*** The time of year at which the PAS is conducted can greatly later perspectives on the functionality of the structure for a given Species Movement Guild because of changes in water flows in different seasons. At locations where terrestrial passage may be significantly affected by changes in water levels, it is recommended that the PAS be conducted two or more times throughout the year to more accurately capture the impacts on terrestrial passage through the structure. Multiple assessments can also provide additional information relating to changes in vegetation growth and signs of animal activity throughout the year.

***Special Note About Urban Environments:*** The Passage Assessment System was developed for the purpose of assessing highway infrastructure located in non-urban environments. This evaluation system may also be applied to structures located in urban environments, however, users should be aware that urban wildlife are more adapted to human activity and infrastructure than their non-urban counterparts and may, therefore, have different tolerances for which the user will need to account when developing enhancement solutions.

## TAB 1: GENERAL QUESTIONS

*This form should be completed for each structure being evaluated.*

<b>Date:</b>	Today's date (dd/mm/yyyy)
<b>Location ID:</b>	Unique location number assigned to a given structure during a given field session (i.e., 01, 02, 03, etc)
<b>Location Code:</b>	Unique identifier code for a given structure written as: route_number_milepost_location id (e.g., 90_234_07 for US90, MP 234, Location #7)
<b>Route #:</b>	Highway number (e.g. US 101)
<b>Milepost:</b>	Milepost number to the nearest tenth mile
<b>GPS ID:</b>	Record ID number automatically generated by the GPS unit
<b>GPS Latitude:</b>	Derived from the GPS unit
<b>GPS Longitude:</b>	Derived from the GPS unit
<b>Structure Functional Class:</b>	Select the appropriate Functional Class of the structure being evaluated: 1 = small underpass (<5' span); 2 = medium underpass (5-8' span x 8' rise); 3 = large underpass (! 20' span x 8' rise, or ! 10' span x 10' rise) ; 4 = extensive bridge; 5 = wildlife overpass; 6 = specialized culverts; 7 = canopy bridge. Refer to the document <i>Functional Classes of Structures</i> for complete descriptions.
<b>Species Movement Guild:</b>	Identify the Species Movement Guilds that have been identified for this location (select all that apply): Low Mobility Fauna; Moderate Mobility Small Fauna; Adaptive High Mobility Fauna; High Openness High Mobility Fauna; Adaptive Ungulates; Very High Openness Fauna; Arboreal Fauna; Aerial Fauna. Refer to the document <i>Terrestrial Species Guilds</i> for complete descriptions.
<b>Bridge Number:</b>	WSDOT identification number
<b>Divided or Undivided:</b>	Note if the highway along this segment is divided or undivided at the point of the structure being evaluated.
<b>Highway Direction:</b>	Note if the primary direction of the roadway is east-west or north-south.
<b>Roadway Photo Numbers:</b>	Enter photo id numbers. Pictures are extremely helpful - take a lot!

## TAB 2 or 3: DIVIDED OR UNDIVIDED HIGHWAY

**Select the appropriate form for evaluating a given structure based on whether the structure is at a divided or undivided highway.**

While the questions posed are the same for a divided or undivided highway, they must be posed independently for each structure at a divided highway site. Evaluation questions are divided into distinct sections to guide the evaluation process. Some questions are repeated to capture conditions on both sides of a structure.

### Preliminary Questions

These are a collection of targeted questions designed to determine if there is a 'fatal flaw' with the structure relative to the Species Movement Guild(s) of interest. Each question should be considered relative to the Species Movement Guilds indicated. If a fatal flaw is identified, then the user need not complete all of the Passage Evaluations System questions as the fatal flaw renders the structure unsuitable for a enhancement; a redesigned and reconstructed structure is required to pass wildlife at that location.

**Is the structure longer than 300 feet?** A 'Yes' response is considered a fatal flaw for *Adaptive Ungulates* and *Very High Openness Fauna* and the structure is not suitable for enhancements. If the response is 'No', the user continues with the evaluation.

**Is the culvert slope > 30 degrees and 100' or longer?** A 'Yes' response is considered a fatal flaw for all *Species Movement Guilds* and the structure is not suitable for enhancement. If the response is 'No', the user continues with the evaluation. This threshold is intended as a general guideline; it may be adjusted based on additional research or local expertise.

**Is there extensive human development/pavement in the immediate vicinity of one or both sides of the structure?** A 'Yes' response is considered a fatal flaw for *all* Species Movement Guilds and the structure is not suitable for enhancement. While structures in a developed landscape may pass some animals that have adapted to that landscape, these structures offer limited use for passing wildlife populations and improving connectivity. If the response is 'No', the user continues with the evaluation.

**Can you see through the structure to the other side (for divided highways, consider each structure individually)?** A 'No' response is considered a fatal flaw for several species guilds and the structure is not suitable for enhancement. If the response is 'No', the user continues with the evaluation.

### Structure

**What is the shape of the structure?** Select one: Round Pipe, Squash Pipe, Box Culvert, Arch Culvert, Bridge Underpass with sloped sides, Bridge Underpass with straight sides, Bridge Overpass or Other (describe).

**What is the structure material?** Refers to the material used to construct the structure, on the inside of the structure that an animal passing through would experience. This question does not refer to the presence of natural or deposited sediment on the floor of the structure. Select one: Concrete, Metal, Plastic/Fiberglass

<b>[If Shape = Box] Are there multiple chambers?</b>	If the structure is a box culvert, the user is prompted to answer this question. Multiple chambers occur if the box has one or more divisions, resulting in discrete chambers. If the response is yes, there are multiple chambers, then the user is prompted to select the most appropriate chamber for responding to all subsequent questions (e.g., the largest or driest chamber)
<b>[If Shape = Bridge Underpass] Is this a single span or multispans structure?</b>	If the structure is a Bridge Underpass, the user is prompted to answer this question. A single span bridge has supports only at either end of the structure; a multispans bridge has one or more supports at intervals along the length of the structure.
<b>[If Shape = Bridge Underpass] What is the material of the abutments on the West/North side?</b> -What is their ratio?	If the structure is a Bridge Underpass, the user is prompted to answer this question. Select one: Concrete, Concrete/Soil mix; Soil, Riprap, Gabian Wall, or Other (describe)  What is the approximate ratio of the side slope on the West or North side of the structure?
<b>[If Shape = Bridge Underpass] What is the material of the abutments on the East/South side?</b> -What is the slope ratio?	If the structure is a Bridge Underpass, the user is prompted to answer this question. Select one: Concrete, Concrete/Soil mix; Soil, Riprap, Gabian Wall, or Other (describe)  0:1 = vertical; 1:1 = 45° angle; 2:1 = gentle low slope
<b>Road Attributes</b> <b>Number of lanes of road:</b>	Enter the total number of lanes, in both travel directions, including center lanes and turning lanes. Do not include highway exits or frontage roads.
<b>Is there parallel infrastructure such as railroads, recreational paths, frontage roads, etc?</b>	Describe any additional transportation infrastructure adjacent to the roadway.
<b>Notes:</b>	Provide any additional information about the structure or its situation in the surrounding environment that is not covered elsewhere.

## INLET/OUTLET SIDE

***For sites without water flow through the structure, the user should designate the uphill side as the inlet and the downhill side as the outlet. At locations where an uphill and downhill side cannot be distinguished, the user should simply designate one entrance to represent the inlet and the other the outlet.***

<b>Photo Number:</b>	Enter photo id numbers. Pictures are extremely helpful - take a lot!
<b>Is there an apron at the inlet/outlet?</b>	Yes or No. If yes, indicate whether metal or concrete
<b>Does the culvert have wing walls?</b>	Yes or No

**Is the outlet perched?**

A perched outlet refers to a culvert whose base is perched above the ground level. This situation often occurs with pipes either by design, or because the ground immediately beneath the culvert has eroded.

**Structure Approximate Dimensions (functional dimensions if partially buried)**

Actual or Estimated Measurements?

Indicate whether the structure was measured precisely or if the measurements were estimated.

-Height/Rise (feet):

Measure the height of the structure in feet

-Width/Span (feet):

Measure the width (span) of the structure in feet. Refers to the width of the structure from the perspective of an animal passing through.

-Length (feet):

Measure the length of the structure in feet. Refers to the length of the structure from the perspective of an animal passing through.

**Obstructions**

**Is the immediate entrance blocked?**

Are there physical barriers at the immediate entrance that may block entry for target species that may try to enter the structure? Select one: None, Cattle Fence (4-strand barbed wire), Boulders so big a human would have to climb over them, Riprap larger than a volleyball, Riprap larger than a baseball, Some rocks (not continuously blocking the entrance), Thick Vegetation, Gate, or Other (describe).

**Are there structures that block the entrance within 25 feet?**

Are there physical barriers within 25 feet that may block passage through the structure? Select one: None, Cattle Fence, Small Mesh Fence, Boulder Field, Stream Flow, High/Steep Cut or Fill Slope.

**Fill Slope**

**Is the structure located in a fill slope?**

Select one: No or Yes. If yes, is the slope less than 20' high or greater than or equal to 20' high?

-If yes, how is the structure situated in the slope?

Note the location of the structure relative to the fill slope. Select one: At the base; Midway on fill slope; or Near the top of fill slope

**Approach Vegetation & Cover**

**Is there vegetation/cover within 25' of the inlet?**

Select one: No, Yes - partial cover, or Yes - complete cover

-If yes, select predominant type:

Select one: Grasses, Bushes, Bushes/Trees mix

**Is there vegetation/cover within 25-50' of the inlet?**

Select one: No, Yes - partial cover, or Yes - complete cover

-If yes, select predominant type:

Select one: Grasses, Bushes, Bushes/Trees mix

**Land Use Within 100 feet**

Predominant land use:

Select the predominant land use within 100 feet of the structure entrance: Forest, Prairie/Grassland, Agriculture, Wetlands, Shrub/Steppe, Mixed Human/Natural, Residential, Commercial, or Other

## **Noise**

**What does passing traffic sound like at the entrance to the structure?**

Loud traffic noise at the entrance to a structure may deter passage use by some species. Select one of the following to best characterize how passing traffic sounds when standing in front of the entrance to a structure: Silent; Low Rumble; or Loud and Jarring.

## **Road Attributes**

**How wide is zone of maintained vegetation (allowing extra visibility along the road shoulder)?**

This refers to the portion of the right-of-way that is maintained to keep it clear of high vegetation and other obstructions. Note the approximate width of the apparent zone of maintained vegetation to the left and right of the structure.

**Is there a guard rail or jersey wall above the structure?**

No, Yes - immediately above the structure only, or Yes - extensive along the roadway segment

**Notes:**

## **INSIDE STRUCTURE**

**Photo Number:**

Enter photo id numbers. Pictures are extremely helpful - take a lot!

## **Visibility**

**Does the inside of the structure appear much darker than the outside lighting?**

Note High or Low Light Contrast. In some cases, animals (e.g., ungulates) may be deterred from structures where the lighting inside the structure contrasts significantly with the lighting outside the structure.

**Is there a clear line of sight from one end of the structure(s) to the other?**

A clear sight line means that you have visibility from one end of the structure to the other. Some wildlife have a higher tendency to use structures with clear lines of sight than those they cannot see the open area out the other end. Note if the line of sight is completely clear, partially obscured, or completely obscured.

## **Water Features**

**Is there perennial water flow through structure?**

Note the depth of perennial water flow through the structure: None; < 3' deep; 3-10' deep; or >10' deep

**Does there appear to be a dry natural substrate/dirt pathway through the structure during average flows?**

A dry, natural pathway through a structure from one end to the other is important to structure functionality for a number of terrestrial species. Select one: None, Dry Dirt Pathway, Rock/Dirt Pathway, or Dry Rocky Pathway.

**Is there evidence that the dry pathway may be obliterated seasonally or during high water events?**

The purpose of this question is to determine whether there are certain time periods when a structure may become unusable for certain species due to high water. Select: No, Yes, or Uncertain.

## **Substrate**

**What is the substrate of the floor at the bottom/center of the structure?** Select one: Concrete/Asphalt, Metal, Plastic, Rocks, Soil, Stream Bottom, or Other (describe).

-Is there a natural bottom through the length of the structure? Does a natural surface (non-manmade) extend the full length of the structure, for as least some portion of the width of the structure? Answer Yes or No.

-Is there a natural bottom across the width of the structure? Does a natural surface (non-manmade) extend across the entire width or some portion of the width of the structure? Answer Yes, No - less than 6"; No - 6" or greater

## **Pathway Floor Substrate**

**Does the substrate through the structure appear similar to substrate outside of the structure?** Yes or No.

-If No, what is the floor substrate? Select one: Concrete, Concrete with Baffles/Stabilizers, Steel, Riprap greater than a baseball, Riprap greater than a volleyball, Boulders, or Other (describe)

-If Yes, what is the minimum width of the dry natural pathway all the way through the structure? Select one: <2 feet; 2-5 feet; 5-10 feet; 10-20 feet; 20-50 feet; or Over 50 feet

## **Vegetation**

**Is there vegetative cover and/or woody debris through the structure?** Vegetation in a structure may provide protective cover which can encourage use by some species. Select one: None; Some Logs or Down Trees; Some Grass/Brush; Grasses; Mix of Brush/Bushes/Trees.

## **Noise**

**What does passing traffic sound like from the middle of the structure?** A broad, subjective assessment of traffic noise levels for animals crossing through the structure. Question does not consider traffic volumes. Select one: Silent; Low Rumble; or Loud and Jarring

## **Other**

**Is there a road or trail through the structure?** Select all that apply: None, Paved Road, Dirt Road, Railroad, Paved Trail, Dirt Trail.

**Are there obstructions inside the structure?** Indicate whether there are any features that could obstruct movement through the structure for the Species Guilds of interest. Select all that apply: None, Natural Debris, Soil, Human Structures/Equipment, Gaps/Trenches, Baffles.

**Is there a sky light in structure?** Yes or No

**Notes:**

## Fencing/Walls (completed for both inlet and outlet sides of the structure)

**Photo Number:** Enter photo id numbers. Pictures are extremely helpful - take a lot!

**Is there fencing associated with the structure?** Yes or No

**Select type of fencing to *right/left* when facing structure:** These questions apply to the fencing only, they do not apply to structure wingwalls. Select one: Curb (short wall to guide amphibians), Wall, Chain Link Fence, Wildlife Fence, Sediment Fence, 4-Strand Wire Fence, or Other (specify).

-If curb or wall, does it have a lip? Yes or No. (A lip inhibits animals from climbing over the wall)  
-What is the height of fencing/wall? Select one: ! 6"; > 6" to ! 2'; 2' to 4'; 4 to 6'; 6 to 8', >8'  
-What is the mesh size? Mesh size refers to the spacing of the fence strands. Small animals may be able to pass through larger mesh sizes. Select one: None; 6x6"; 6x6", graduating smaller to 2x3 at base; Other (describe)

-Is it connected to the structure? Note if there are gaps between the structure and the start of the fencing or wall, where an animal may be able to pass through. Select one: Yes, No - small gap (! 0.5'), No - large gap (>0.5')

-Does the fencing reach all the way to ground level without gaps? Yes or No. Animals may be able to pass underneath fencing if it does not extend to ground level along the full length of the fencing.

-Is the fencing entrenched in the ground to prevent animals from digging under it? Yes or No. Digging animals may be able to pas underneath fencing that is not entrenched into the ground.

- Is the ROW fencing the same as the fencing that is immediately adjacent to the structure? Yes or No. If no, what is the ROW fencing type: Curb (not including wingwalls); Walls (not including wingwalls); Chain Link; Wildlife Fence; Sediment Fence; 4-Strand Wire; or Other (specify).

-Minimum distance fence extends from structure: This question characterizes the purpose of the fencing as guide fencing or continuous fencing along a segment of roadway. Select the option that best approximates the length of the fencing: ! 10 feet; 10-50 feet; 50-100 feet; >100; ~1/2 mile; miles (may be determined if the user has driven a long segment of roadway); or end not known or visible.

**What is the general condition of the fencing?** The condition of fencing is important to capture in the evaluation as poorly maintained fencing with gaps may allow animals to pass through and become trapped inside the right-of-way. Select all that apply: Gaps and areas where fence is down; Some tacking up of fence needed; Vegetation needs to be cleared from fence; Fence in good working order.

**Is there an escape ramp(s) within a 1/2 mile of the structure in either direction?** Escape ramps are designed to allow ungulates (in particular) and other large mammals that have become trapped inside the right-of-way to escape back to the other side of the fencing. Indicate if ramps are present along the fencing: No; Yes - 1; Yes - 2 or more.

**Is there a one-way gate(s) within a 1/2 mile of the structure in either direction?** One-way gates are a previously-used mechanism for allow ungulates that have become trapped inside the right-of-way to escape back to the other side of the fencing, however they are difficult to maintain and often themselves become gaps in the fencing. Their installation is no longer recommended as an effective mitigation measure. Indicate if ramps are present along the fencing: No; Yes - 1; Yes - 2 or more.

**Are there uncontrolled driveways, intersections or exit ramps that cause breaks in the fencing within a 1/2 mile of the structure in either direction?** An uncontrolled driveway, intersection or exit ramp is point where there is a break in the fencing to allow vehicular access to adjacent infrastructure that also acts as a gap in the fencing for wildlife. Such breaks may be controlled by double cattle guards, specifically-designed electric mats, gates, or other mechanisms, however controlling these breaks can be expensive if there are multiple breaks in a segment of fencing. Select one: None; 1; 2-5; 6-10; >10

**Notes:** Provide any additional information about fencing

## General

**Photo Number:** Enter photo id numbers. Pictures are extremely helpful - take a lot!

### Wildlife Use

**Are there signs of wildlife use in the structure such as tracks?** Select all that apply: Tracks, Scat, Live Animal, None or Other (describe)

-If yes, describe

Note species, if known, and other pertinent information

**Are there signs of wildlife within 30 feet of the entrances?** Select all that apply: Tracks, Scat, Live Animal, None or Other (describe)

-If yes, describe

Note species, if known, and other pertinent information

### Human Use

**Is there apparent human activity in the structure?** Yes - Frequently/Daily; Yes - Occasional; or No evidence Found

-What type(s) of activity?

Select all that apply: Camping/Occupancy, Vehicle/ATV use, Trail, Recreation, Dog, Night Use, Other

**Which description best matches human activities immediately adjacent to the structure?** The purpose of this question is to get a general understanding of human activity - not including permanent development - at the structure, in terms of frequency, location (at one or both entrances) and the setting itself. Select one: Daily human activity at both entrances; Daily human activity at one entrance; Recreational use in wild setting; Wild setting with infrequent human activity; Other.

**Notes:**

## Species Movement Guild Rankings

*The following questions are designed to get a general impression while the user is in the field of how functional the structure is for each of the Species Movement Guild of interest. They are subjective and responses should be based on the user's overall impression having completed the rest of the structure assessment. Refer to Species Movement Guilds for complete descriptions.*

*Each question should be ranked as follows:*

A = This animal could make it though as is, or with small modifications

C = With modest modifications this structure could be functional

F = Can't be fixed with a retrofit

Rate this structure for **Low Mobility Small Fauna**, e.g., slow-moving animals that require a consistent environmental conditions, such as frogs or salamanders:

A                      C                      F

Rate this structure for **Moderate Mobility Small Fauna**, e.g., small animals that are fairly adaptable, such as squirrels, skunks, raccoons, fishers and some turtles:

A                      C                      F

Rate this structure for **Adaptive High Mobility Fauna**, e.g., fairly tolerant medium-sized animals, such as bobcat, coyote and black bear:

A                      C                      F

Rate this structure for **High Openness High Mobility Carnivores**, e.g., larger animals that prefer larger structures, such as grizzly bear or mountain lion

A                      C                      F

Rate this structure for **Adaptive Ungulates**, e.g., ungulates that require good visibility through a structure, such as deer, moose or mountain goats:

A                      C                      F

Rate this structure for **Very High Openness Fauna**, e.g., animals that require large structures with clear lines of sight that are less than 100' long, such as elk, pronghorn and turkey:

A                      C                      F

**Which features could be changed to make the structure more functional for any Species Movement Guild given an A or C rank?**

*This question offers an opportunity for the user to suggest potential retrofits to improve the structure functionality. These may, of course, be amended later, but it is often helpful to capture initial impressions and ideas while still in the field.*

## APPENDIX C. PASSAGE ENHANCEMENT TOOLBOX FOR IMPROVING EXISTING STRUCTURES FOR TERRESTRIAL WILDLIFE

PASSAGE ENHANCEMENT SOLUTION	SPECIES MOVEMENT GUILDS	STRUCTURE FUNCTIONAL CLASS	NOTES & REFERENCES
<b>Remove Obstacles to Wildlife Passage</b>			
Remove obstruction or barrier at one or both structure entrances, inside the structure, or in the approaches to the structure (e.g., cattle fencing across structure entrances; trash or debris).	Low Mobility Small Fauna Moderate Mobility Small Fauna Adaptive High Mobility Fauna High Openness High Mobility Carnivores Adaptive Ungulates Very High Openness Fauna	ALL	
Clear debris and install sediment traps and/or regularly maintain to prevent structure from being blocked, filled or clogged.	Low Mobility Small Fauna Moderate Mobility Small Fauna Adaptive High Mobility Fauna	Class 1, 2	Yanes, M., J.M. Velasco, and F. Suárez. 1995. Permeability of roads and railways to vertebrates: the importance of culverts. <i>Biological Conservation</i> 71:217-222.
Keep culvert entrances clear of heavy vegetation growth that could block wildlife passage.		Class 1, 2, 3	Clevenger, A.P., B. Chruszcz, and K. Gunson. 2001. Drainage culverts as habitat linkages and factors affecting passage by mammals. <i>Journal of Applied Ecology</i> 38:1340-1349.

PASSAGE ENHANCEMENT SOLUTION	SPECIES MOVEMENT GUILDS	STRUCTURE FUNCTIONAL CLASS	NOTES & REFERENCES
<b>Facilitate Movement and Create Pathways</b>			
Add a dry, natural pathway through structure, on both sides of waterway if a stream or river is present.	Adaptive Ungulates Very High Openness Fauna	Class 3, 4, 5	Forman, R. T., Sperling, D., Bissonette, J. A., Clevenger, A. P., Cutshall, C. D., Dale, V. H., et al. 2003. Mitigation for wildlife. Pages 139-167 in: Road Ecology: Science and Solutions. Island Press, Washington, D.C.
Minimize or cover riprap on side-slopes with dirt to create a dry, smooth pathway.	Adaptive Ungulates Very High Openness Fauna	Class 3, 4, 5	
Install interlocking brick to support slopes instead of riprap to open up a pathway and facilitate wildlife passage.	Adaptive Ungulates Very High Openness Fauna	Class 3, 4, 5	
Install a raised shelf through water-filled culverts to provide a dry pathway for small mammals; Include a shelf tube to provide protective cover for voles.	Low Mobility Small Fauna	Class 1, 2	
Add baffles to culvert floor to retain sediment on artificial culvert floor (where water flows occasionally through the culvert).	Moderate Mobility Small Fauna Adaptive High Mobility Fauna High Openness High Mobility Carnivores Adaptive Ungulates Very High Openness Fauna	Class 1, 2, 3	

PASSAGE ENHANCEMENT SOLUTION	SPECIES MOVEMENT GUILDS	STRUCTURE FUNCTIONAL CLASS	NOTES & REFERENCES
Install woody debris (e.g., down logs) through a structure for small species requiring cover from predators.	Low Mobility Small Fauna Moderate Mobility Small Fauna	Class 2, 3, 4, 5	Ehinger, W., P. Garvey-Darda, R. Gersib, K. Halupka, P. McQueary, W. Meyer, R. Schanz and P. Wagner. 2006. Interstate 90 Snoqualmie Pass East Mitigation Development Team: Recommendation package. Submitted to: U.S. Department of Transportation, Federal Highway Administration and Washington State Department of Transportation.
Maintain natural streambanks through the structure.	Low Mobility Small Fauna Moderate Mobility Small Fauna (riparian species)	Class 2, 3, 4	
Add a strip of natural substrate and vegetation along one or both sides of a road through a structure.	Low Mobility Small Fauna Moderate Mobility Small Fauna	Class 3	
Where scour has resulted in perched culverts, build up scour resistant materials to create a navigable pathway into the culvert. Use natural materials; if riprap is used to build up the entrance pathway, it should be covered with natural substrate.	Low Mobility Small Fauna Moderate Mobility Small Fauna	Class 1, 2,	

PASSAGE ENHANCEMENT SOLUTION	SPECIES MOVEMENT GUILDS	STRUCTURE FUNCTIONAL CLASS	NOTES & REFERENCES
Rerrange substrate material around inlet/outlet of small culverts to allow greater visibility through structures.	Low Mobility Small Fauna Moderate Mobility Small Fauna	Class 1	
Add salamander ramps at curbs.	Low Mobility Small Fauna		
Add grates to existing culverts to allow light/moisture/temperature penetration into the culvert.	Low Mobility Small Fauna	Class 1, 6	Carr, T., R. Dacanay, K. Drake, C. Everson, A. Sperry and K. Sullivan. 2003. Wildlife Crossings: Rethinking Road Design to Improve Safety and Reconnect Habitat. Portland State University Planning Workshop, Prepared for Metro. 111 pp.
Modify existing trenched drains to allow animals to enter.	Low Mobility Small Fauna	Class 6	Bank, F.G., C.L. Irwin, G.L. Evink, M.E. Gray, S. Hagood, J.R. Kinar, A. Levy, D. Paulson, B. Ruediger, and R.M. Sauvajot. 2002. Wildlife Habitat Connectivity Across European Highways. Federal Highway Administration. Alexandria, VA. URL: <a href="http://international.fhwa.dot.gov/wildlife_web.htm">http://international.fhwa.dot.gov/wildlife_web.htm</a>

PASSAGE ENHANCEMENT SOLUTION	SPECIES MOVEMENT GUILDS	STRUCTURE FUNCTIONAL CLASS	NOTES & REFERENCES
For Multi-chambered structures with waterflow, divert waterflow so that one chamber remains dry for terrestrial wildlife.	Moderate Mobility Small Fauna Adaptive High Mobility Fauna High Openness High Mobility Carnivores Adaptive Ungulates Very High Openness Fauna	Class 2, 3, 4	
Promote waterflow through culverts to prevent standing water from inhibiting passage through a culvert or deterring entry into the culvert.	Moderate Mobility Small Fauna Adaptive High Mobility Fauna High Openness High Mobility Carnivores Adaptive Ungulates Very High Openness Fauna	Class 1, 2, 3	
Prevent polluting agents and road sediment from being flushed through culverts.	Low Mobility Small Fauna Moderate Mobility Small Fauna	Class 1, 6	
<b>Reduce Intimidation</b>			
Replace steep abutment slopes or walls with natural 2:1 slopes.	Adaptive Ungulates Very High Openness Fauna	Class 2, 3, 4	Dodd, N.L., J.W. Gagnon, A.L. Manzo, and R.E. Scheinsburg. 2007. Video surveillance to assess highway underpass use by elk in Arizona. Journal of Wildlife Management 71(2):637-645.

PASSAGE ENHANCEMENT SOLUTION	SPECIES MOVEMENT GUILDS	STRUCTURE FUNCTIONAL CLASS	NOTES & REFERENCES
Remove fill predator perches - ledges or places where prey species may be fearful of unseen predators.	Adaptive Ungulates Very High Openness Fauna	Class 2, 3, 4	Little, S.J., R.G. Harcour, A.P. Clevenger. 2002. Do wildlife passages act as prey-traps? Biological Conservation 107:135-145.
Add median skylights or openings. [This measure is not appropriate for all culvert situations. Avoid creating very high contrast conditions inside the culvert; Avoid where there is a narrow median that would result in a large increase in traffic noise inside the culvert; Avoid allowing precipitation to enter the culvert where winter temperatures could cause the creation of ice mounds inside the culvert, thereby inhibiting wildlife passage].	Adaptive Ungulates Very High Openness Fauna	Class 2	Reed, D.F., T.N.Woodard, T.M. Pojar. 1975. Behavioral Response of Mule Deer to a Highway Underpass. J. Wild Manage. 39(2):361-367.

PASSAGE ENHANCEMENT SOLUTION	SPECIES MOVEMENT GUILDS	STRUCTURE FUNCTIONAL CLASS	NOTES & REFERENCES
Avoid/remove highway lighting near structure entrances.	ALL	ALL	Jackson, S. D. (2000). Overview of Transportation Impacts on Wildlife Movement. <i>Wildlife and Highways: Seeking Solutions to an ecological and Socio-economic Dilemma</i> . T. A. Messmer and B. West, The Wildlife Society.
Implement measures to reduce traffic noise inside culvert and/or at structure entrances (e.g., concrete shoulder barriers placed above the structure)	ALL	ALL	Jackson, S. D. (2000). Overview of Transportation Impacts on Wildlife Movement. <i>Wildlife and Highways: Seeking Solutions to an ecological and Socio-economic Dilemma</i> . T. A. Messmer and B. West, The Wildlife Society.
To the extent possible, avoid laying trails or other human access through crossing structures. Where trails do pass through a structure, separate human trails from wildlife pathways through the structure.	High Openness High Mobility Carnivores Adaptive Ungulates Very High Openness Fauna	Class 2, 3, 4, 5	Hartmann, M. (2003). Evaluation of Wildlife Crossing Structures: Their Use and Effectiveness.

PASSAGE ENHANCEMENT SOLUTION	SPECIES MOVEMENT GUILDS	STRUCTURE FUNCTIONAL CLASS	NOTES & REFERENCES
Install signs near crossing structures or where trails cross through structures to limit human activity in and around wildlife crossings [Avoid drawing attention to unobtrusive crossing structures with unnecessary signage]	ALL	ALL	Clevenger, A. and N. Waltho. 2005. Performance indices to identify attributes of highway crossing structures facilitating movement of large mammals. <i>Biological Conservation</i> 121:453-464.
Install barriers (e.g., large boulders) to prevent motorized travel through crossing structures.	High Openness High Mobility Carnivores Adaptive Ungulates Very High Openness Fauna	Class 3, 4, 5	
<b>Enhance Structure Approaches</b>			
Enhance/maintain native vegetation cover in front of structure entrances.	ALL	ALL	Ng, S., J. Dole, R. Sauvajot, S. Riley, and T. Valone. 2004. Use of highway undercrossings by wildlife in southern California. <i>Biological Conservation</i> 1115:499-507.
Thin heavy vegetation that may obstruct wildlife passage at structure entrances.	Adaptive High Mobility Fauna High Openness High Mobility Carnivores Adaptive Ungulates Very High Openness Fauna	Class 2, 3	Maintain a balance between enough cover for prey species to feel safe entering a culvert, but not so much that animals cannot enter or have good visibility into and through the culvert.
Avoid the use of herbicides around structure entrances.	Low Mobility Small Fauna	ALL	

PASSAGE ENHANCEMENT SOLUTION	SPECIES MOVEMENT GUILDS	STRUCTURE FUNCTIONAL CLASS	NOTES & REFERENCES
Plant bushes in the median to provide better cover and insulation from highway traffic noise and lights.	High Openness High Mobility Carnivores Adaptive Ungulates Very High Openness Fauna	Wherever open median is present	
Avoid the use of erosion netting in landscaping around crossing structures, which may ensnare snakes.	Moderate Mobility Small Fauna	ALL	
Convert cattle fencing near structure approaches to wildlife-friendly rail fencing to allow young to pass through to access structures.	Adaptive Ungulates Very High Openness Fauna	Class 2, 3, 4	
<b>Fencing and Barriers</b>			
Add wildlife fencing and/or guide walls to existing suitable structures - do not install extensive fencing where there are no suitable crossing structures.	ALL - type, design & height of fencing or guide wall depends on species (see notes)	N/A	For guidance on different types of wildlife fencing, see: <a href="http://www.azdot.gov/highways/EPG/EPG_Common/PDF/Technical/Wildlife_Connectivity/Wildlife_Funnel_Fencing/Wildlife_Funnel_Fencing_Summary.pdf">http://www.azdot.gov/highways/EPG/EPG_Common/PDF/Technical/Wildlife_Connectivity/Wildlife_Funnel_Fencing/Wildlife_Funnel_Fencing_Summary.pdf</a>
Modify existing right-of way fencing by adding height to convert it to wildlife fencing.	High Openness High Mobility Carnivores Adaptive Ungulates Very High Openness Fauna	N/A	FHWA. Keeping it Simple - Arizona. <a href="http://www.fhwa.dot.gov/environment/wildlifeprotection">http://www.fhwa.dot.gov/environment/wildlifeprotection</a>

## **APPENDIX D.**

### **STRUCTURE EVALUATIONS, MONITORING RESULTS AND RECOMMENDATIONS FOR IMPROVING PERMEABILITY FOR TERRESTRIAL WILDLIFE IN WASHINGTON STATE**

*Conducted by:*

Julia Kintsch, ECO-resolutions, LLC

Dr. Patricia Cramer, Utah State University

*For:*

Washington State Department of Transportation

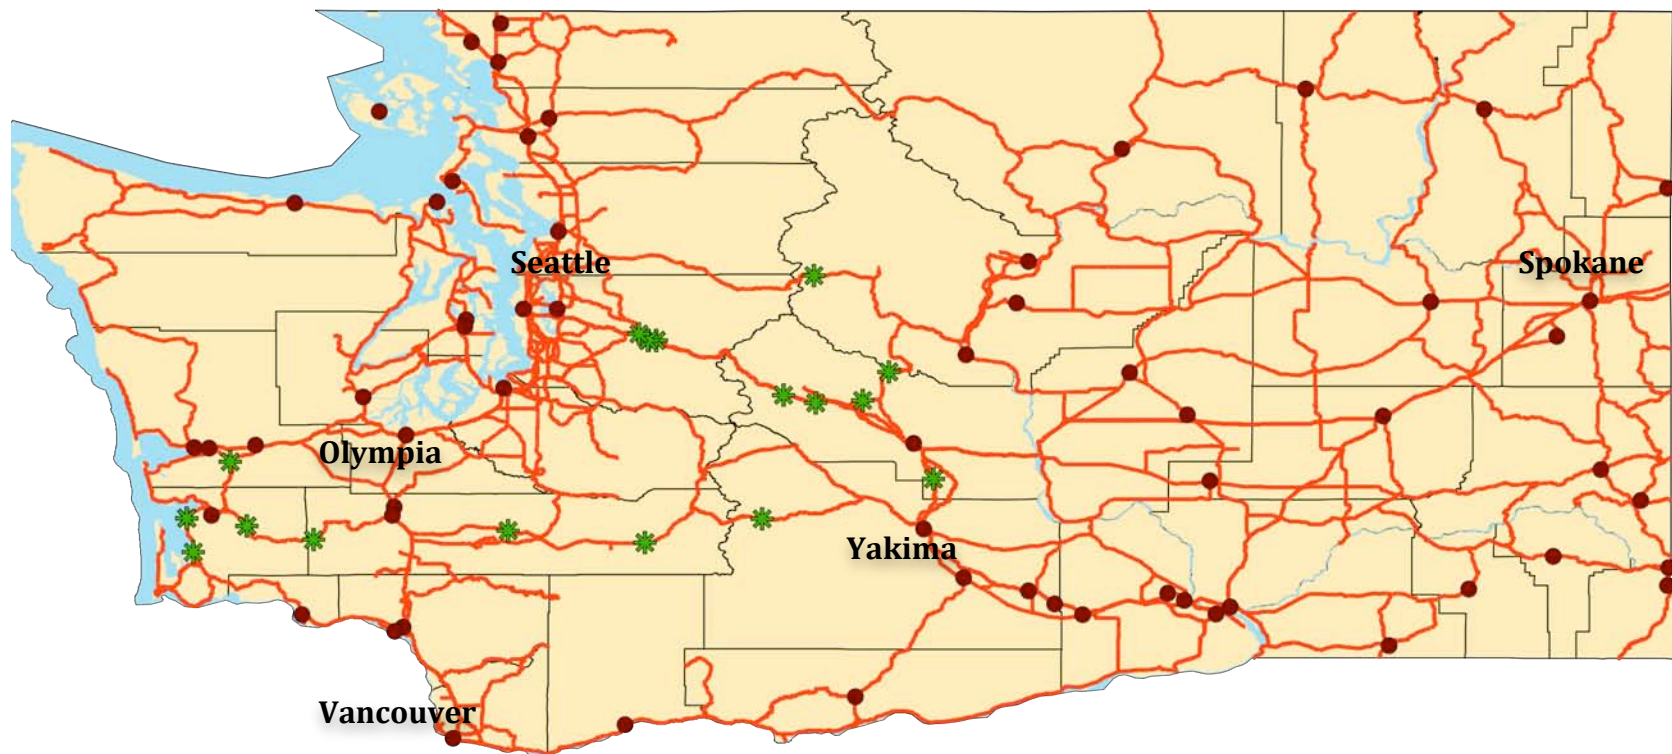

April 2011

Site assessments were conducted at seventeen highway structure locations (i.e., bridges or culverts) along eight state-maintained roadways between June 21 to 24, 2010 (Map 1). The purpose of these assessments was to test a system for evaluating existing structures with regards to their potential to pass different types of wildlife. The evaluation system is designed to help WSDO identify barriers to wildlife passage in existing transportation infrastructure and opportunities for retrofitting these structures so that they are more functional for passage of the diverse wildlife in Washington.

Following are the results of this evaluation and subsequent retrofit recommendations at all 17 of the assessed locations. These results are provided as examples of the evaluation system and how it can be used to determine preliminary recommendations for retrofitting or replacing bridges and culverts to enhance permeability for terrestrial wildlife. Each example includes descriptions of the roadway situation and general environs, the structure, and the surrounding habitat and terrain. These descriptions are followed with specific recommendations and guidance as to how the authors came to these recommendations.

Monitoring cameras were placed at 6 of these evaluation sites (2 cameras at each site) for 6 months. Two additional sites near North Bend were removed from the monitoring study due to vandalism. Summaries of the monitoring results are presented for each site after the site evaluation. The monitoring summaries provide

**Map 1.** Location of culverts and bridges evaluated in this study for their ability to pass terrestrial wildlife (green stars). Major cities are denoted by dark circles.

an overview of the photographic data including the number of deer and elk at the site, if the animals used the structure or were repelled (animals that looked into the structure's passage and turned away), seasonal use of the structure by deer, and tallies of all species detected at the site. For each site six sample pictures of the camera data are displayed to demonstrate wildlife activity at the site. These datasets can help WSDOT determine how different species will use certain structures more readily than others. The summaries also help support and clarify conclusions drawn during the site evaluations and refine the recommendations provided to better adapt the crossings for wildlife passage.

Monitoring at these sites entailed the placement of motion-triggered trail cameras inside metal utility boxes. Cameras were placed at either end of the outside edges of the structure. The cameras were locked to bicycle cables which were embedded in 60 to 120 pounds of concrete on the inside bottom of the utility box. Cameras were checked every two weeks. Camera visits entailed changing batteries and exchanging flash cards with photographic data. Data was transferred to Dr. Cramer via exchanges of thumb drives. Data was analyzed and entered into Excel spreadsheets for final tallies.

Of particular note during this study was elk use of two large bridged structures under I-90. Research throughout the western United States has documented the species' reluctance to pass through confined spaces such as culverts or small, restricted bridges. However, photographic evidence compiled through this research project shows elk movements under bridges that were wide, but less than 10 feet (3 m) high. This new insight may help WSDOT and other agencies to better design cost-effective bridged structures suitable for elk, and realize the potential for elk passage at existing bridges.

A very interesting site included in this study is a pair of corrugated steel culverts under I-90 near North Bend, Washington (Milepost (MP) 29). These culverts are located in a thickly vegetated area. Judging from the characteristics of the structures and the fact the small stream through this crossing was placed underground for half the crossing, and is above ground on the north side, it appears these culverts were designed specifically for wildlife passage. If wildlife were not considered, the stream could have been shunted underground for the entire length of the passage. This culvert appears to be among the most successful black bear crossings in the western U.S., as demonstrated by 31 black bear observations during 5 months of study. In comparison, at over 40 camera sites in two states combined (Montana and Utah) there have been less than 12 successful black bear crossings tallied over the course of two years. This passage is very successful particularly for black bear, whereas only three bobcats approached and crossed through the structure, and 7 of 19 approaches by coyotes were repelled. Our camera technician on several occasions could smell the bear presence in the culverts when she came to check the cameras. This may explain the low diversity of species using it. It may also support the idea that in an area of high species diversity, multiple crossings may be necessary for prey, predator and even competitor species.

## **Location Name: Mosquito Creek**

**Location ID:** 101\_76.5\_01

**Route:** 101

**Milepost:** 76.5

### Roadway & Site Description

This segment of Route 101 is a two-lane road that runs north-south along the southwestern coast of Washington, traversing several drainages that feed into the coastal waters. The surrounding habitat is largely forested in nature.

### Structure Description

*Type:* Concrete box culvert

*Structure Functional Class:* Class 2 (medium underpass)

*Dimensions:* 7' high x 15'9" span x 138' long

Mosquito Creek is a small, seasonal creek. Water flow through the structure at the time of the survey was shallow. The stream channel is naturally entrenched upstream and downstream of the roadway with thick bushes and trees to the edges of the banks. While the concrete box culvert at this location is large enough to allow for a relatively natural water flow through the structure, the stream channel is not maintained through the structure and the flow instead flattens out across the width of culvert. During low flows, muddy/gravelly pathways are present through the structure, although these likely become obliterated during higher flow periods.

There is no fencing associated with either side of the structure. Guardrail is present above the structure for the span of the structure, but not along the rest of the roadway segment. There is no apparent human activity at this structure.

### Wildlife

Raccoon, muskrat and small rodent tracks were observed in the muddy banks inside the structure. Raccoon tracks were also observed outside of the structure.

### *Species Movement Guild Rankings*

This site was identified by WSDOT biologists as important for species in each of the Movement Guilds. This location received an 'A' rank for Low Mobility Small Fauna, Moderate Mobility Small Fauna, and Adaptive High Mobility Fauna, meaning that the field evaluators concluded that animals from each of these guilds could successfully pass through this structure as is or with small modifications. The structure received a 'C' rank for High Openness High Mobility Carnivores and Adaptive Ungulates, indicating that the structure could be modified to be made functional for species of these Movement Guilds. The structure received an 'F' rank for Very High Openness Fauna, meaning that the structure cannot be retrofitted to accommodate these species.

## **Recommendations**

Overall, the evaluators determined that the culvert, as is, is not quite high enough to be a highly functional passageway, although it can still be used by some individuals of the more reluctant species, such as black-tailed deer. The addition of wildlife fencing tied into the structure would enhance usage by High Openness High Mobility Carnivores, such as bear or mountain lion, and Adaptive Ungulates, such as black-tailed deer. Greater functionality for bucks as well as does and fawns, and for Very High Openness Fauna such as elk would require replacement with a larger structure. Maintaining built up dirt banks along one or both of the inside edges of the culvert can also help to provide dry pathways for smaller animals during higher water flows.

**Figure 1.** Rte 101 looking south

**Figure 2.** View from outlet

**Figure 3.** Muddy pathway through culvert

**Figure 4.** Looking towards outlet

## **Monitoring Results**

### **US 101 Mosquito Creek Culvert**

This concrete box culvert is under US 101 south of Aberdeen, Washington. At times of low flow, there is a muddy path to the side of the creek. There is no wildlife fencing at this site. The area is heavily vegetated and forested. WSDOT estimates for Average Daily Traffic approximates 5,000 vehicles. On June 9, 2010, two cameras were placed at the culvert entrances, both positioned facing inward.

In 138 days of monitoring, this culvert was most heavily used by black-tailed deer, specifically does and fawns. Of the 71 deer observations at the site, only two were of black-tailed deer bucks, the remainder was of does and fawns, probably the same family of three moving to either side of the road. One buck repelled from the structure, the second followed a doe and fawns through the structure, see photos below. Deer use peaked in June and early July, see Figure 5. Deer data is presented in Table 1.

**Table 1.** Black-tailed deer observation data tabulated for US 101 Mosquito Creek box culvert.

Camera Days Analyzed	Deer Photo-obs. at Site	Deer Photo-obs. per Day	Number of Successful Crossings through structure	Successful Deer crossings per day	Success Rate (%)	Rate of Repellency (%)	Parallel Rate (%)
138	71	0.51	60	0.43	84.5	5.6	9.9

**Figure 5.** Black-tailed deer passes through culvert per week at US 101 Mosquito Creek culvert over the weeks of monitoring in 2010.

One elk was photographed grazing at the entrance to the culvert. It did not enter the structure, (see photos below). The remaining species observed are presented in Table 2.

**Table 2.** Species and number of detections at the US 101 Mosquito Creek culvert.

**Species**

**Mammals**

- Black-tailed deer - 71
- Raccoon - 18 events, 36 individuals
- Cat - 18
- Humans - 2

Figure 11. The only elk photographed at US 101 Mosquito Creek culvert. It did not enter the culvert.

## **Location Name: Middle Fork Nemah River**

**Location ID:** 101\_38.8\_02

**Route:** 101

**Milepost:** 33.8

### Roadway & Site Description

This segment of Route 101 is a two-lane road north-south along the southwestern coast of Washington, traversing several drainages that feed into the coastal waters. Traffic levels at the time of the evaluation were low, but regular. A 10-minute traffic count resulted in an estimated daily average of 5,000 vehicles, which could inhibit some wildlife from attempting to cross at-grade. The surrounding habitat is largely forested in nature.

### Structure Description

*Type:* Wooden multi-span

*Structure Functional Class:* Class 3 (large underpass)

*Dimensions:* 8'5" high x 61'4" span x 29' long

This structure is a multi-span bridge underpass with wooden supports. The center span bridges the main portion of the stream while the two outside spans bridge the stream banks although water may pass through these sections during periods of high flows. The full height of the structure is realized only beneath the center span, whereas the outside chambers have higher stream banks/sediment, resulting in a significantly shorter functional height for animals passing through these sections. Water flow through the structure was approximately 3-10' deep at the time of the evaluation

There is no fencing associated with the structure. Guardrail is present above the structure for the span of the structure. There is no apparent human activity at this site.

### Wildlife

A roadside ditch along the east side of the road containing standing water and vegetation was found to have a Northwestern salamander egg mass, though no larvae remained in the eggs. A shrew was also observed at the inlet side of the structure.

### *Species Movement Guild Rankings*

This site was identified by WSDOT biologists as important for species in each of the Movement Guilds. This location received an 'A' rank for each of the target Species Movement Guilds, meaning that the field evaluators determined that animals from each of these guilds could successful pass through this structure as is or with small modifications.

### Other Considerations

The following considerations warrant additional follow-up:

- What is the land-ownership in this area? Are there any concerns with private lands development near the structure?

### **Recommendations**

Despite the 'A' rankings for all of the Species Movement Guilds, several retrofit recommendations are advised at this site:

- Remove the center supports to create a more open single-span structure (may not be possible without replacing the entire structure);
- Construct dry, natural dirt pathways on both sides of the stream that remain dry during seasonal high water;
- Minimize or cover riprap on side-slopes with dirt to create a dry, smooth pathway;
- Maintain the structure height for the full length of the span (so that the distance from the ground level to the ceiling of the structure is high enough to allow the passage by ungulate species and other larger mammals);
- Install wildlife fencing for larger mammals and salamander walls to guide animals towards the structure.

Figure 16. Stream bank under outside span

Figure 17. View from structure to east (inlet side)

## **Location Name: Bone River**

**Location ID:** 101\_45.3\_03

**Route:** 101

**Milepost:** 45.3

### Roadway & Site Description

This segment of Route 101 is a two-lane road north-south along the southwestern coast of Washington, traversing several drainages that feed into the coastal waters. The surrounding habitat is largely coastal marsh and forest.

### Structure Description

*Type:* Wooden bridge underpass

*Structure Functional Class:* Class 4 (extensive bridge)

*Dimensions:* 100' span x 25' long

This structure is an extensive wooden bridge traversing a tidal river. The river is broad and deep, as the roadway is parallel to Willapa Bay. The river is highly influenced by the tides. While the river is largely confined within its channel, at high tide the adjacent riverbanks are flooded, eliminating any dry pathways for wildlife through the structure. The north side of the structure is reinforced with concrete sand bags, eliminating the natural banks through the structure.

There is no fencing associated with the structure. Guardrail is present above the structure for the span of the structure. There are no immediate signs of human activity at this structure, although camera monitoring did capture some human activity.

### Wildlife

No wildlife signs were observed at the time of the evaluation, but most signs are likely obliterated during daily high tide events, and camera monitoring revealed a variety of wildlife activity at this location.

### *Species Movement Guild Rankings*

This site was identified by WSDOT biologists as important for species in each of the Movement Guilds. This location received an 'A' rank for Moderate Mobility Small Fauna, meaning that the field evaluators determined that animals from each of these guilds could successfully pass through this structure as is or with small modifications. The structure received a 'C' rank for all other species guilds, indicating that the structure could be modified to be made functional for species of these Movement Guilds. Given that this location is a tidal system, it was not evaluated for Low Mobility Small Fauna, such as frogs and salamanders.

### **Recommendations**

Given the tidal nature of this system, a structure at this location is not useable by wildlife during the daily high tides. The following recommendations can help make the structure more functional during low and high tides

- Expand the span to include more of the riverbanks, including a minimal dry or semi-dry pathway during high tides.
- Install wildlife fencing for larger mammals and salamander walls to guide animals towards the structure.

Figure 18. Inlet side, looking west.

Figure 19. Bank on south side of structure during low tide.

Figure 20. Roadway looking south

Figure 21. Structure looking southeast

Figure 22. Bank under structure on north side

## **Monitoring Results**

### **US 101 Bone River Bridge**

The highly tidal Bone River runs under this bridge. The river is wide, over 50 meters across. The northern end of the bridge has a dry land passage on the 2 to 1 slope under the bridge, while the southern end has a steeper, rip rap slope that is difficult to use for terrestrial passage. Cameras from both ends of the bridge documented high tides that could make terrestrial passage difficult. Average Daily Traffic approximates 2,700 vehicles. There is no wildlife fencing at this site. The area is heavily vegetated and forested, with the west side gradating to tidal marsh. On April 13, 2010, two cameras were placed at this high arch bridge, along US 101, south of South Bend, Washington. The cameras were positioned on dry ground pointed toward the underside of each end of the bridge.

In 197 days of monitoring, the bridged area was rarely used by deer. There were 16 deer observations at the north end of the bridge for an average of 0.08 deer observations per day. All deer photographed were black-tailed deer does and fawns. All deer were photographed between May 12 and July 30, 2010. In six of the 11 events when deer were photographed, the deer could be seen moving under the bridge, solely on the north end of the structure. This amounts to 10 deer out of 16 using the structure, for a success rate of 62.5%. The rest of the movements were parallel. Eight deer events were during the day, 2 occurred at night, and one at dawn.

No other ungulates were photographed. Human use was fairly high at this structure, with 37 events where people came by to prepare the area for construction, apply pesticides, collect plants, fish, hike, clam, and ride in boats up and down the river. One pair of travelers spent the night camping in front of the south camera. Meso-mammals were fairly common at this site, with more raccoon and coyote observations occurring in front of these cameras than any other sites in the study.

**Table 3.** Species detected at the US 101 Bone River bridge culvert and the number of observations for that species.

#### ***Species***

##### **Mammals**

Black-tailed deer - 16

Humans - 37

Raccoon 54 events - 68 individuals

Coyote - 14 events, 15 individuals

River Otter - 1

Rabbit - 1

Seasonal use of the area by all species was tallied. Wildlife detection rates were fairly constant per month over time (Table 4).

**Table 4.** Monthly tallies for number of wildlife events recorded by cameras at Bone Creek Bridge, US 101.

Month	Number of wildlife events recorded	Month	Number of wildlife events recorded
April	17	August	5
May	11	September	13
June	11	October	11 (all raccoon events)
July	12	-	-

## **Location Name: Willapa River**

**Location ID:** 6\_6.8\_04

**Route:** 6

**Milepost:** 6.8

### Roadway & Site Description

This segment of State Highway 6 is an east-west running, undivided two-lane road. A bike path runs parallel to the roadway along the north side along an old railroad grade. The structure spans the Willapa River as it is bisected by the highway. The surrounding landscape is largely agricultural with some residences.

### Structure Description

*Type:* Concrete span bridge

*Structure Functional Class:* Class 4 (extensive bridge)

*Dimensions:* 25' high x 100' span x 28' long

This structure is large multi-span bridge spanning the river and adjacent river banks. The height of the structure over the grassy river banks is approximately 15', leaving sufficient room for even large animals to pass beneath the structure.

There is no fencing associated with the structure. Guardrail is present above the structure for the length of the structure. There were no evident signs of human activity at this structure, however camera monitoring at this location captured dozens of human events throughout the monitoring period.

### Wildlife

A wildlife trail crosses under the structure and deer tracks were observed at the time of the evaluation.

### *Species Movement Guild Rankings*

This site was identified by WSDOT biologists as important for species in each of the Movement Guilds. This location received an 'A' rank for each of the target Species Movement Guilds, meaning that the field evaluators determined that animals from each of these guilds could successfully pass through this structure as is or with small modifications.

### **Recommendations**

Wildlife appeared to be using the structure, a conclusion that was verified through the camera monitoring (see monitoring results below). Wildlife fencing could be constructed to guide animals to the structure; however, it is uncertain whether such a measure is necessary. We recommend first assessing animal-vehicle collision rates at this location and communicating with adjacent landowners to determine whether animals are crossing at-grade along this segment of roadway.

Figure 32. Looking upstream

Figure 33. Primary section of span where river flows

## Monitoring Results

### SR 6 Willapa River Bridge

This bridge straddles the Willapa River several miles southeast of Raymond, Washington. The road is high above the river and surrounding upland, allowing for ample terrestrial movement on both banks under the bridge. Grass is the dominant vegetation at this bridge. Homes are within 50 meters at both the east and west sides of the road and north and south of the river, but there are also agricultural fields that are adjacent to the bridge on other corners. There is no wildlife exclusion fencing at this site. WSDOT estimates of Average Daily Traffic volume varies from 1,700 to 2,700 vehicles.

On April 14, 2010, two cameras were placed at each base of the bridge, on each side of the river. In 196 days of monitoring, the north camera was in operation 173 days and the south camera 148 days. From June 24 through July 14 no cameras were in operation. There were a total of 82 deer observations. The average deer observations per day was 0.42. Of the total deer, there were seven males, 56 females, and 19 young. Due to the dense grass vegetation and camera placement, actual repels and parallels could not be calculated. The 82 deer observations occurred in 51 events. The majority of these events (36) occurred on the north (west) end of the bridge. The majority of the events (36, 70.6%) occurred during the day. Deer use peaked in late June and early July, but otherwise was consistent throughout the study period. See Figure 34 below.

Figure 34. Black-tailed deer observations per week at SR 6 Willapa River Bridge over the weeks of monitoring in 2010.

Other species of wildlife were present at this bridge. This was the crossing for opossum, with 90 observations of this species, many of which were of different sizes, indicating more than just one or two animals. A single cat was responsible for the 73 cat events. It would sit in front of the camera, apparently watching for wildlife. One night an opossum did come and run directly in front of the cat, see picture below. Human use was persistent, with 43 events of people coming to the area to swim, bring tubes to float the river, fish, hike, walk dogs, and canoe. The majority of human events occurred at the north (west) end of the structure.

**Table 5.** Species observations at the SR 6 Willapa River Bridge.

 Humans (only) - 41  
 Humans with dogs - 2

Birds

Robins - 1 event, 2 individuals

Wildlife events were fairly consistent across the months. After removing all events involving humans, dogs and cats, the pure wildlife events (including deer) were tallied for each month (Table 6). June was the month with the greatest wildlife activity.

**Table 6.** Monthly tallies for number of wildlife events recorded by cameras at Willapa River Bridge, SR 6.

Month	Number of wildlife events recorded	Month	Number of wildlife events recorded
April	18	August	26
May	15	September	25
June	41	October	7
July	21		

**Figure 35.** Black-tailed deer doe entering area under north side of bridge.

**Figure 36.** Two black-tailed deer does using area under south side of bridge.

**Figure 37.** Opossum using area under north side of bridge. Vegetation near opossum is attached to its tail.

**Figure 38.** Black-tailed deer doe and fawn in area where grass has been cut, north end of SR 6 Willapa River Bridge.

**Figure 39.** Black-tailed deer entering south end of bridge. Note long grass.

**Figure 40.** Cat and opossum under north side of bridge. Cat and opossum ran away in opposite directions.

## **Location Name: Rock Creek**

**Location ID:** 6\_26\_05

**Route:** 6

**Milepost:** 26

### Roadway & Site Description

This segment of State Highway 6 is an east-west running, undivided two-lane road. A bike path runs parallel to the roadway along the north side along an old railroad grade. Rock Creek runs through the structure, which is surrounded by forest cover to both the north and south.

### Structure Description

*Type:* Concrete span bridge

*Structure Functional Class:* Class 3 (large underpass)

*Dimensions:* 16'7" high x 106' span x 24' long

This structure is an old multi-span bridge underpass (plaque indicated it was constructed in 1924) with concrete support posts, which provide a more open feel through the structure. The center span bridges the main portion of Rock Creek – which was approximately 3-10' deep at the time of the assessment – while the two outside spans bridge riprap side slopes. The riprap is mostly larger sized (i.e., larger than a volleyball), although on the east side of the creek there is a narrow dry pathway composed of smaller riprap and dirt.

There is no fencing associated with the structure on the inlet (south) side. Limited 4-strand barbed wire fencing extends to the west for approximately 100' on the north side of the structure. This fencing is in poor condition with multiple holes and areas where the vegetation is pulling down the fence. Guardrail is present above the structure for the length of the structure. There is little evidence of human activity at this structure, although a few footprints were observed.

### Wildlife

Deer, raccoon, and small rodent tracks were observed by the structure, and ermine scat was found beneath the structure.

### *Species Movement Guild Rankings*

This site was identified by WSDOT biologists as important for species in each of the Movement Guilds. This location received 'C' ranks for Low Mobility Small Fauna, Adaptive Ungulates, and Very High Openness Fauna, meaning that structure could be retrofitted to better accommodate species of these guilds. All other species guilds received an 'A' rank. In general, the field evaluators determined that the structure is large and open enough to accommodate each of the target Species Guilds, but the riprap decreases the functionality of the structure for several Species Guilds.

## **Recommendations**

Following are the recommended retrofits at this site:

- Alter or cover riprap on side slopes to provide a dirt pathway through the riprap on either side of the creek; Maintain natural stream banks to the extent possible.
- Maintain native vegetation growth at the structure entrances and avoid the use of herbicides in these areas.
- Install wildlife fencing for larger mammals and small mammals to guide animals towards the structure.

**Figure 41.** Highway 6 looking east

**Figure 42.** Highway 6 looking west

**Figure 43.** Bridge and riprap side slopes

**Figure 44.** Main span

Figure 45. Bridge and adjacent forest

Figure 46. 4-strand barbed wire fencing on northwest side of structure

## **Location Name: Unnamed Tributary, Tilton River**

**Location ID:** 508\_24\_06

**Route:** 508

**Milepost:** 24

### Roadway & Site Description

Highway 508 is an east-west running two-lane highway through in southwestern Washington. This segment of the road crosses through forested, mountainous terrain.

### Structure Description

*Type:* Wooden bridge

*Structure Functional Class:* Class 2 (medium underpass)

*Dimensions:* 3'6" high x 24' span x 20' long

This structure is a small bridge underpass with straight, wooden abutments that spans a small stream, less than 3' deep at the time of the assessment. The structure spans only the stream itself and does not include any dry bank area beneath the bridge

There is no fencing associated with the structure. Guardrail is present above the structure for the length of the structure. There is no apparent human activity at this structure.

### Wildlife

No wildlife signs were observed at this structure.

### *Species Movement Guild Rankings*

This site was identified by WSDOT biologists as important for species in each of the Movement Guilds. Because of the lack of a dry terrestrial pathway through the structure, this location received 'C' ranks for Low Mobility Small Fauna, Moderate Mobility Small Fauna and Adaptive High Mobility Fauna. The structure received 'F' ranks for High Openness High Mobility Carnivore, Adaptive Ungulates, and Very High Openness Fauna because it is too small to accommodate species in these Movement Guilds, and cannot be retrofit to accommodate them. A new structure would be required at this location to provide a safe passage for members of these Guilds.

### Recommendations

Following are the recommended retrofits at this site:

- Improve for small mammals by providing a dry pathway on one side of the stream either by constructing an artificial bank through the structure using small-diameter riprap and dirt, or by installing a small mammal shelf through the structure.

Following are the recommendations for replacing the structure to accommodate larger wildlife, such as deer, coyote and elk:

- Elevate the roadway to accommodate a higher structure;
- Construct a wider structure that spans the banks on either side of the stream to provide a dry pathway. Or create a double structure that accommodates the stream on one side, and the terrestrial passage an overflow in the other.
- Install wildlife fencing for larger mammals and small mammals to guide animals towards the structure.

Figure 47. Route 508 looking west

Figure 48. Outlet side

Figure 49. Looking downstream from outlet

Figure 50. Inlet side

## **Location Name: Cowlitz River**

**Location ID:** 12\_112.8\_07

**Route:** 12

**Milepost:** 122.8

### Roadway & Site Description

This segment of State Highway 12 is an east-west running, undivided two-lane road. A small county road intersects the highway immediately to the west of the structure. The surrounding landscape is largely agricultural, with a narrow strip of riparian forest lining the river. A wide clear zone adjacent to the road pavement is maintained on both sides of the road.

### Structure Description

*Type:* Steel and concrete span bridge

*Structure Functional Class:* Class 4 (extensive bridge)

*Dimensions:* 22' high x 200' span x 33' long

This structure is an extensive bridge spanning a broad river and adjacent banks, with multiple rows of concrete support posts along the length of the span. The bridge spans across the natural high bank slopes, such that there is a wide terrestrial area beneath the structure, even during periods of high flows. However, there is little vegetation cover beneath the structure itself. A dirt road extends from the highway to the structure entrance on the northwest side, for people to directly access the river.

There is no wildlife fencing associated with the structure, although the adjacent agricultural fields are fenced. There is a limited segment of guardrail associated with the structure. Human activity is apparent at the structure, and both human and dog tracks were observed.

### Wildlife

Deer tracks were observed under the structure, and both deer and elk tracks were observed in the vicinity of the structure. Elk tracks were also found along the roadside. A game trail was found leading from the riparian zone along the fenced-off agricultural fields on the southwest side up to the guardrail.

### *Species Movement Guild Rankings*

This site was identified by WSDOT biologists as important for species in each of the Movement Guilds. This location received an 'A' rank for each of the target Species Movement Guilds, meaning that the field evaluators determined that animals from each of these guilds could successfully pass through this structure as is or with small modifications.

## **Recommendations**

Following are the recommended retrofits at this site:

- Install wildlife fencing for larger mammals and small mammals to guide animals towards the structure.
- Minimize human activity at the structure; provide river access further up- or downstream from the structure itself.

Figure 51. Inlet side

Figure 52. Terrestrial area beneath bridge

Figure 53. Outlet side

Figure 54. Looking towards inlet

Figure 55. Game trail from riparian Zone and fenced fields to guardrail

Figure 56. Roadway

## **Location Name: Indian Creek**

**Location ID:** 12\_159\_08

**Route:** 12

**Milepost:** 159

### Roadway & Site Description

This segment of State Highway 12 is an east-west running, undivided two-lane road. The surrounding landscape is forested and in National Forest ownership. A horse ranch operates on the north side of the highway.

### Structure Description

*Type:* Steel and concrete span bridge

*Structure Functional Class:* Class 4 (extensive bridge)

*Dimensions:* 8' high\* x 150' span x 32' long

\**Note:* this is the functional height of the terrestrial pathway under the bridge, not the height from the river to the bridge.

This structure is an extensive bridge spanning a mountainous river drainage. The bridge spans the river as well as the adjacent high banks. It is supported by concrete pillars on both sides of the river and riprap reinforcement at the abutments. A defined dirt pathway is evident crossing through the structure, and appears to be used by horseback riders and wildlife alike. There is no vegetation cover beneath the structure itself.

There is no wildlife fencing associated with the structure, although the adjacent agricultural fields are fenced. Guardrail is present above the structure for the length of the structure. Human activity at the structure appears limited to occasional use by horseback riders. An interview with the horse ranch operators could confirm the level of human use.

### Wildlife

A game trail passes through the structure and a number of both deer and elk tracks were observed under the structure and in the adjacent habitat, as well as leading up to the roadsides. Small rodent scat was also found in the structure. Heavy elk droppings were observed in areas leading to the structure.

### *Species Movement Guild Rankings*

This site was identified by WSDOT biologists as important for species in each of the Movement Guilds. This location received 'A' ranks for Moderate Mobility Small Fauna, Adaptive High Mobility Fauna, and High Openness High Mobility Carnivores. The structure received 'C' ranks for Adaptive Ungulates and Very High Openness Fauna because the lack of a dry pathway on the west side of the river makes it impassable for species in these groups through that portion of the structure. The structure received a 'F' for Low Mobility Small Fauna because of the lack of natural riparian stream banks through the structure.

## **Recommendations**

Following are the recommended retrofits at this site:

- Construct natural substrate pathways along the water's edge for riparian species moving along that edge.
- Install wildlife fencing for larger mammals and small mammals to guide animals towards the structure and prevent at-grade crossings.
- Minimize human/horse activity at the structure; ensure appropriate access and controls for the horse ranch to ensure that if new wildlife fencing is installed it will not be in conflict with their needs.
- Maintain vegetation cover at structure entrances.

Figure 57. Roadway looking east

Figure 58. Inlet side

Figure 59. Steep bank on west side

Figure 60. Dry pathway on east side

Figure 61. View towards inlet

## **Location Name: McPherson Creek**

**Location ID:** 823\_13.8\_09

**Route:** 821

**Milepost:** 13.8

### Roadway & Site Description

State Highway 823 is a north-south running, undivided two-lane highway. The surrounding landscape is sagebrush. There is no development along this segment of roadway. Average daily traffic is predicted to be less than 2,000 vehicles.

### Structure Description

*Type:* Concrete box culvert

*Structure Functional Class:* Class 2 (medium underpass)

*Dimensions:* 6' high x 5' span x 165' long

This structure is a box culvert at the base of an approximately 15-foot high fill slope. The structure is positioned at an angle to the roadway, and appears as a long, narrow tunnel. The culvert floor is concrete. The drainage on the inlet side is wide and open, whereas on the outlet side it is narrow and steep. Woody debris and tumbleweeds have built up at the structure outlet, partially blocking the entrance. It appears the culvert is placed for an occasional flash flood.

Four-foot high barbed wire fencing is present on the inlet (east) side of the structure. The fence does run across the top of the fill slope and extends approximately 100 feet in either direction. There is no wildlife fencing associated with the outlet (west) side of the structure. There is no evidence of human activity at this location.

### Wildlife

Deer tracks were observed in the drainage on the inlet (east) side of the structure. The tracks do not approach the structure, but instead lead up the side of the fill slope, suggesting that they are crossing at-grade.

### *Species Movement Guild Rankings*

This site was identified by WSDOT biologists as important for species in each of the Movement Guilds. This location received an 'A' rank for Moderate Mobility Small Fauna and a 'C' rank for Adaptive High Mobility Fauna. The structure received 'F' ranks for Low Mobility Small Fauna, High Openness High Mobility Carnivores, Adaptive Ungulates and Very High Openness Fauna, meaning that it cannot be retrofit to accommodate species in these Movement Guilds.

### Recommendations

The existing structure is insufficient for most Species Movement Guilds and would have to be replaced with a larger box culvert, arch or bridge structure to provide a suitable passage for animals in these groups. Barring replacement, the structure could be made more functional for Moderate Mobility Small Fauna and Adaptive High Mobility Fauna by the following measures:

- Clear debris from the outlet and maintain on a regular basis.
- Add baffles to the culver floor to retain a dirt floor through the length of the structure.

Figure 62. Box culvert at base of fill slope

Figure 63. Long, narrow tunnel effect

Figure 66. Roadway looking north

## **Location Name: Teanaway River Bridge**

**Location ID:** 970\_6.3\_10

**Route:** 970

**Milepost:** 6.3

### Roadway & Site Description

SR 970 is an east-west running, undivided two-lane highway. The surrounding landscape is a mix of agricultural fields and forest, with riparian habitat maintained along the river corridor.

### Structure Description

*Type:* Concrete bridge

*Structure Functional Class:* Class 4 (extensive bridge)

*Dimensions:* 17' high x 300' span x 43' long

This structure is a concrete bridge spanning a large river. The bridge has vertical support walls at intervals along its span. At either end of the structure the walls are further reinforced with riprap slopes. The riprap slopes occupy much of the terrestrial area beneath the bridge, particularly on the east side, where the riprap extends for approximately 50 feet beyond the structure. The riprap is less continuous on the west side, although there is no defined terrestrial pathway through the structure.

Four-foot high four-strand barbed wire fencing is present on both sides of the structure, extending for approximately 1 mile in either direction. There is also extensive guardrail present on both sides of the roadway. No signs of human activity were observed at this location.

### Wildlife

Despite the lack of a well-defined pathway, deer tracks were observed crossing through the structure on the west side of the river along the flattest, least rocky section of the support slope.

### *Species Movement Guild Rankings*

This site was identified by WSDOT biologists as important for species in each of the Movement Guilds. This location received an 'A' rank for Moderate Mobility Small Fauna, Adaptive High Mobility Fauna and High Openness High Mobility Carnivores, meaning that the field evaluators concluded that animals from each of these guilds could successfully pass through this structure as is or with small modifications. The structure received a 'C' rank for Adaptive Ungulates and Very High Openness Fauna, indicating that the structure could be modified to be made functional for species of these Movement Guilds. The structure received a 'C' rank for Low Mobility Small Fauna, meaning the area under the bridge can be retrofitted to accommodate these species.

## **Recommendations**

The following measures are recommended to improve the functionality of this structure.

- Create dirt pathways through the riprap on both sides of the river.
- Revegetate the stream banks through the structure to accommodate Low Mobility Small Fauna and other riparian-dependent wildlife.
- Replace the barbed-wire fencing with 8'-foot high wildlife fencing to guide animals towards the structure and discourage at-grade crossings.

Figure 67. Roadway

Figure 68. Support wall

Figure 69. Side slope on west side of river

Figure 70. Bridge view from outlet

Figure 71. Riprap on east side of river outlet

Figure 72. View of drainage from outlet

**Location Name: Swauk Creek**

**Location ID:** 970\_159.7\_11

**Route:** 97

**Milepost:** 159.7

Roadway & Site Description

State Highway 970 is an east-west running, undivided two-lane highway. A 10-minute traffic count resulted in an estimated daily average of 8,000 vehicles, which could inhibit some wildlife from attempting to cross at-grade. This segment of roadway is located in a completely forested landscape.

Structure Description

*Type:* flat-bottomed metal pipe

*Structure Functional Class:* Class 2 (medium underpass)

*Dimensions:* 6' high x 9' span x 100' long

This structure is a flat-bottomed metal pipe with perennial stream flow situated in a low fill slope. The outlet is perched more than 0.5' feet above the channel and drops into a pool.

There is no fencing associated with the structure. Guardrail extends for approximately 200' in either direction on both sides of the roadway. No signs of human activity were observed at this location.

Wildlife

Deer tracks were observed in the drainage and appear to cross up and over the highway.

*Species Movement Guild Rankings*

This site was identified by WSDOT biologists as important for species in each of the Movement Guilds. This structure received a 'F' rank for all species movement guilds and cannot be retrofitted to accommodate terrestrial wildlife.

**Recommendations**

This structure must be replaced with a new structure to accommodate terrestrial wildlife passage for most Species Guilds at this location. A raised shelf could be placed along the length of the inside of the pipe and, with some effort, connected to the landscape at either end of the pipe to facilitate passage for smaller animals.

Figure 73. Riparian forest and culvert meadow at outlet

Figure 74. Flat-bottomed pipe

Figure 75. Roadway and adjacent forest

Figure 76. Inlet

## **Location Name: Mill Creek**

**Location ID:** 2\_70.2\_12

**Route:** 2

**Milepost:** 70.2

### Roadway & Site Description

This segment of the east-west running state Highway 2 is a divided four-lane highway through the forested Cascade Mountains.

### Structure Description

*Type:* Arch culvert

*Structure Functional Class:* Class 3 (large underpass)

*Dimensions:* 12' high x 36' span x 140' long\*

*\*Note both the north and south structures have approximately the same dimensions, although the south structure was not directly measured because of the lack of access due to the steep riprap slopes.*

There are two structures at this location; one under the eastbound lanes and another under the west bound lanes. Both structures are large arch culverts with perennial water flow through the structure. The structures are separated by wide (~200') vegetated median. The stream comes in from the south, where it is bisected by the highway, and meanders through the heavily-vegetated median, such that the north structure is offset from the southern one by about 1/10-mile. The north structure is situated in a low fill slope while the south structure is situated at the base of a somewhat higher and significantly longer fill slope.

Extensive riprap is associated with both structures as well as the stream banks through the median. At the north structure, riprap lines the stream banks (~30' wide) and adjacent fill slopes on both the outlet and median (inlet) sides of the structure. At the south structure, the extensive fill slope is reinforced with rip rap along its entire length.

Boulders have been placed inside of the structures to simulate a more natural flow. The culvert is completely occupied by the stream and, while the stream is not deep (less than 3' at the time of the evaluation), it is unlikely that even larger mammals would cross through these culverts.

There is no fencing associated with the structure. Guardrail extends throughout this segment on both sides of the roadway above both the north and south structures. While human use does not appear to occur regularly at this location, graffiti was found on the northern structure.

### Wildlife

Deer and elk tracks were observed in the vicinity of the north structure on both the outlet and median sides. In one place, deer tracks were found crossing through the narrowest portion of the riprap to ascend the fill slope. Road kill was also found at

this location, most likely a squirrel or rabbit. Tracks were found along the roadway at both the north and south structures. Possible bighorn sheep tracks were observed along the road at this site.

### *Species Movement Guild Rankings*

This site was identified by WSDOT biologists as important for species in each of the Movement Guilds. This structure received a 'F' rank for all species movement guilds and cannot be retrofit to accommodate terrestrial wildlife. Notably, the structure has received awards for its ability to accommodate fish passage, highlighting the need to consider terrestrial as well as aquatic passage when designing and constructing structures.

### **Recommendations**

While the structure must be replaced with a new structure to accommodate terrestrial wildlife passage, several improvements could be made to make the location more wildlife-friendly. These include:

- Minimize riprap on the slopes adjacent to the structure and/or provide 'escape pathways' for ungulates that are trapped on the roadway side of the riprap.
- Remove the slope netting, which may ensnare snakes and small animals.

Figure 83. From eastbound lanes looking across median towards north structure

## **Location Name: Cle Elum River Bridge (aka Bullfrog)**

**Location ID:** 90\_79\_13

**Route:** I-90

**Milepost:** 79

### Roadway & Site Description

This segment of Interstate 90 is an east-west running, 4-lane divide highway (2 lanes in each direction). The surrounding landscape is largely forested.

### Structure Description

*Type:* Concrete and Steel Bridges

*Structure Functional Class:* Class 4 (extensive bridge)

*Dimensions:* 12' high x 150' span x 30' long\*

*\*Note both the north and south structures have approximately the same dimensions.*

There are two structures at this location; one under the eastbound lanes and another under the west bound lanes. Both structures are large concrete and steel bridges with concrete support walls. The Cle Elum River flows through the structure. The structures are parallel to one another and separated by 60'-wide vegetated median. There is minimal vegetation (some grasses) beneath the structures themselves.

The river occupies much of the span under the bridges, however there is a 50 feet wide dirt river bank on the west side of the river. On the east side, there is little terrestrial area – the concrete support wall is close to the waters edge and further supported by riprap. Visibility through both structures is very high.

There is no fencing associated with the structure. There appears to be occasional human activity at this location. The purpose of such visits is unclear, but may be recreational (e.g., river access).

### Wildlife

Numerous deer tracks and scat were found under the structures on the west side of the river.

### *Species Movement Guild Rankings*

This site was identified by WSDOT biologists as important for species in each of the Movement Guilds. This structure received an 'A' rank for all species movement guilds, indicating that animals from each of the Movement Guilds could successfully pass through this structure as is, although passage could be further enhanced with some modifications.

## **Recommendations**

Currently, the structure is highly functional for wildlife passage on the west side of the river, but remains largely non-functional on the east side. A pathway through the riprap would improve passage opportunities on the east side.

**Figure 84.** View from beneath south structure

**Figure 85.** WSDOT staff and researcher in front of bridge

**Figure 86.** Riprap banks on east side of river

**Figure 87.** Dirt, rocky area on west side of river

**Figure 88.** East side median

## Monitoring Results

### I-90 Cle Elum River Bridge (Bullfrog Bridge)

This bridged structure is actually two bridges, each one accommodating opposing lanes of traffic. The median is naturally vegetated. The Cle Elum River runs through the site. There is no wildlife exclusion fencing present. WSDOT records indicate Average Daily Traffic is 26,547 vehicles, but a 15-minute count on a Friday afternoon in spring estimated 65,000 vehicles. There are natural forested areas on both sides of the west end of the bridge, west side of the river. The area to the east end of the bridge was not monitored, as there is little terrestrial passage opportunity. The area to the east is agricultural and cleared.

Two cameras were placed under the bridge on the west side of the river. One was placed along the south side of the bridge along the west side of the river, and a north camera was placed at the north bridge abutment. Both cameras faced inward toward the area under the paired bridges. Cameras were in operation from April 14 through October 21, totaling 189 days of camera coverage. The south camera was off 27 days in July and August. The north camera was on continuously. Mule deer results are below. There were 172 individual observations of deer at the site. These do not represent as many deer, but often in later summer and fall, these were repeat visits to the site by does and fawns. There were no obvious repels or parallel movements, see Table 7. The deer gender and ages of the animals photographed included: 95 does, 66 young, 6 bucks, 5 unknown. Males comprised 3.48% of passes recorded.

**Table 7.** Mule deer data tabulated for I-90 Cle Elum Bridge.

Camera Days Analyzed	Number of Deer Obs. at Site	Number of Deer Obs. per Day	Number of Successful Crossings through structure	Number of Deer crossing per day	Success Rate (%)	Rate of Repellency (%)	Parallel Rate (%)
189	172	0.91	172	0.91	100	0	0

Deer presence at the bridge was continuous through this phase of the study see Figure 89. In the 109 deer events recorded, 50(45.87%) occurred during daylight, and the remaining occurred at night or dawn or dusk.

Eight elk were photographed under the bridge in April in May. These consisted of four cows, two calves, one male, and one unknown. There was a multitude of other species of wildlife photographed at the bridge. Table 8 presents the animal species and the number of events with those animals. Human presence of the area was fairly regular, with 17 events. This is the site where a car crashed in the Cle Elum River directly in front of the South camera. Other human uses of the area include

swimming, hiking, fishing, and WSDOT maintenance ranging from trash pickup to cranes coming under the bridge for upkeep.

Figure 89. Mule deer passes per week at I-90 Cle Elum Bridge over the weeks of monitoring in 2010.

## **Location Name: Tucker Creek MP 73 Double Box Culvert**

**Location ID:** 90\_73\_14

**Route:** I-90

**Milepost:** 73

### Roadway & Site Description

This segment of Interstate 90 is an east-west running, 4-lane divide highway (2 lanes in each direction). The surrounding landscape is semi-natural, forested with nearby residential development.

### Structure Description

*Type:* Concrete Box Culvert Underpass

*Structure Functional Class:* Class 2 (medium underpass)

*Dimensions:* 4'10" high x 9' span\* x 58'3" long

The structure is composed of two separate two-chambered concrete box culverts. There is a grassy, wet median (approximately 35' wide) separating the two structures. A small stream flows through the structures. The stream flow flattens out as it passes through the structure. There was no dry pathway all the way through the structure, although the water level was low and slow-moving at the time of the evaluation. The stream likely dries up partially by mid-summer, leaving more dry passage in both chambers. Similarly, dry pathways will likely be completely obliterated during high water events. The substrate through the structure is muddy and without rocks or gravel. A railroad runs parallel to the interstate on the south side of the structure, where the stream is channeled through an additional box culvert.

The surrounding habitat on both the north and south sides of the structure is largely forested. There are no obstructions or debris at any of the culvert entrances. Visibility through the structure is clear, but little light enters into the structure and there is a high light contrast compared to the daylight outside of the structure.

Barbed-wire right-of way fencing is present on both the north and south sides of the structure for the entire roadway segment. In addition, there is a guardrail immediately above the structure itself. There is no evidence of human activity at this location.

### Wildlife

Deer tracks were observed at both the north and south side entrances; any possible tracks inside the structure or in the median would be obscured by the water flow. A live deer was also observed approaching near the north-side entrance. Raccoon tracks were inside the west chamber of the south structure. Very high traffic volumes on the interstate (25,000 to 65,000 average vehicles per day) acting as a barrier are likely to incentivize deer and other animals to use these structures to the extent possible, despite the limitations. Raccoon tracks were inside the west chamber of the south structure.

### *Species Movement Guild Rankings*

This site was identified by WSDOT biologists as important for species in each of the Movement Guilds. This location received an 'A' rank for Moderate Mobility Small Fauna and Adaptive High Mobility Fauna, meaning that the field evaluators concluded that animals from each of these guilds could successfully pass through this structure as is or with small modifications. The structure received a 'C' rank for High Openness High Mobility Carnivores, indicating that the structure could be modified to be made functional for species of these Movement Guilds.

This structure received an 'F' rank for Adaptive Ungulates and Very High Openness Fauna – this ranking may seem contrary to the evidence of deer usage of the structure, however, the structure is only minimally functional for these animals as a result of the high traffic volumes, which leave no other option for accessing habitat bisected by the interstate. Use of the current structure by these species is likely limited to resident animals that have adapted to the only available passageway. To truly provide functional connectivity at this location for species in these Movement Guilds, a new, larger structure is needed.

The structure also received an 'F' rank for Low Mobility Small Fauna. The structure may be functional for some species in this group during certain times of the year (e.g., hydrophilic frogs during the wet season), but due to the ephemeral nature of the stream flow and the lack of riparian banks through the structure, there is no consistently reliable habitat through the structure year-round.

### **Recommendations**

The existing structure is insufficient for Adaptive Ungulates and Very High Openness Fauna and would have to be replaced with either a larger single-chamber box culvert, a large double box culvert, one side for stream flow, the other for overflow and more terrestrial passage, or an arch or bridge structure to provide a suitable passage for animals in these groups. The roadway could be gradually raised from both sides to accommodate the greater height of a new structure.

Barring replacement, the structure could be marginally improved by the following retrofits:

- Install a shelf through the culverts or buildup sediment on one side of the structure to provide a consistent dry pathway all the way through the structure during all seasons.
- Plant bushes in the median to provide better cover and insulation from highway traffic noise and lights.

## **Monitoring Summary**

### **I-90 Mile Post 73 Double Box Culvert**

There is a small stream through these double box culverts. There is an open median area. There is forested vegetation away from the right away, with grassy areas extending from the highway to the forest. There is no wildlife fencing to “guide” animals to the culvert. WSDOT estimates Average Daily Traffic is approximately 26,000 vehicles, but field estimates have put the value closer to 65,000 vehicles. Two cameras were placed at this double box culvert, each facing into the entrance of the culvert on each side of the highway.

Cameras were in operation from June 23 through October 21, totaling 120 days of coverage. There were 226 mule deer observations at the culvert, meaning these are the number of individual deer that were photographed. Although the total numbers include 143 females, 28 males, and 55 young, these pictures were often the same animals. It is estimated from viewing the photos that there were approximately six to seven bucks, and approximately six does and fawns. Of the 28 buck photos at the entrance, nine of the animals (32.14%) were repelled. Males comprised 9.70% of the successful passes recorded. For further numbers please see table below. The number of deer at the site peaked from the last week of June through the last week of July, see figure below. This number correlates with the period of time when the fawns of the year begin to follow the does through the culvert, which began July third. This period of time is also when 60% of the bucks appeared at the entrance to the culvert. Table 9 presents the success and repellency rates for deer at this site.

**Table 9.** Mule deer observation data tabulated for I-90 MP 73 double box culvert.

Camera Days Analyzed	Number of Deer Obs. at Site	Number of Deer Obs. per Day	Number of Successful Crossings through structure	Successful Deer Crossings per day	Success Rate (%)	Rate of Repellency (%)	Parallel Rate (%)
120	226	1.89	196	1.63	86	11	3

In the 156 deer events recorded, 75(48.08%) occurred during daylight, 69 (44.23%) occurred at night, and 12 (7.70%) occurred at dawn or dusk. No other ungulates were photographed at the culvert site.

There were several other species of wildlife photographed at the culvert. Below, Table 10 presents the animal species and the number of events with those animals. Human presence of the area was fairly regular. There were 22 events where humans came through the culvert, in all but two cases they were riding motorcycles and atvs.

Figure 101. Mule deer passes per week at I-90 MP 73 box culverts over the weeks of monitoring in 2010.

## **Location Name: MP 33 Large Span Bridge**

**Location ID:** 90\_34\_15

**Route:** I-90

**Milepost:** 33.2

### Roadway & Site Description

This segment of Interstate 90 is an east-west running, 4-lane divide highway (2 lanes in each direction). The surrounding landscape is semi-natural, forested with nearby residential development.

### Structure Description

*Type:* Concrete Bridge Underpass

*Structure Functional Class:* Class 3 (large underpass)

*Dimensions:* 30' high x 58'7" span\* x 80' long

*\*Span measured as functional distance between support walls.*

This location has two structures – one under the eastbound lanes and another under the westbound lanes. Both structures are large span bridges with concrete support walls and sloping dirt side slopes (2:1 slope). A 2-lane road runs parallel to the interstate on the north side of the structure.

A wide dirt/gravel recreational trail runs through the center of the structure. There is some grassy cover through the structures on either side of the trail. Grass/shrub leading into forest cover is present at both entrances on either side of the trail. The trail receives regular use by walkers, joggers, cyclists and, presumably, dogs. Nearby neighborhoods are present on both the north and south sides of the interstates, and the evaluators also found evidence of night-time use and partying at the site.

A 145' vegetated median separates the two structures and provides partial bush/tree cover along both sides of the recreational trail. Barbed wire fencing connects the two structures through the median, however large gaps in the fencing do not provide a continuous barrier to wildlife access to the median.

Six to eight foot high chain link fencing extends along the interstate in both directions from the structure, though it contains many gaps along its length. The fencing on the southeast side of the structure is 4'-high barbed wire rather than the taller chain link. A large gap in the fence has evidence of elk passage with an ungulate trail with elk scat leading through this gap and providing access into the highway right-of-way. Guardrail is present immediately above the structure itself.

### Wildlife

Elk scat was observed on an ungulate trail that crosses through a gap in the fencing on the south side. A road killed rabbit was also observed on the highway.

### *Species Movement Guild Rankings*

This site was identified by WSDOT biologists as important for species in each of the Movement Guilds. This location received an 'A' rank for all species movement guilds except Low Mobility Small Fauna, for which it received a 'C' rank, meaning that this structure is suitable with small modifications for all types of species, though it could be improved to also be functional for Low Mobility Small Fauna.

### **Recommendations**

The existing primary limitation at this structure is the level of human activity, which may deter some wildlife activity, if they are not habituated to human presence, and the serious gaps in the existing fencing, which are likely to cause animals to become trapped inside of the highway right-of-way.

The following improvements are recommended to increase the efficacy of this structure for wildlife passage:

- Add cover and down logs through the structure and the median to improve crossing habitat for Low Mobility Small Fauna.
- Repair gaps in fencing and replace barbed wire fencing on south side with 8'-high chain link or wildlife fencing.
- Night-time policing to minimize human activity during the night hours when wildlife could be encouraged to use the structure.

### **Monitoring Summary**

#### **I-90 MP33 Bridges**

Two cameras were installed at this site on April 15 and 16, 2010. The initial day and night of monitoring revealed only human passages through the structure. By the third night, the camera utility boxes were broken into and the cameras were broken and stolen. This ended monitoring at this site. A camera was later recovered in a nearby river several months later.

Figure 111. Large gap in barbed wire fencing through median

## **Location Name: Snoqualmie River Bridge, North Bend**

**Location ID:** 90\_30.5\_16

**Route:** I-90

**Milepost:** 31.5

### Roadway & Site Description

This segment of Interstate 90 is an east-west running, 4-lane divide highway (2 lanes in each direction). The surrounding landscape is largely forested.

### Structure Description

*Type:* Concrete Bridge

*Structure Functional Class:* Class 4 (extensive bridge)

*Dimensions:* 6'10" high x 90' span\* X 95' long

*\*Height and span measurements refers only to the eastern-most span of the north structure, where it spans the trail. The full structure is too large to measure directly.*

There are two structures at this location; one under the eastbound lanes and another under the west bound lanes. Both structures are large concrete bridges with three concrete support walls. The Snoqualmie River flows under both bridges. The bridges are parallel to one another and separated by 223'-wide vegetated median and the river. There is minimal vegetation (some grasses) beneath the structures themselves, but extensive Himalayan blackberry along the river banks at both ends of the structure which may limit wildlife movement along the banks. Visibility through both structures is very high.

The bridge spans the river as well as the banks and a substantial amount of upland area on either side of the river. A recreational trail runs through the east side of the structure, and the high banks are reinforced with riprap, which may prevent animals from accessing the upland trail from the river. However as people regularly use the trail (which provides access for the adjacent neighborhood), wildlife may be largely disinclined from sharing the trail during daylight hours. The trail appears to receive daily use by walkers/joggers and dogs.

Eight-foot tall chain link fencing is present on both the north and south sides of the structure. The fencing ties into the structure both in the median and at the ends of the bridge. The fence extends east and west along the highway for at least a mile. On the south side of the westbound bridge, in the median area, it is present only intermittently with large gaps allowing wildlife access to the median, and there is a game trail leading directly up to the highway.

### Wildlife

A mule deer was observed crossing through the structure from west to east at the time of the assessment. A lone doe crossed moved along the shallows to the riparian vegetation on the other side. Where the vegetation got particularly thick with Himalayan blackberry she swam across the river and exited on the other side. This observation was particularly interesting because no deer tracks were observed on

the riparian banks through the structures, where numerous dog and human tracks were observed. The animal instead chose to walk through the shallow water. Deer tracks were also observed on the trail 30 feet from the structure entrance. During an earlier visit when the monitoring cameras were installed, elk tracks were also observed.

#### *Species Movement Guild Rankings*

This site was identified by WSDOT biologists as important for species in each of the Movement Guilds. This structure received a 'C' rank for Low Mobility Small Fauna because of the lack of continuous riparian habitat through the structure. The structure received an 'A' rank for all other species movement guilds, indicating that animals from each of the Movement Guilds could successful pass through this structure as is, although passage could be further enhanced with some modifications.

#### **Recommendations**

Currently, the structure is highly functional for most wildlife, although regular human activity may limit some wildlife passage. The following recommendations would enhance successful crossings:

- Repair gaps in fencing and escape ramps for extensive stretches of fencing.
- Improve stream bank habitat on both sides of the river. Establish a riparian access area for people and their pets away from the structure and inhibit such human/dog activity directly under the structure itself.
- Control Himalayan blackberry brambles so wildlife can move through the riparian vegetation and their movements can be separated from recreationists and dogs on the trail.
- Add soil pathways over the riprap on both sides of the river (at least one pathway under each structure and in the median).

Figure 118. Doe jumping through brambles before swimming to opposite bank

## Monitoring Results

### **I-90 at Snoqualmie River**

Two cameras were installed under this bridge on April 15, 2010. They were positioned behind the existing chain link fence because the area is used as a trail by local citizens, thereby increasing the cameras' vulnerability to vandalism. Cameras pointed toward the trail near the median on the east side of the river. The area is known to be frequented by local elk headed to and from a golf course on the south side of the highway. On April 17 three cow elk were photographed moving under the bridges at this site (see photos below). No other wildlife was photographed. On the night of April 17 the pair of cameras nearby along the King County Trail were vandalized and stolen. On the night of April 18 several suspicious individuals were photographed at this site at 3:00 in the morning. These cameras were pulled immediately to protect them from theft. The elk photos are a major finding of this study. This is one of two places in this study where elk have been photographed successfully passing through a structure. The bridge is less than seven feet high where the elk traversed underneath, and over 20 feet high where the structure straddles the Snoqualmie River. Regardless, the section where elk moved through is among the lowest recorded heights for structures that elk have used in the United States. The fact these elk are habituated to humans in the North Bend area may make them more apt to use this type of structure.

Figure 120. Three cow elk passing under bridge for I-90 over Snoqualmie River, near North Bend, WA.

## **Location Name: I-90 MP 29 Corrugated Steel Culverts**

**Location ID:** 90\_29\_17

**Route:** I-90

**Milepost:** 29

### Roadway & Site Description

This segment of Interstate 90 is an east-west running highway with four lanes of westbound traffic and three lanes of eastbound. The surrounding landscape is densely forested.

### Structure Description

*Type:* Metal Arch Culvert

*Structure Functional Class:* Class 3 (large underpass)

*Dimensions:* North Structure: 12' high\* x 29' span X 120' long

South Structure: 12' high\* x 29' span x 144' long

*\*Estimated height; not measureable.*

There are two structures at this location; one under the eastbound lanes and another under the west bound lanes. Both structures are large arch culverts with natural dirt bottoms separated by a 180'-wide vegetated median. Visibility through both structures is high, although the culverts allow limited natural light, so there is a high light contrast inside the structures relative to outside daylight. A small ephemeral stream flows through the south structure, but is buried under the structure, reemerging in the median and the north structure. Both culvert bottoms slope towards the south, the north culvert to a greater degree. Forest cover is abundant at both structure entrances.

Eight-foot tall wildlife fencing with a 6x6" mesh connects the two structures through the median and extends in each direction along the roadway for an unknown distance. The fence appears to be in good overall condition, although there is a small gap between the ground level and the bottom of the fencing through the median, and the fencing is not completely connected to the structure at all edges.

There were no apparent signs of human activity at either structure, although domestic dog tracks were observed.

### Wildlife

A number of tracks were observed inside both structures, including raccoon, black bear, fox and coyote. Bear scat was also found in the median area. A western toad and multiple slugs were seen in the structure at the time of the inventory. While no elk tracks were observed around the structures, they were seen along the above roadway.

### *Species Movement Guild Rankings*

This site was identified by WSDOT biologists as important for species in each of the Movement Guilds. This structure received a 'C' rank for Low Mobility Small Fauna because of the lack of continuous habitat and structure through the structure. The

structure also received a 'C' rank for Adaptive Ungulates and Very High Openness Fauna because the structures are quite long and enclosed for species in these groups. The structure received an 'A' rank for all other species movement guilds, indicating that animals from each of the Movement Guilds could successful pass through this structure as is, although passage could be further enhanced with some modifications.

### **Recommendations**

Currently, the structure is highly functional for a wide variety of wildlife. The following recommendations would enhance successful crossings:

- Repair gaps in fencing and escape ramps for extensive stretches of fencing.
- Add down logs to enhance structural complexity through the structure for Low Mobility Small Fauna. Monitoring data revealed use by carnivores but no raccoon, fox, skunk, rodents, or smaller wildlife which may be threatened by continuous carnivore presence. Even the researcher checking the cameras could smell the bear presence.
- Instead of burying the small creek as it passes through the structures, allow it to meander through the structure – perhaps by building up the grade further upslope – to provide additional habitat for Low Mobility Small Fauna and to enhance the structure's appeal for other species.
- Control the spread of invasive species around the structure.

### **Monitoring Results**

#### **I-90 Mile Post 29 Corrugated Steel Culverts**

This dense forest location is just west of Bend, Washington. The culvert lies in an area that is heavily vegetated and forested, with no obvious human paths or roads to or near the area. There is a heavily vegetated median between the culverts and a small stream entering the culvert at the south (uphill) side. The stream is diverted to an underground culvert and reappears in the median. It then runs over the surface through the north culvert. There is eight feet high (2.4 meters) wildlife exclusion fencing made of chain link present at the site. The Average Daily Traffic for this area is 51,500 vehicles. Two cameras were placed at this pair of large steel culverts, on June 23, one on each entrance. Wildlife use was fairly consistent throughout the

monitoring period, with a high of 14 wildlife events in July, and a low of eight wildlife events in September.

In 120 days of monitoring, this culvert proved to be a heavily used by black bear. There were 31 black bear observations in 21 events. Of those, there were five events where a sow and two cubs were observed moving through the culvert. There were one to several yearling sized bears, and three distinct large bears, possibly males. On one occasion, a bear was repelled, otherwise, all bears moved through the culvert. Bear use during the daylight hours occurred in 60% of the bear passes.

Mule deer were observed in three events: all events involved a doe and two fawns. They went through the culvert on two occasions. On the third occasion the doe was photographed on the road right of way on the other side of the fence while the fawn was below at the entrance to the culvert. The three deer events occurred during dawn (1), day (1), and dusk (1). No bucks were photographed.

Single coyotes were observed at the cameras on 19 occasions. Their use of the culvert was not always definite. There were three occasions where the coyote repelled, and four occasions where the coyote paralleled the culvert. Of the 19 coyote observations, only four (21%) occurred during the day. Bobcat was observed on three occasions, and the animal(s) moved through the culvert on each one. All bobcat observations occurred at night. Total numbers for each species are presented in Table 11. Humans were observed in three events, all during daylight hours.

**Table 11.** Species detected at the I-90 MP 29 corrugated steel culvert and the number of observations for that species.

## Acknowledgements

This research study was funded by the Colorado Department of Transportation and Colorado Parks and Wildlife with support from Muley Fanatic Foundation, Rocky Mountain Elk Foundation and the Woodcock Foundation.

The authors would also like to thank the Study Panel for their ongoing support and guidance. Multiple people generously volunteered their time to help with camera field checks over the years – our many thanks to Rachel Sralla, Wendy Allison, Charlee Manguso, Brad Schrom, Doreen Sumerlin, Cinnamon Levi-Flinn and Catherine Ventling. In addition, Charlee Manguso, Brian Suchey and Mary Emanuel tirelessly screened millions of photos to facilitate our data entry. We are also grateful for the many people who assisted with camera set-up at the outset of this research: Lyle Sidener, Wendy Allison, Justin Kuhn, Jason Simpson and CDOT Maintenance in Kremmling. The research team would like to extend our sincere gratitude to Justin Kuhn and Grant Anderson at CDOT for their dedication to this project and assistance in integrating an adaptive management component into the Phase 2 construction. Fraser Shilling at the University of California, Davis provided cell cameras for a separate research study, which has provided the researchers with the unique opportunity to receive real-time images at select locations. Finally, CDOT Maintenance in Kremmling continues to ensure the long-term success of the project with their commitment to maintenance and repairs of the wildlife mitigation features.

## Executive Summary

The State Highway 9 (SH 9) Colorado River South Wildlife and Safety Improvement Project in Grand County was designed by the Colorado Department of Transportation (CDOT) and partners to improve motorist safety by reducing wildlife-vehicle collisions (WVC) while providing opportunities for wildlife to move beneath and over SH 9 through wildlife crossing structures. Prior to the project, WVC were the most common accident type on this segment of highway, accounting for 60% of all accidents reported to law enforcement. In response to these concerns and with partner support, CDOT installed two wildlife overpass structures, five wildlife underpasses, 10.4 miles of eight-foot-high wildlife exclusion fencing, 61 wildlife escape ramps, and 29 wildlife guards to help reduce WVC while providing safe passages for wildlife. This research study evaluates the effectiveness of the mitigation infrastructure through the use of motion activated cameras and analyses of WVC carcass and accident data. The study maintained a total of 62 motion-triggered cameras at 40 locations in Year 3 to record animal movements and responses to the mitigation. Cameras were placed at crossing structure entrances and in the nearby habitat, at wildlife guards, escape ramps, and the south fence end. This progress report focuses on post-construction monitoring from December 2015 through April 2018.

Mule deer activity and success movements through or over the wildlife crossing structures increased each winter (Fig. E-1) resulting in a total of 45,759 mule deer success movements over the course of the study. From Winter 2016-17 to Winter 2017-18, the overall success rate for mule deer passage increased slightly from 96% to 97%. The total number of mule deer success movements increased by 17%, suggesting that the mitigation is succeeding in improving connectivity for mule deer across SH 9. In each year of the study, mule deer activity was highest during the winter months, corresponding with deer presence on winter range; however, some deer remained in the study area throughout the year. Among each of the crossing structure locations, mule deer activity varied substantially and patterns in crossing structure use also varied relative to the previous winter. Overall, mule deer use of wildlife crossing structures ranged from an average of 5 to 36.9 mule deer success movements per day in Winter 2017-18.

Figure E-1. Total number of mule deer movements and successful movements at crossing structures during each winter of the monitoring research study. In Winter 2015-16, only the north portion (Phase 1) of the project area was constructed and monitored.

Elk, white-tailed deer, moose, pronghorn, and bighorn sheep were also documented successfully using the wildlife crossing structures, although in much lower numbers than mule deer. Success movements by these species remained roughly consistent or increased from Year 2 to Year 3, with success rates ranging from 87% for moose ( $n=38$ ); 91% for elk ( $n=76$ ); 92% for white-tailed deer ( $n=39$ ); 98% for pronghorn ( $n=52$ ); and 100% for bighorn sheep ( $n=13$ ). In general, elk were recorded using underpass and overpass structures in the northern portions of the study area (from MP 131.6 – MP 136), with the highest level of elk success movements at the North Overpass (MP 134.3). The majority of elk success movements were by lone individuals or, in some cases, small groups of up to four animals. In addition to ungulates, success movements were made by other large and medium-sized mammals at all of the wildlife crossing structures, including black bear, mountain lion, coyote, red fox, bobcat, badger, hare, skunk and raccoon.

The researchers evaluated two different wildlife guard designs (round bar and flat bar), and found that round bar wildlife guards were, on average, more successful in deterring mule deer

from entering the fenced roadway (90% repel rate) than flat bar wildlife guards (78% repel rate). However, much of this difference may be attributed to plowed snow packed in-between the flat bars creating a surface for animals to walk across. In Winter 2017-18, no breaches occurred in this manner, possibly due to the low snow year or changes in plowing practices. From Year 2 to Year 3, the total number times mule deer attempted to breach the wildlife guards decreased by 30% and the number of successful breaches decreased 68% to a total of 23 breaches at all guard types. In Year 3, breach rates were nearly the same at both guard types (9% for round bar guards and 8% for flat bar guards), although the total number of breaches by ungulate species was higher at round bar guards ( $n=20$ ) than at flat bar guards ( $n=9$ ). Regardless of guard type, jumping the guard was the most common method of breaching a guard.

Researchers placed monitoring cameras on select escape ramps to evaluate the effects of ramp slope and the presence of perpendicular rail fencing placed to guide animals up a ramp on deer and elk use of escape ramps to exit the fenced right-of-way. Mule deer and elk escape rates off the escape ramps were comparatively low (13% for mule deer, 9% for elk) and results were mixed with respect to the two different slope designs and the presence of perpendicular rail fence. Escape ramps without perpendicular fences had higher intercept rates (61%) than ramps with perpendicular fencing (36%) but perpendicular fence did not have a discernable influence on the likelihood of deer or elk using the ramps to escape the right-of-way. At this point, there are great variations in usage rates at all ramp types and continued monitoring and analyses will help determine the most favorable designs.

Three wildlife-vehicle collision (WVC) datasets described a decreasing trend in WVC carcasses and accidents following the completion of mitigation construction in the SH 9 project area: Blue Valley Ranch/Colorado Parks and Wildlife (CPW) carcass reports; CDOT Maintenance carcass reports; and CDOT Traffic and Safety accident data. In Winter 2017-18, six mule deer and no elk carcasses were recorded in the Blue Valley Ranch/CPW carcass dataset, resulting in a decrease of 89% relative to the pre-construction 5-year average of 56.4 carcasses (Fig. E-2). This decrease was slightly greater than the 86% decrease reported the previous winter. No WVC carcasses were reported in the CDOT Maintenance carcass database in Winter 2017-18. Data from Winter 2017-18 were not available from CDOT Traffic and Safety at the time of this writing but, as of

Winter 2016-17, the number of reported WVC accidents dropped 100% from a pre-construction winter average of 10.2, and just one WVC accident was reported for the entire study period. These results support the assertion that wildlife crossing structures and other mitigation features have been effective in reducing WVC along SH 9, while also providing wildlife connectivity across the highway.

Figure E-2. Mule deer and elk carcass counts recorded by BVR and CPW compared to the five-year pre-construction average of 56.4 carcasses per year.

The results from the first three years of monitoring on SH 9 are promising and several performance measures for the mitigation project regarding mule deer use of crossing structures have already been achieved. Other objectives, for example, regarding elk use of crossing structures or ungulate use of escape ramps, have not yet been achieved, but will continue to be monitored and evaluated. The study will continue to evaluate and report on all of these features through Winter 2019-20, and the researchers will continue to work with CDOT and CPW to adaptively manage the structures, fencing, wildlife guards and escape ramps and to use these results to inform future wildlife-highway mitigation projects.

## Introduction

The State Highway 9 (SH 9) Colorado River South Wildlife & Safety Improvement Project installed seven large wildlife crossing structures and 10.4 miles of wildlife exclusion fence between Kremmling and Green Mountain Reservoir in Grand County, Colorado. The project was designed to improve driver safety while providing permeability for wildlife. The highway runs north-south through the lower Blue valley, a broad sagebrush ecosystem between the Gore Range to the west and the Williams Fork Mountains to the east. The Blue River also runs from south to north through the valley, west of the highway, to its confluence with the Colorado River.

The lower Blue River valley supports a high concentration of mule deer (*Odocoileus hemionus*) and American elk (*Cervus canadensis*) during the winter months as wildlife settle onto their winter range. Resident mule deer and elk herds also inhabit the valley throughout the year. Other species include moose (*Alces alces*), pronghorn (*Antilocapra americana*), bighorn sheep (*Ovis canadensis*) American black bear (*Ursus americanus*), bobcat (*Lynx rufus*), red fox (*Vulpes vulpes*), coyote (*Canis latrans*), and mountain lion (*Puma concolor*). Some animals make daily movements across SH 9, where the highway bisects an individual's range, while other animals may make more infrequent movements. These concentrations of wildlife have resulted in numerous wildlife-vehicle collisions (WVC), particularly during the winter months.

During the five winters (December through April) prior to the onset of project construction in 2015, reported WVC crashes were the most common accident type on this segment of highway, accounting for 60% of all accidents reported to law enforcement personnel. During this timeframe, 50 WVC accidents with mule deer or elk were reported, 4% of which resulted in injuries to humans. However, accident reports underestimated the full extent of the conflict between traffic and wildlife on SH 9. More comprehensive winter carcass counts conducted by Blue Valley Ranch during this same timespan recorded 282 WVC mule deer and elk carcasses, more than triple the number of reported accidents.

The goal of this mitigation project was to reduce vehicle conflicts with wildlife while providing permeability for animals to move safely through passages below or over the highway. To meet

these objectives, two wildlife overpasses and five arch underpasses and 10.4 miles of 8-foot high wildlife fencing on both sides of the highway were constructed in two construction phases. Other mitigation features include wildlife guards installed at all road intersections and private driveways; wildlife escape ramps; and pedestrian walk-through gates to provide a pathway for people through the wildlife fence. The project includes drainage culverts, including several medium-sized culverts (8' box or pipe culverts) that are integrated into the fencing and may provide passage for small or medium-sized fauna. This project is the culmination of a comprehensive and collaborative effort by the Colorado Department of Transportation (CDOT), Colorado Parks and Wildlife (CPW), and the privately-owned Blue Valley Ranch (BVR), as well as many other public and private partners. CDOT and CPW are supporting this research study to evaluate how well the wildlife mitigation achieves these goals.

This research study uses motion-triggered cameras to monitor wildlife activity at wildlife crossing structures, wildlife escape ramps, wildlife guards, pedestrian walk-through gates and the southern terminus of the wildlife exclusion fence to evaluate the wildlife mitigation with several performance measures. Cameras were deployed to correspond with the two project construction phases. Phase 1 construction was in the northern portion of the project area (milepost [MP] 131 – 137) and was completed in November 2015. Mitigation features in this phase included one wildlife overpass, three underpasses, six miles of continuous 8-foot high wildlife exclusion fencing on both sides of the highway, 34 escape ramps, 12 wildlife guards and 2 pedestrian walk-through gates. Phase 2, completed November 2016, was in the southern portion of the project area (MP 126 – 131), and included a second overpass, two wildlife underpasses, continued wildlife exclusion fencing through the project area, and an additional 27 escape ramps, 17 wildlife guards and 5 pedestrian walk-through gates.

In addition to camera monitoring, this research study analyzes WVC rates in each phase of the project area, using three long-term datasets. Long-term datasets offer a pre-construction baseline to which post-construction WVC rates may be compared.

This progress report focuses on post-construction monitoring from its onset at the completion of the Phase 1 segment (December 2015) through April 2018.

## Research Objectives

The following research objectives were established by the Study Panel for the five-year research study:

1. Determine to what extent the wildlife and safety mitigation measures reduce WVC.
2. Determine the level of effectiveness of wildlife overpasses and underpasses in allowing wildlife, primarily ungulates, to move underneath or above the highway.
3. Determine the ability of animals that breach the fenced right-of-way to use escape ramps to exit the fenced road area.
4. Determine if the fence end, pedestrian walk-through gate and wildlife guard designs are effective at deterring wildlife (ungulates primarily) from entering the fenced road area.
5. If utilization rates differ among the crossing structures, determine why.
6. Determine if any of the wildlife mitigation features appear to need modification to improve effectiveness.
7. Determine correlation of historic ungulate crossing patterns pre-completion to utilization of post-construction crossing patterns.
8. Compare pre-completion crossing rates to post-construction over/underpass crossing rates.

## Methods

Mitigation effectiveness was measured with two general types of measures: the number of movements made by mule deer, elk and other wildlife through the crossing structures and success vs. repel rates for each species; and the reduction in WVC. Complete camera monitoring, photo analysis and WVC data analysis methods and performance measures are presented in [Appendix A](#).

Pre-construction monitoring was conducted using motion triggered cameras at all crossing structure locations from November 2014 to the onset of mitigation construction in March 2015 by CPW. At each planned structure location, a camera was set up in the natural areas on either side of the highway to document wildlife presence. Additional pre-construction monitoring was conducted by the research team in the Phase 2 segment through Winter 2015-16. The results of pre-construction camera monitoring were presented in the Year 2 Progress Report and are available in [Appendix B](#). Post-construction monitoring commenced in December 2015 in the Phase 1 segment and in December 2016 in the Phase 2 segment and will continue through Winter 2019-20. Post-construction monitoring involved the deployment of 62 cameras at 49 locations, including 40 locations that were monitored in Year 3.

Definitions of the indices calculated for each monitoring location are defined as follows:

- **Total movements** – the sum of all success movements, repel movements, and parallel movements by a species at a given location.
- **Success rate** – For each species at a given crossing structure location, the total number of individual movements of the species that were recorded moving through the structure divided by the total movements by that species.
- **Repel rate** – For each species at a given crossing structure location, the total number of individual movements of the species that were recorded being repelled at a structure divided by the total movements by that species. Repel rate was also calculated for deer and elk at small culverts, wildlife guards and fence ends.
- **Parallel rate** – For each species at a given monitoring location, the total number of individual movements of the species that were recorded moving parallel to the mitigation

feature divided by the total movements by that species. This metric is calculated for crossing structures small culverts and escape ramps.

- **Intercept rate** – This metric is calculated for deer and elk at escape ramps. It is the total number of times deer/elk were recorded ascending an escape ramp divided by the number of times deer/elk approached an escape ramp.
- **Escape rate** – This metric is calculated for deer and elk at escape ramps. It is the total number of times deer/elk were recorded successfully jumping down from an escape ramp divided by the number of times cameras captured deer/elk ascending the escape ramp.
- **Breach rate** – This metric is calculated for deer and elk at wildlife guards, escape ramps, pedestrian walk-through gates, and fence ends. It is the total number of times individual deer/elk breached the mitigation feature divided by the total number of times deer/elk approached that mitigation feature. For example, at a wildlife guard, breaches occur when animals cross over the guard; at escape ramps, breaches occur when animals jump up onto an escape ramp from the habitat side of the wildlife exclusion fencing; at a pedestrian walk-through gate, breaches occur when animals pass through the gate; at the fence end, breaches occur when animals enter into the fenced right-of way from beyond the fence end.
- **Average deer per day** – The total number of unique deer movements (not individuals) observed at the structure divided by the sampling effort. Sampling effort is calculated as the number of days a camera was in operation (or the average number of days for locations with two cameras) and is useful for standardizing the number of mule deer photographed when there is variation in the number of days that cameras were in operation at different monitoring locations. Deer per day may also be calculated for wildlife guards.
- **Average mule deer success movements per day** – The total number of times deer successfully used a structure divided by sampling effort.

Monitoring locations are listed in Table 1; Figures 1 & 2 depict the locations of all monitoring sites across the study area. At various points during this research, monitoring cameras were moved to new locations to capture different mitigation features using a limited number of cameras.

**Table 1.** Monitoring Locations. Monitoring periods are defined as: Year 1 (December 2015 – April 2016); Year 2 (May 2016 – April 2017); Year 3 (May 2017 – April 2018). Highlighted gray rows were not monitored in Year 3.

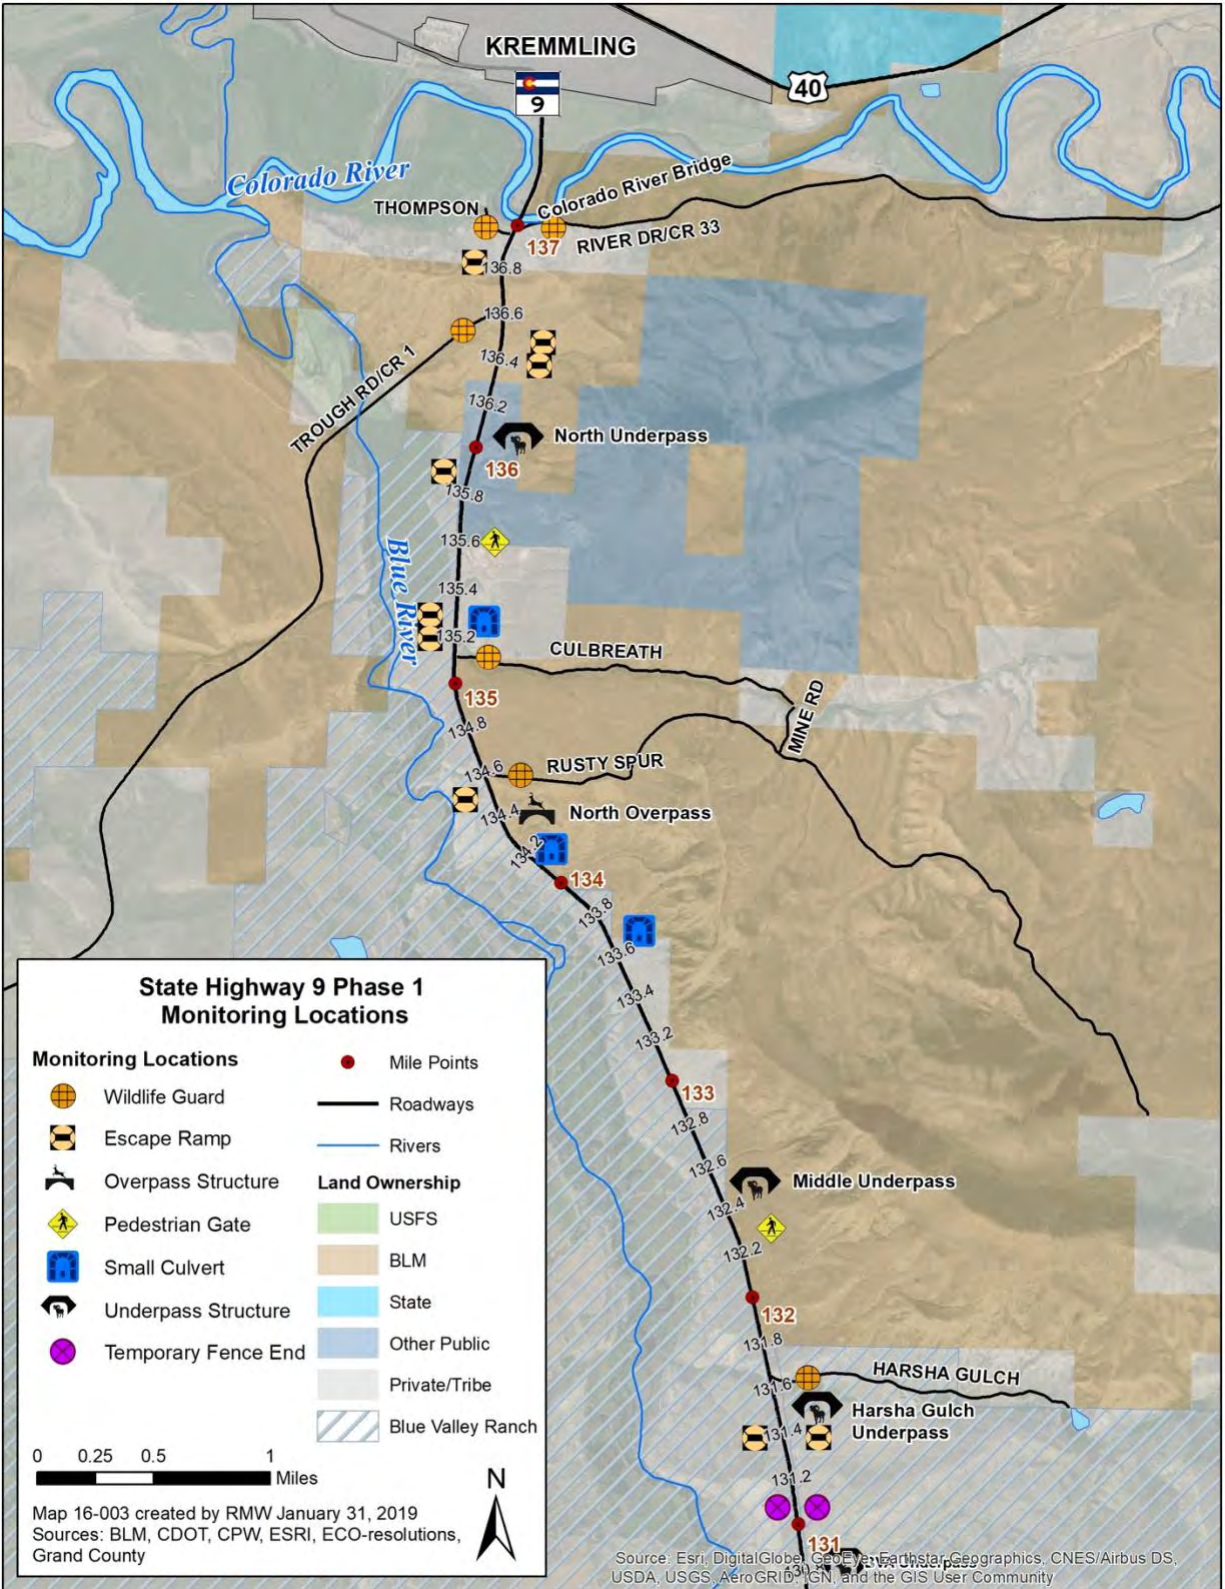

Figure 1. Phase 1 (north segment, MP 131 – 137) monitoring locations through April 2018.

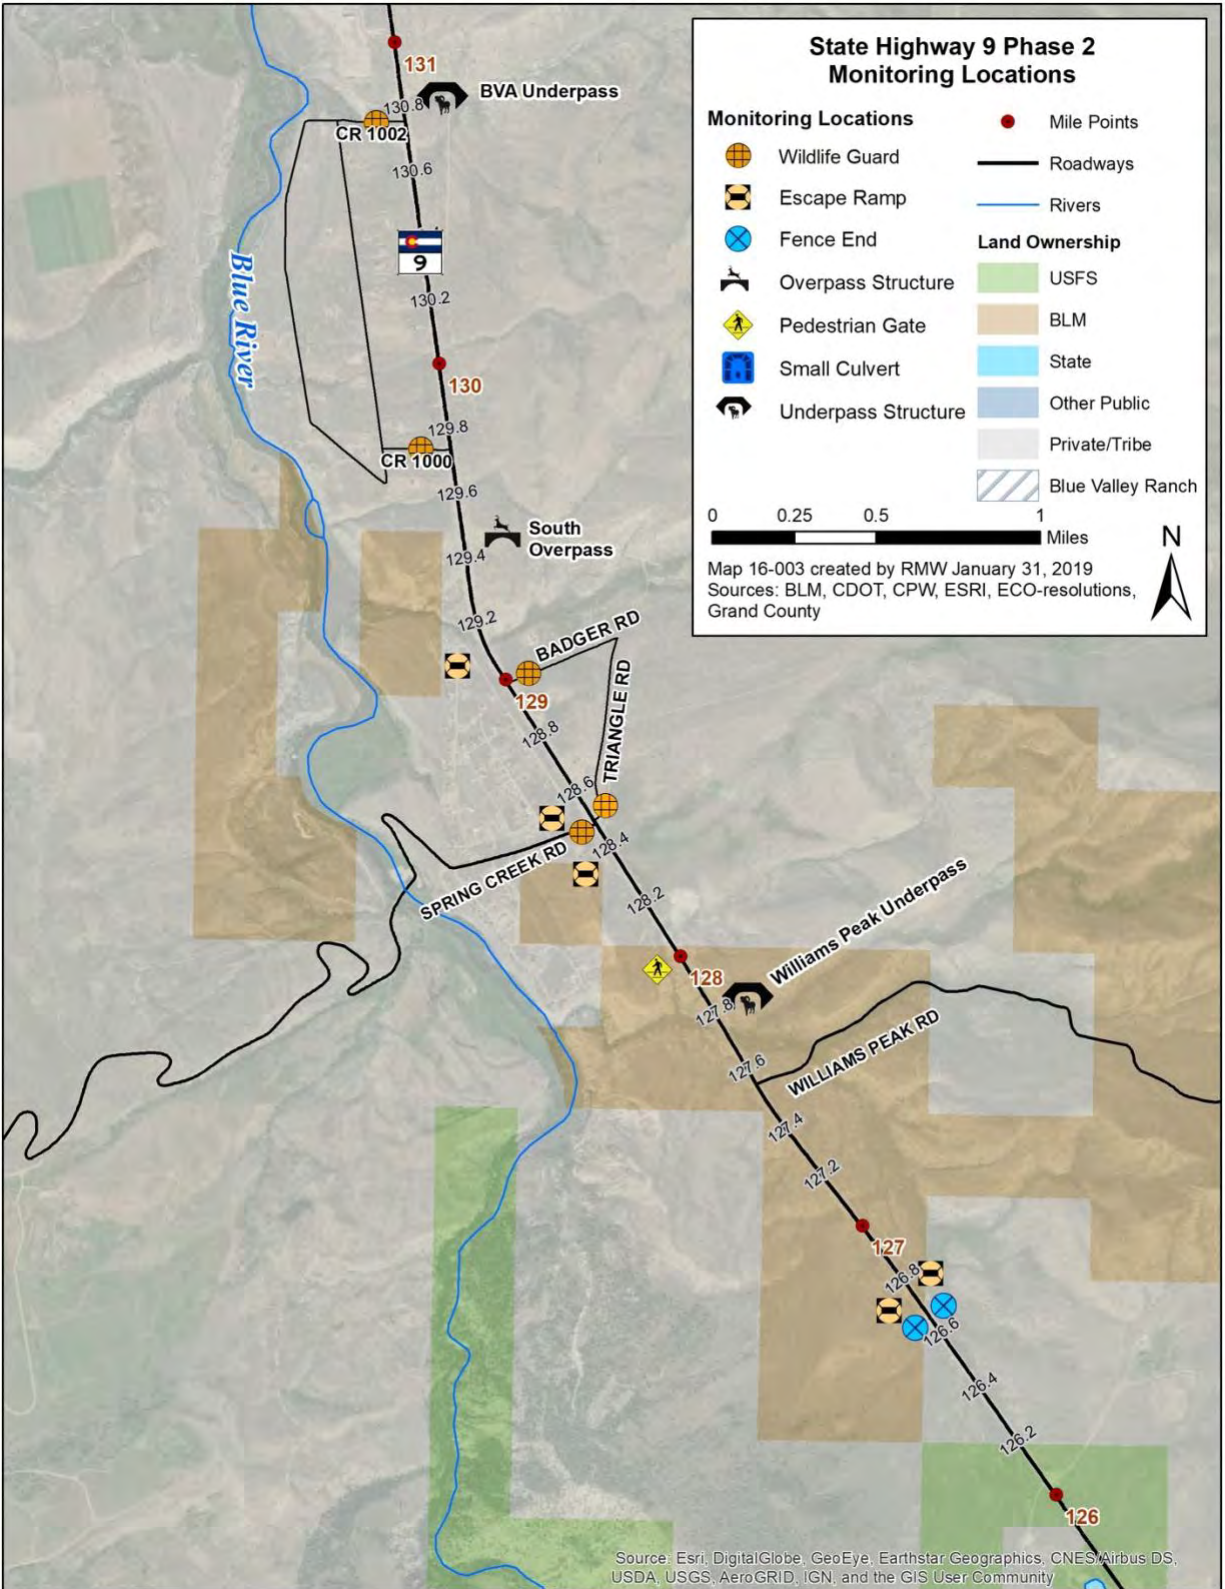

Figure 2. Phase 2 (south segment, MP 126 – 131) monitoring locations through April 2018.

## Results

### Post-Construction Monitoring

In Year 3, cameras were in operation for 226 days during the non-winter months of 2017 (April 19 – November 30) and 140 days during Winter 2017-18 (December 1 – April 19). Cameras were in operation for varying lengths of time depending on location. Battery depletions and equipment malfunctions also decreased the number of monitoring days at certain locations.

Since the start of this study in December 2015, monitoring cameras have recorded a total of 45,759 success movements by mule deer through or over the designated crossing structures. For the Year 3 reporting period, large and medium-bodied wildlife were recorded at crossing structures 24,707 times, including 23,808 success movements for an overall success rate of 96% for all structures combined. Mule deer account for the bulk of this activity, having made 23,691 individual movements at crossing structures, resulting in 22,863 success movements. From Winter 2016-17 to Winter 2017-18, the overall success rate for mule deer passage increased slightly from 96% to 97%, and the total number of mule deer success movements increased by 17%.

Mule deer activity was highest during the winter months, corresponding with deer arrival on winter range; however, some deer remained in the study area throughout the year. These resident deer made 6,441 success movements during the non-winter months of 2017 with an overall success rate of 95%. For this reporting period, elk were detected only during the non-winter months. Species such as black bear, moose, white-tailed deer, red fox and pronghorn were most commonly observed during non-winter months. Others, such as bighorn sheep, bobcat, coyote and moose were observed throughout the year. Mountain lions were most common during the winter months.

### Mule Deer Use of Wildlife Crossing Structures During Winter 2017-18

Mule deer activity and success movements through or over the crossing structures has increased each year of this research study since the completion of the Phase 1 construction in Winter 2015-16 (Fig. 3).

Figure 3. Total number of mule deer movements and successful movements at crossing structures during each winter of the monitoring research study. In Winter 2015-16, only the north portion (Phase 1) of the project area was constructed and monitored.

Table 2 summarizes mule deer activity at each of the crossing structures in Winter 2017-18 and compares changes in success movements to the previous winter. Across all structure locations success rates were 95% to 98%. The highest number of repels was observed at the BVA Underpass and the North Overpass, though the repel rate at each of these locations was only 1% and 2%, respectively. Repel rates decreased at the Williams Peak Underpass and the North Underpass from 10% in Winter 2016-17 to 4% and 3%, respectively, in Winter 2017-18.

As in the previous winter, mule deer activity varied substantially at each of the wildlife crossing structures during Winter 2017-18 (Fig. 4). While overall mule deer success movements at the crossing structures increased by 50%, several changes in the patterns of use at the crossing structures were observed. In Winter 2016-17, the North Overpass had the highest number of mule deer success movements of all the structures. In Winter 2017-18, the number of success movements at this location decreased by 36%; however, this location still had the third highest

number of mule deer success movements in Winter 2017-18. The greatest number of success movements occurred at the BVA Underpass. The Williams Peak Underpass remained the structure with the lowest number of mule deer movements, although success movements increased by 214% from the year prior.

**Table 2.** Mule deer movements at wildlife crossing structures during Winter 2017-18.

Monitoring Location	Total Move-ments	Success Move-ments	Change in Success Move-ments from Winter 2016-17	Average Deer per Winter day	Average Success per Winter Day	Success Rate	Repel Rate	Parallel Rate
<b>MP 127.7</b> Williams Peak Underpass	726	696	214%	5.2	5	96%	4%	<1%
<b>MP 129.5</b> South Overpass	2,972	2,919	19%	21.2	20.9	98%	1%	1%
<b>MP 130.8</b> BVA Underpass	5,246	5,145	30%	37.6	36.9	98%	1%	1%
<b>MP 131.6</b> Harsha Gulch Underpass	1,645	1,614	112%	11.8	11.5	98%	1.5%	<0.5%

<b>MP 137.0</b> Colorado River Bridge	60	57	n/a*	0.4	0.4	95%	5%	0%

\*Camera failures at the Colorado River Bridge during Winter 2016-17 prevent this metric from being calculated.

Figure 4. Total number of mule deer movements and success movements at each crossing structure location during Winter 2017-18.

Mule deer use of overpass structures versus underpass structures was compared between Winter 2017-18 and the previous winter (2016-17). Because there are two overpasses and five underpasses in the study area, the averages for the combined number of success movements at underpass structures versus the combined overpass structures was used to account for the unequal number of underpasses and overpasses. Overall in Winter 2017-18, 65% of all mule deer success movements occurred at the five underpasses and 35% at the two overpasses. However, when considered on a per unit basis, mule deer use of an overpass structure remained higher than underpass structures in Winter 2017-18, although not as high as in Winter 2016-17. Figure 5 depicts the average number of success movements across all crossing structure locations as a function of structure type (overpass versus underpass) during both post-construction winters. In Winter 2016-17, mule deer success movements were, on average, 138% higher at overpass structures than at underpass structures. In Winter 2017-18, mule deer success movements were, on average, 34% higher at overpass structures than at underpass structures.

Figure 5. Average number of success movements by mule deer at overpass versus underpass structures during Winter 2016-17 and Winter 2017-18.

Movements through or over the crossing structures occurred in both directions, originating from the east and moving west, or originating from the west and moving east. During the winter months, east-to-west movements (51%) were nearly equal to west-to-east movements (49%). As the project area is located within winter range, many of the same animals are making regular movements through the structures to access the habitat and resources on either side. In general, the proportion of east-to-west movements increased during the fall migration and west-to-east movements increased during the spring migration. Movements during the summer months by resident animals occurred in both directions in roughly equal proportions.

Gender of mule deer was noted in photo analysis when possible. The numbers of males, females and fawns were recorded, although, in many cases, gender was undetermined, for example, in males who had shed their antlers or because of photo quality or animal position relative to the camera. Numbers and percentages for each gender of individual mule deer whose movements were detected are presented in Table 3. Across crossing structure locations, males represented 13% of the movements, females 41% and fawns 22%.

**Table 3.** Gender of mule deer whose movements were detected at wildlife crossing structures, Winter 2017-18.

Monitoring Location	% Male	% Female	% Fawns	% Unknown
Williams Peak Underpass	13%	31%	27%	29%
South Overpass	7%	26%	21%	45%
BVA Underpass	17%	53%	21%	9%
Harsha Gulch Underpass	24%	49%	21%	6%
Middle Underpass	19%	43%	19%	20%
North Overpass	4%	23%	26%	47%
North Underpass	11%	63%	16%	10%

#### Mule Deer Use of Wildlife Crossing Structures over Time

Figure 6 displays mule deer success movements at each of the crossing structures from the onset of the study in December 2015 through April 2018. Winter 2015-16 represents the first winter following construction of the Phase 1 (northern) segment of the project area. Monitoring in the Phase 2 (southern) segment began in late November and early December of 2016. Periods of

peak mule deer activity differed at each crossing structure location and varied from one year to the next. In general, mule deer numbers began decreasing in April as migratory herds moved to summer range and increased in October as these herds returned to winter range in the study area.

During Winter 2017-18, several locations had more than one peak in mule deer success movements. Mule deer activity peaked at several structures in January and, while there was a dip in activity in February at most structures, there was a peak in activity at the North Overpass during this timeframe. The highest number of mule deer success movements over all the years of the study were at the North and South Overpasses and the BVA Underpass, when compared to the other wildlife crossing structures.

Figure 6. Mule deer success movements by month at each of the wildlife crossing structures from December 2015 through April 2018.

The following subsections describe the camera monitoring results at each crossing structure location. For each crossing structure, the total number of mule deer movements detected relative to mule deer success movements by month of the year is presented (note that the y-axis scale varies for each graph). For a given month, the closer the paired orange and blue bars are in height, the greater the success rate for that month. Mule deer activity was recorded at each structure every month of the year when cameras were active.

*Williams Peak Underpass, Milepost 127.7*

Figure 7 presents mule deer total movements and success movements by month at the Williams Peak Underpass. Winter movements increased at this structure from Year 2 to Year 3 of this research with the highest peak in Winter 2017-2018 occurring in December and January. Mule deer use continued through the summer months.

Figure 7. Mule deer total movements and success movements by months of the year at the Williams Peak Underpass (MP 136). Note y-axis scale is 0 – 250.

*South Overpass, Milepost 129.5*

Figure 8 presents mule deer total movements and success movements by month at the South Overpass. The peak in monthly movements in Year 2 was nearly as high as the peaks observed in Year 3; however, in Year 2 this peak occurred in February, while in Year 3, two peaks were observed in January and March, with a dip in activity in February. Mule deer use continued through the summer months.

Figure 8. Mule deer total movements and success movements by months of the year at the South Overpass (MP 136). Note y-axis scale is 0 – 900.

*BVA Underpass, Milepost 130.8*

Figure 9 presents mule deer total movements and success movements by month at the BVA Underpass. The peak in monthly movements in Year 2 was higher than the peak in Year 3; however, in Year 2 there was a single peak in February, while in Year 3, two peaks were observed in January and March, with a dip in activity in February and overall activity was higher throughout the winter months. Figure 10 depicts a success movement at the BVA Underpass. Mule deer use continued through the summer months.

Figure 9. Mule deer total movements and success movements by months of the year at the BVA Underpass (MP 130.8). Note y-axis scale is 0 – 1,600.

Figure 10. Example of mule deer success movement at the BVA Underpass.

*Harsha Underpass, Milepost 131.6*

Figure 11 presents mule deer total movements and success movements by month at the Harsha Underpass. Winter movements increased each year at this structure with the highest activity recorded in January 2018. The lack of mule deer activity during the non-winter months of 2016 is attributed to ongoing construction activities at this location. In 2017, mule deer movements decreased from March through June and increased in July and again in November.

Figure 11. Mule deer total movements and success movements by months of the year at the Harsha Underpass (MP 131.6). Note y-axis scale is 0 – 500.

*Middle Underpass, Milepost 132.5*

Figure 12 presents mule deer total movements and success movements by month at the Middle Underpass. Winter movements increased each year at this structure with the highest activity recorded in March 2018. Mule deer use during the summer months was greater in 2017 than in 2016.

Figure 12. Mule deer total movements and success movements by months of the year at the Middle Underpass (MP 132.5). Note y-axis scale is 0 – 800.

*North Overpass, Milepost 134.3*

Figure 13 presents mule deer total movements and success movements by month at the North Overpass. This is the only location where mule deer activity decreased from Year 1 to Year 3. The highest peak in success movements occurred in March 2016. Wintertime peaks in activity in Years 2 and 3 were substantially lower, although overall activity at this structure remained high. Mule deer use continued through the summer months. Figure 14 depicts a mule deer success movement at the North Overpass.

Figure 13. Mule deer total movements and success movements by months of the year at the North Overpass (MP 134.3). Note y-axis scale is 0 – 2,500.

Figure 14. Mule deer doe with two fawns crossing the North Overpass.

*North Underpass, Milepost 136.0*

Figure 15 presents mule deer total movements and success movements by month at the North Underpass. Mule deer success movements increased from Years 1 to 2 at this location and, while there was not a peak in activity as observed in Year 2, overall activity remained high throughout Winter 2017-18. Each year, mule deer movements sharply increased at this structure in January. Mule deer use of the structure continued during the summer months in low numbers.

Figure 15. Mule deer total movements and success movements by months of the year at the North Underpass (MP 136). Note y-axis scale is 0 – 400.

## Other Species Use of Wildlife Crossing Structures

In addition to mule deer, a variety of other species were documented using the wildlife crossing structures. Table 4 lists the total number of success, repel and parallel movements for each species across all crossing structures and the corresponding success and repel rates for those species. Success rates for all species ranged from 81-100%.

**Table 4.** Movements by species other than mule deer at wildlife crossing structures, Years 1-3. Success, repel, and parallel movements are the total number of each movement across crossing structures. Success and repel rates are calculated for each species.

Species	Total Movements	Success Movements	Repel Movements	Parallel Movements	Success Rate	Repel Rate
Bighorn Sheep	13	13	0	0	100%	0%
Black Bear	140	139	1	0	99%	1%
Bobcat	85	75	6	4	88%	7%
Coyote	861	820	14	27	95%	2%
Elk	76	69	6	1	91%	8%
Fox, Red	200	161	9	30	81%	5%
Moose	38	33	3	2	87%	8%
Mountain Lion	69	68	1	0	99%	1%
Pronghorn	52	51	1	0	98%	2%
White-tailed Deer	39	36	2	1	92%	5%

Ungulate passage through and over the crossing structures for species other than mule deer remained roughly consistent or increased from Year 2 to Year 3. The number of success movements increased for bighorn sheep (from 2 to 11); moose (from 7 to 22); and pronghorn (from 9 to 42). For elk and white-tailed deer the number success movements decreased slightly between Years 2 and 3. While success rates are high for all of these ungulate species (87% or greater), the total number of movements for these species remains relatively low.

Elk passage continued to be highest at the North Overpass ( $n=12$ ) in Year 3. Elk success movements were observed at most crossing structures, with the exception of the BVA and Williams Peak Underpasses, the two southern-most underpasses in the study area (Fig. 16). Overall in Year 3, elk successfully used the overpasses and underpasses equally (15 each),

although more repels were documented at the underpasses (5) than at the overpasses (1). In contrast with years prior, in Year 3, all elk movements occurred during the non-winter months.

Figure 16. Elk total and success movements detected at wildlife crossing structures, Years 1-3.

Since the onset of this research, pronghorn and white-tailed deer have only been documented using the underpass structures. The majority of pronghorn success movements occurred at the BVA Underpass, while the majority of white-tailed deer success movements occurred at the North Underpass. Moose and bighorn sheep have made success movements at both underpasses and overpasses. The majority of bighorn sheep success movements occurred at crossing structures located in the southern portions of the project area, specifically, at the South Overpass and the Williams Peak Underpass. Of eight total success movements at the South Overpass, four of them were part of a single event by a family group (Fig. 17).

Success movements by a variety of other large and medium-sized mammals were also documented at each of the crossing structures (Fig. 18). Black bears were detected primarily during the warmer months, while mountain lions were primarily detected during the winter months. The other mammal species were detected year-round. Coyote and red fox were the only species other than mule deer documented using every crossing structure. Coyote activity increased markedly in Year 3 at both overpass and underpass structures, although the heaviest use occurred at the two overpasses. Red fox activity also increased in Year 3.

*Figure 17.* Bighorn sheep ewe, lamb, ram and yearling crossing the South Overpass.

Black bear have not crossed over either of the overpass structures to date and were observed primarily at the Middle Underpass. Other species documented at crossing structures include badger, bird, hare, raccoon, skunk and domestic animals (cats, dogs and cows).

Lower numbers of wildlife have been documented making successful passages under the Colorado River Bridge, including mule deer, moose, bobcat, red fox, mountain lion and white-tailed deer.

Figure 18. Success movements by medium and large-sized mammals other than mule deer and elk at each wildlife crossing structure from the onset of the study in December 2015 through April 2018.

Habitat cameras were placed approximately 100 feet away from the structure entrances facing outwards to capture wildlife movements in the adjacent habitat. Wildlife movements at habitat cameras relative to movements at crossing structures for species other than mule deer are reported in Table 5. In general, wildlife that were captured at habitat cameras were also captured at crossing structures, although species captured at both locations were not necessarily part of the

*Figure 19.* Mountain lion with 3 kittens approaching the Williams Peak Underpass.

same individual movement. Figure 19 depicts a mountain lion with three kittens approaching the habitat camera on the east side of the Williams Peak Underpass. In a few cases wildlife that were not captured at the habitat cameras were documented at the structure. However, these events occurred in low numbers and are expected as the habitat cameras are only able to capture a portion of the wildlife activity occurring in the vicinity of a structure.

Humans were recorded at each of the crossing structures; this does not include researchers conducting camera checks. Human activity was most common at the Harsha Gulch Underpass, where, during the winter months, humans were documented on average once every ten days in Winter 2017-18. During the first two years of the study some human activity may be attributed to ongoing construction and construction review activities, particularly during the non-winter months.

**Table 5.** Comparison of species presence (other than mule deer) at wildlife crossing structures and habitat camera locations adjacent to wildlife crossing structures, Years 1-3. Note that movements at structures is the sum of all success, repel and parallel movements. Presence at habitat cameras does not imply that animals were moving to or from a crossing structure.

Species	Monitoring Location	Williams Peak UP	South OP	BVA UP	Harsha UP	Middle UP	North OP	North UP
Bighorn Sheep	Structure	3	7	0	0	1	1	1

UP = underpass

OP = overpass

#### Wildlife Movements at Small Culverts

The three small culverts were monitored for varying lengths of time. Monitoring at the BVR Pipe Culvert began at the onset of monitoring in December 2015 and continued into October 2016.

The Culbreath Box Culvert was monitored from October 2016 through April 2018 and the BVR Box Culvert from March 2017 through April 2018.

Wildlife activity at these small culvert locations occurred primarily during the non-winter months. Figure 20 displays success movements at each small culvert location. Mule deer were documented and made success movements at all three culverts, ranging from one through-

passage at the Culbreath Box Culvert to 17 at the BVR Box Culvert. However, less than a third of the mule deer that approached any of these small culverts successfully crossed through.

Black bear, bobcat and coyote were the most common species documented using the small culverts, with much of this activity occurring at the BVR Box Culvert. Domestic dogs and cats were most common at the Culbreath Box Culvert and may have deterred some wildlife activity at this location. Success movements at small culverts were also made by red fox, American badger and northern raccoon.

Figure 20. Success movements by species at each of the small culverts. Total monitoring days at each location are: BVR Box Culvert – 408 days; BVR Pipe Culvert – 306 days; Culbreath Box Culvert – 474 days.

## Wildlife Movements at Other Mitigation Features

### *Wildlife Guards*

Since the onset of this research, ungulates have made a total of 138 breach movements at wildlife guards. The vast majority of wildlife guard breaches by mule deer, elk and white-tailed deer were from the habitat side into the fenced right-of-way. In general, wildlife guards deterred ungulates from entering the fenced right-of-way 83% of the time. The total number of breach movements by mule deer decreased from 71 breaches in Year 2 to 23 breach movements Year 3.

Table 6 displays the number of breaches and repels, as well as breach rates and repel rates for each species. The flat bar guards were 78% effective in preventing mule deer breaches, while the round bar guards were 90% effective. Elk had a higher repel rate at flat bar guards (81%) than at round bar guards (67%), but the total number of movements by elk at round bar guards was only six, compared 16 at the flat bar guards. White-tailed deer had a higher repel rate at round bar guards (75%;  $n=8$ ) than at flat bar guards (67%;  $n=3$ ). Moose and bighorn sheep repelled from both guard types 100% of the time ( $n=9$  and  $n=2$ , respectively).

Black bear ( $n=6$ ), bobcat ( $n=21$ ) and mountain lion ( $n=1$ ) were infrequent visitors to the guards but breached the guards 100% of the time when they did approach. Red fox ( $n=240$ ) and coyote ( $n=84$ ) approached the guards more frequently, with breach rates ranging from 74-100% depending on the guard type. The breach rate for red fox was the same at both round bar and flat bar guards (92%) and nearly the same for coyote (75% at round bar and 74% at flat bar guards). These species were also observed breaching the guards in either direction. In one instance, a bobcat was documented descending into the vault at the County Road 33 Wildlife Guard (Fig. 21). Mountain lion, raccoon, skunk, hare and domestic dogs and cats were also recorded at the wildlife guards.

*Figure 21.* Bobcat entering into the vault at the County Road 33 Wildlife Guard.

**Table 6.** Breach and repel rates for each species at wildlife guards with flat bars (8 locations) versus round bars (4 locations).

Species	Wildlife Guard Type	Total Approach Movements	Breach Rate	Repel Rate
Badger	Flat Bar	1	0%	100%
	Round Bar	0	n/a	n/a
Bighorn Sheep	Flat Bar	1	0%	100%
	Round Bar	1	0%	100%
Black Bear	Flat Bar	3	100%	0%
	Round Bar	3	100%	0%
Bobcat	Flat Bar	15	100%	0%
	Round Bar	6	100%	0%
Coyote	Flat Bar	76	74%	26%
	Round Bar	8	75%	25%
Elk	Flat Bar	16	19%	81%
	Round Bar	6	33%	67%
Moose	Flat Bar	5	0%	100%
	Round Bar	4	0%	100%
Mountain Lion	Flat Bar	1	100%	0%
	Round Bar	0	n/a	n/a
Mule Deer	Flat Bar	372	22%	78%
	Flat Bar with Pedestrian Grate	30	40%	60%
	Round Bar	368	10%	90%
Red Fox	Flat Bar	173	92%	8%
	Flat Bar with Pedestrian Grate	1	100%	0%
	Round Bar	66	92%	8%
White-tailed Deer	Flat Bar	3	33%	67%
	Round Bar	8	25%	75%

Ungulate breach rates varied depending on the guard type. The flat bar guard with a pedestrian grate was only monitored for a short period before it was gated but was breached the most often (12 breaches total for a rate of 0.047 breaches per monitoring day). The flat bar guards were breached on 84 occasions for a rate of 0.026 breaches per monitoring day, and the round bar guards 42 times for a rate of 0.017 breaches per monitoring day. For mule deer, breach movements by walking over snow packed in-between the bars at flat bar guards were the most common breach type in Year 2, while in Year 3, no breaches occurred at any of the guard types by walking on snow (Table 7). In Year 3, mule deer breaches were higher at round bar guards than at flat bar guards, accounting for 74% of all breach movements ( $n=17$ ). The most common

method of breaching, regardless of guard type, was jumping. On several occasions, deer were captured breaching a round bar guard by attempting to walk on top of the bars (Fig. 22) or walking on the support beams despite the presence of angle iron on the beams to prevent these types of breaches (Fig. 23).

**Table 7.** Comparison of breach type for Mule Deer in Winter 2016-17 and Winter 2017-18 at wildlife guards with flat bars (7 locations), flat bars with a pedestrian grate (1 location), and round bars (5 locations).

Wildlife Guard Type	Study Year	Walk on Top	Walk on Support Beams	Walk on Snow	Jump	Walk on Grate
Flat Bar (n=77)	Year 1	11	3	7	5	n/a
	Year 2	10	1	29	5	n/a
	Year 3	0	0	0	6	n/a
Flat Bar with Pedestrian Grate (n=18)	Year 1	5	0	0	3	3
	Year 2	1	0	0	3	3
	Year 3	n/a	n/a	n/a	n/a	n/a
Round Bar (n=37)	Year 1	n/a	n/a	n/a	n/a	n/a
	Year 2	0	1	2	18	n/a
	Year 3	4	2	0	10	n/a

*Figure 22.* Mule deer breaching the Badger Road Wildlife Guard by attempting to walk on top of the round bars.

*Figure 23.* Mule deer breaching the County Road 1002 Wildlife Guard (round bar) by walking on the support beams.

Mule deer breaches were recorded at all monitoring locations but occurred most frequently at County Road 1000 (flat bar), with 29% of all breaches occurring at this location. This was also the location with the highest occurrence of breaches by walking on snow. Breaches by walking

on snow also occurred at the Trough Road Wildlife Guard (flat bar) and County Road 1002, which was the only round bar guard location with the breach type. In this case, snow plowing created a snow berm along the side of the guard and the deer used this berm to breach the guard. Walking on top of the guard was the most common method of breaching at County Road 33 and Spring Creek, both flat bar locations. Walking on top was also the most common breach type at the Culbreath Wildlife Guard during Year 1, despite the presence of a pedestrian grate on this guard. Breaches by jumping were documented at nearly all of the guard locations regardless of guard type, and this was the most common method of breaching at the four round-bar locations.

Several wildlife guard monitoring locations were included in a paired analysis, i.e., adjacent locations with different guard types (flat bar versus round bar) in Year 3. The paired locations included in this analysis were the Thompson (round bar) and County Road 33 (flat bar) wildlife guards; Triangle Road (round bar) and Spring Creek Road (flat bar) wildlife guards; and County Road 1002 (round bar) and County Road 1000 (flat bar). The paired analysis included only movements by ungulate species, and only events that occurred between dusk and dawn the following day to equalize the sampling effort among those cameras that are programmed to be off during the daytime due to higher traffic volumes and those that are not. Breach and repel movements for guards in the paired analysis are presented in Table 8.

**Table 8.** Breach and repel movements at wildlife guards included in the Year 3 paired analysis.

Monitoring Location	Breach Movements	Repel Movements	Walk on Top	Walk on Support Beams	Walk Snow	Jump
Thompson (round bar)	1	14	0	0	0	1
CR 33 (flat bar)	0	2	0	0	0	0
Triangle Rd (round bar)	5	36	0	0	0	5
Spring Creek Rd (flat bar)	3	40	1	0	0	2
CR 1002 (round bar)	6	48	0	2	0	4
CR 1000 (flat bar)	6	34	2	0	0	4

Across all of the pairs, jumping the guard was the most common breach type and occurred at the flat bar and round bar guards in nearly equal numbers for each of the pairs. Walking on top of the

bars was recorded only at flat bar guards in this paired analysis, while walking on the support beams was recorded only at one of the round bar guards.

### *Escape Ramps*

Since the onset of this research, cameras have recorded a total of 171 elk and 645 mule deer movements at escape ramps on the right-of-way side of the fence. Elk and mule deer movements at escape ramps occurred mostly from December through March. In Year 3, no elk were documented inside of the right-of-way fence at the escape ramps and 279 mule deer movements were recorded – slightly fewer than in Year 2. Mule deer have been documented at each of the 13 monitored escape ramp locations, with the highest frequencies at the East Fence End Escape Ramp at MP 126.7, Badger Road Escape Ramp at MP 129.1 (both 3:1 slope with no rail fence) and the North Overpass Escape Ramp at MP 134.3 (2:1 slope with no rail fence).

When an animal approached an escape ramp on the right-of-way side of the fence, it either walked around the ramp or ascended (intercepted) it. Table 9 summarizes elk and mule deer approaches and intercept rates for the different escape ramp types. For elk, 3:1 slope ramps without perpendicular rail fence had the highest intercept rate (54%). For deer, ramps without perpendicular rail fence (both 2:1 and 3:1 slopes) had the highest intercept rates (72% and 55%, respectively).

**Table 9.** Intercept rate by elk and mule deer at escape ramps with 2:1 versus 3:1 slopes and with or without perpendicular rail fence through Year 3. Intercept rate is the percentage of the total movements by animals that ascended the ramp relative to the total number of movements by animals that approached the ramp.

Species	Escape Ramp Type	Total Approaches	Intercept Rate
Elk	2:1 slope with rail fence (n=5)	3	33%
	2:1 slope without rail fence (n=1)	0	n/a
	3:1 slope with rail fence (n=2)	0	n/a
	3:1 slope without rail fence (n=5)	168	54%
Mule Deer	2:1 slope with rail fence (n=5)	65	43%
	2:1 slope without rail fence (n=1)	106	72%
	3:1 slope with rail fence (n=2)	126	34%
	3:1 slope without rail fence (n=5)	348	55%

Animals whose movements were intercepted by a ramp either walked up and turned around or jumped down to the habitat side. Table 10 summarizes jump down (escape) rates for deer and elk at each of the different escape ramp types. The highest number of mule deer escapes were at the North Overpass Escape Ramp (2:1 slope without rail fence;  $n=14$ ) and the Badger Road Escape Ramp (3:1 slope without rail fence;  $n=12$ ), with escape rates of 18% and 26%, respectively. All of the other ramps recorded four or fewer escape movements. For example, the Culbreath 3:1 Escape Ramp (no rail fence) had the highest escape rate of 33% but only twelve total movements were recorded at this location including four successful jump downs. The East Fence End Escape Ramp (3:1 slope ramp without rail fence) had the highest number of mule deer walk up the ramp ( $n=83$ ), but none of these deer jumped down to the habitat side.

In Year 3, bighorn sheep were recorded ascending the South Spring Creek Escape Ramp (3:1 slope with rail fence), but no successful escape movements were recorded. Moose, pronghorn and white-tailed deer were not recorded at any of the ramps. Humans were recorded in low numbers at most of the ramps, and in most cases appear to be curious passersby, including people on foot, dirt bikes, ATVs, and snowmobiles.

**Table 10.** Escape rates by elk and mule deer at escape ramps with 2:1 versus 3:1 slopes and with or without perpendicular rail fence through Year 3. Escape rate is the percentage of the total movements by animals that escaped to the habitat side of the fencing relative to the total number of movements by animals that ascended the ramp.

Species	Escape Ramp Type	Total Ascend Ramp	Escape Rate
Elk	2:1 slope with rail fence ( $n=5$ )	1	100%
	2:1 slope without rail fence ( $n=1$ )	n/a	n/a
	3:1 slope with rail fence ( $n=2$ )	0	n/a
	3:1 slope without rail fence ( $n=5$ )	90	8%
Mule Deer	2:1 slope with rail fence ( $n=5$ )	28	11%
	2:1 slope without rail fence ( $n=1$ )	76	18%
	3:1 slope with rail fence ( $n=2$ )	43	14%
	3:1 slope without rail fence ( $n=5$ )	192	11%

A number of ungulates, other wildlife and domestic cows were documented on the habitat side of the escape ramps. No ungulates attempted to jump up onto the ramp from the habitat side. On one occasion a bighorn sheep ewe appeared to investigate the ramp from the habitat side of the fence but made no attempt to jump up. Bobcat is the only species captured climbing up the backside of a ramp from the habitat side to enter into the fenced right-of-way.

#### *Pedestrian Walk-Through Gates*

All of the pedestrian walk-through gates in the study area were gated by CPW in Summer 2017 and monitoring ceased. Monitoring results for the pedestrian walk-through gates are available in the *State Highway 9 Wildlife Crossings Monitoring Year 2 Progress Report* (Kintsch et al. 2018).

#### *South Fence End*

Wildlife exclusion fence runs along the right-of-way line throughout the project area. The northern terminus ties into the Colorado River Bridge south of Kremmling. The southern terminus is at MP 126.6. At this fence end the fence line angles in towards the pavement, ending 20' from the pavement edge so that it is not inside the clear zone. Monitoring at the south fence end commenced on October 10, 2016 and will continue through the duration of this research.

A total of 777 movements were recorded of deer and elk at the south fence end. Movements into the fenced right-of-way occurred when animals moved from the habitat side of the fence and either walked around the fence end into the right-of-way on the same side of the road or crossed the road and entered the right-of-way on the opposite side. Movements out of the fenced right-of-way occurred when animals already inside the fenced area of the right-of-way moved out to the habitat side of the fence. Movements beyond the fence include movements where animals crossed the road beyond the fence end as well as those where the animal did not cross the road but repelled from the road and remained beyond the fence end. The majority of movements for all species occurred beyond the fence end without movements into or out of the fenced right-of-way, including 91% of all deer movements and 62% of all elk movements. Some human movements were documented at the fence end, primarily involving ATVs, dirt bikes or snowmobiles driving around the fence end on the west side.

The total number of ungulate movements at the south fence end increased from Winter 2016-17 to Winter 2017-18 by 40% and the majority of all movements continue to occur beyond the fence end (Fig. 24). Total movements decreased during the non-winter months as migratory herds moved out of the study area to high elevation summer ranges.

Figure 24. Ungulate movements at the south fence end.

### Wildlife-Vehicle Collision Rates

#### BVR/CPW Carcass Data

In Winter 2017-18, six mule deer and no elk carcasses were reported inside the project area, for a decrease of 89% relative to the pre-construction average (Fig. 25). This decrease was slightly greater than Winter 2016-17 which saw a decrease of 86% (eight carcasses reported). In Winter 2016-17, three additional deer carcasses were reported within a mile south of the south fence end, while in Winter 2017-18, this number increased to six. Four of these WVC carcasses were located less than 30 meters from the fence end. At the north end of the study area, one deer

carcass was reported within a mile of the north fence end in Winter 2017-18; no elk or pronghorn carcasses were recorded.

Figure 25. Mule deer and elk carcass counts recorded by BVR and CPW compared to the five-year pre-construction average of 56.4 carcasses per year.

#### CDOT Maintenance Carcass Data

In Winter 2017-18, no WVC carcasses were reported by CDOT Maintenance patrols inside the project area; nor were any reported the previous winter (Fig. 26). Since construction was completed, one carcass was reported during the non-winter months inside the project area – this WVC event occurred near the south fence end in late November 2017, during the fall migration. However, carcasses continue to be recorded beyond the fence ends, particularly south of the project area (Fig. 27). Since construction was completed, 12 WVC carcasses have been reported within 1.5 miles of the south fence and one WVC carcass was reported north of the project area.

Figure 26. Wintertime mule deer and elk carcass counts recorded by CDOT Maintenance within the project area (MP 216.6 – 137.0) compared to the five-year pre-construction average of 38.8 carcasses per year.

Figure 27. Mule deer and elk carcass counts recorded by CDOT Maintenance by milepost. Pre-construction totals comprise 5 years; post-construction totals comprise two winters and the intervening non-winter months. The 5-year pre-construction average was calculated for each one-mile segment.

#### CDOT Traffic and Safety Accident Report Data

Within the project area, the number of reported WVC accidents dropped 100% in Winter 2016-17, the first winter following construction of the entire mitigation project. During the five winters prior to mitigation construction (Winter 2010-11 through 2014-15), WVC were the most common accident type on this segment of highway, accounting for 60% ( $n=51$ ) of all accidents reported to law enforcement. These data demonstrate that WVC accidents occur year-round, with the highest WVC rates occurring during the winter months (Fig. 28). No WVC accidents were reported immediately north or south of the project area since construction was completed. Post-construction data for April 2017 through April 2018 were not available at the time of this analysis.

Figure 28. Wildlife-vehicle collision accidents within the project area (MP 216.6 – 137.0) reported to law enforcement involving mule deer or elk compared to the 5-year pre-construction average of 10.2 reported accidents, which is calculated for the winter months only so that it may be compared to the BVR carcass data.

#### Wildlife-vehicle Collision Rates on US 40

In addition to WVC rates on SH 9, the researchers also analyzed the CDOT Maintenance carcass dataset for US 40 from MP 182-190, an east-west highway that runs through the town of Kremmling, north of the project area. Comparisons were made between the number of ungulate (mule deer, elk and pronghorn) carcasses five-years pre-construction and two years post-construction (Fig. 29). Data from Winter 2015-16 were excluded from the analysis as this corresponds with the timeframe during which only the Phase 1 portion of the project area had been constructed. The purpose of this analysis was to determine whether the mitigation on SH 9 may have contributed to a shift in wildlife movements, particularly elk, from SH 9 north across US 40, with a resulting increase in WVC on US 40. During the five years pre-construction, 28 deer carcasses and eight elk carcasses were recorded. Post-construction, four carcasses of each species have been recorded during Winter 2016-17 and Winter 2017-18.

Figure 29. Ungulate carcass counts recorded by CDOT Maintenance on US 40 east and west of Kremmling (MP 185) for five winters prior to mitigation construction and two winters post-construction. The 5-year pre-construction winter average was calculated for each one-mile segment.

## Discussion

### Wildlife Use of Crossing Structures

Mule deer activity and success movements through or over the crossing structures increased each year of this research. The 45,759 mule deer success movements at wildlife crossing structures in addition to the mule deer success rates ranging from 95% to 98% demonstrate the success of this mitigation system for mule deer. The 89% reduction in WVC carcasses collected by BVR and CPW in addition to the reduction in WVC carcasses reported by CDOT Maintenance and WVC accidents reported to law enforcement further attest to the success of the mitigation in reducing wildlife hazards for motorists. The observed changes in the number of success movements by mule deer and other species over time, as well as variations in the patterns of use across the seven structures can inform a greater understanding of wildlife movements in the study area and the effectiveness of the different wildlife crossing structure types.

### Mule Deer Structure Use and Periods of Peak Activity

The 17% increase in mule deer movements in Winter 2017-18 relative to the winter prior suggests that the mitigation is succeeding in improving connectivity for mule deer across SH 9. The high number of mule deer movements and the high success rates at each of the crossing structures reflect regular movements that appear to have been made by many of the same individuals on winter range. Periods of peak mule deer activity varied among crossing structures and from one winter to the next. In general, activity increased in October, marking the onset of migratory herds arriving on winter range, and began decreasing again in April as these herds moved to high elevation summer ranges. While in Winter 2016-17 peak activity was concentrated in January and mid-February, in Winter 2017-18, peak activity at several locations didn't occur until March. Given that crossing structures in the Phase 2 segment were completely new in Winter 2016-17, shifts in peak activity are expected in the first few years of post-construction monitoring. Fluctuations in snowfall is another likely contributor to annual variability.

In addition to movements by migratory mule deer on winter range, resident mule deer continued to use the crossing structures during the non-winter months with an overall success rate of 95%. Mule deer success movements were recorded at all of the wildlife crossing structures during the non-winter months of 2017 and accounted for 29% of all movements at crossing structures in

Year 3. These results demonstrate that the wildlife-highway mitigation provided safe passages for resident herds as well as wintering migratory herds. The mitigation has also successfully reduced WVC conflicts for resident herds, as no WVC crashes or carcasses were reported during the non-winter months in Year 3 (based on CDOT Maintenance carcass reports and CDOT Traffic and Safety accident reports; BVR does not collect carcass data during the non-winter months).

#### Variations in Mule Deer Structure Use from Prior Winter

Mule deer activity varied substantially among the wildlife crossing structures during Winter 2017-18, and patterns in crossing structure use also varied relative to the previous winter. While the number of mule deer success movements at the North Overpass remained high relative to other crossing structures through both post-construction winters, this was the only location where a decrease in success movements was observed in Winter 2017-18. Meanwhile, success movements at the two adjacent structures to the north (North Underpass) and south (Middle Underpass) increased by 44% and 37%, respectively. The highest levels of mule deer activity occurred at the BVA Underpass ( $n=5,246$ ), which, in Winter 2017-18 surpassed the North Overpass as the crossing structure with the greatest number of success movements. Regardless of this variation, success rates were high at all locations and during all monitoring periods, indicating that mule deer have adapted quickly to these mitigation features.

Landscape factors may influence wildlife crossing structure use. Given the relatively homogenous nature of the project area (rolling terrain and sagebrush vegetation) and that the structure designs for the two overpasses and five underpasses were the same throughout the project, spatial variations in mule deer use of crossing structures may be due to a combination of factors, such as the location of each structure relative to where mule deer wintered, local terrain features at each structure, winter severity and snow accumulations, or variability in mineral composition and forage quality (e.g., Peterson 2008). A comparison of mule deer activity at overpass structures versus underpasses in the project area further suggest a leveling out of mule deer activity based on structure type. Whereas in Winter 2016-17 overall mule deer success movements were 138% greater at overpass structures than at underpasses on a per unit basis, in Winter 2017-18 success movements at overpasses were only 34% greater than at underpasses on a per unit basis. Overall, mule deer success movements were high at overpasses and underpasses,

and both structure types appear to function well for mule deer passage within the project area. Mule deer were also documented making success movements at all three small culverts ( $n=17$ ), although the majority of mule deer approaches to small culverts were parallel ( $n=46$ ) or repel movements ( $n=39$ ).

#### Mule Deer Preferences with Respect to Gender and Age Class

Gender and age status appeared to affect mule deer use of underpass versus overpass structures, Male mule deer may have a potential preference for underpass structures – while buck movements comprised 11-24% of total mule deer movements at the five underpass structures, bucks were only 4-7% of movements on the two overpasses. In Year 3, the research team began recording fawns as a separate category. Accordingly, the percentage of deer categorized as unknown gender decreased in Year 3. Fawn movements were recorded at all of the crossing structures and were highest at the BVA underpass ( $n=1,127$ ) and the North Overpass ( $n=734$ ) and lowest at the North Underpass ( $n=170$ ). The final report for this study will compare the ratio of bucks and does in the population to the buck:doe ratios at the crossing structures, based on photographic data taken from when antler growth is sufficient to determine gender.

#### The Diversity of Species

Movements by other ungulate species occurred in much lower numbers than mule deer. Success movements by species such as bighorn sheep, moose and pronghorn increased from Year 2 to Year 3 but decreased slightly for elk and white-tailed deer. These numbers reflect the relative proportion of these species in this landscape but are expected to increase through the duration of this research as individual animals become more comfortable with the crossing structures and as more individuals learn to use the structures. Overall success rates at wildlife crossing structures for these ungulate species ranged from 87% for moose ( $n=38$ ); 91% for elk ( $n=76$ ); 92% for white-tailed deer ( $n=39$ ); 98% for pronghorn ( $n=52$ ); and 100% for bighorn sheep ( $n=13$ ). Success movements by other large and medium-sized mammals were also detected at all the wildlife crossing structures.

Elk were photographed primarily in the northern portions of the study area, with the highest number of elk detected at the North Overpass ( $n=30$ ). In the Phase 2 segment, elk were only documented at the South Overpass ( $n=4$ ). In pre-construction monitoring, the greatest number of

elk were documented in the Phase 2 segment ( $n=66$ ) and only one elk was detected in the Phase 1 segment. Elk were not detected as often at the cameras in Year 3 when compared with the previous year and winter. In Year 3, 32 elk were detected, but none occurred during the winter months, whereas in Year 2, 34 elk were detected, and 22 of those were during the winter months. Notably, Winter 2017-18 was a mild winter and fewer elk may have been present on winter range in the lower Blue River valley. The majority of elk success movements at crossing structures have been made by individual animals or, in some cases, small groups of up to four animals. Across crossing structure locations, elk have used overpasses and underpasses in nearly equivalent numbers ( $n=32$  and  $n=37$ , respectively), although underpass structures outnumber overpasses in the study area. At this stage of the research and given the low amount of overall elk activity and the complete absence of larger groups of elk at the crossing structures, a preference for underpasses versus overpasses cannot be assessed.

Since the onset of this research, pronghorn and white-tailed deer were documented using only underpass structures, although the overall number of movements by these species are still low ( $n=52$  and  $n=39$ , respectively). Both species have been detected by the habitat camera at the North Overpass, although neither has been observed using the structure. Moose and bighorn sheep successfully used both underpass and overpass structures throughout the study area. Moose used overpasses 10 times, and underpasses 21 times. Moose movements were most common in the northern portion of the project area, with the most success movements occurring at the North Overpass and North Underpass. Bighorn Sheep movements were most common in the southern portion of the study area with most movements occurring at the South Overpass and the Williams Peak Underpass. Bighorn sheep used both overpasses a total of eight times and used underpass structures five times. Success movements at the crossing structures by bighorn sheep included both movements by individuals and use by a family group, documenting use by both genders and all age groups.

In addition to ungulates, a diversity of carnivore species was also photographed using the crossing structures and provide some evidence of taxa-specific preferences. Coyote and red fox were the only species other than mule deer documented using every crossing structure. The high number of coyote passages at the South Overpass ( $n=420$ ) may suggest that one or several

individuals have incorporated the overpass into their home ranges and are making regular movements to either side of the highway, although such use cannot be confirmed by this study.

Black bear activity was concentrated at the Middle Underpass, with 106 success movements – it is likely these were primarily by the several individuals moving regularly back and forth at this location. This structure is located in an ephemeral drainage with a more diverse and complex vegetation component than the other crossing structures. This diversity may help explain why this structure had the highest level of carnivore species use of all the structures. No black bear movements were detected at either of the overpass structures, suggesting a potential preference for the underpass structures.

Success movements at the small culverts were made primarily by carnivore species, including black bear, bobcat, coyote and red fox. The greatest species diversity is documented at the Culbreath Box culvert; however, the greatest number of success movements occurred at the BVR Box Culvert ( $n=94$ , including black bear, bobcat, coyote and mule deer). Domestic cats and dogs were most commonly photographed using the Culbreath Box Culvert, which is near a private ranch and home site, and may affect wildlife use of this culvert.

## Wildlife Activity at Other Mitigation Features

### Wildlife Guards

From Year 2 to Year 3, the total number times mule deer attempted to breach the wildlife guards decreased by 30% and the number of successful breaches decreased 68% to a total of 23 breaches at all guard types. In Year 3, breach rates were nearly the same at both guard types (9% for round bar guards and 8% for flat bar guards), although the total number of breaches by ungulate species was higher at round bar guards ( $n=20$ ) than at flat bar guards ( $n=9$ ). In addition, regardless of guard type, jumping the guard was the most common method of breaching a guard, both in the general analysis and in the paired guard analysis. In contrast with Year 2, walking on snow packed in-between the bars was the most common method of breaching a guard, yet in Year 3, no breach events of this type were recorded. This may be attributed to more mild winter conditions or to conversations with plow drivers to bring their attention to this issue. In the Year 2 progress report the authors speculated that the round bars may prevent deer from breaching by

walking on top of the bars. However, in Year 3, four breach movements were documented of deer walking on top of the round bars and two of deer walking on the support beams, despite the presence of angle iron on the support beams of the round bar guards.

Carnivore species continued to have the highest breach rates regardless of guard type. The wildlife guards are designed to primarily target ungulates (the species most frequently involved in WVC) to prevent them from entering the fenced right-of-way, and breaches by non-ungulate species are unsurprising, as their paws can more easily traverse the guards. In addition, these species were more likely to be documented breaching the guards both to get into or out of the right-of-way.

#### Escape Ramps

While fewer mule deer movements were detected in Year 3 than in Year 2 inside of the right-of-way at the escape ramps and no elk movements were detected, there were still 279 mule deer movements at the ramps in Year 3, demonstrating that animals continued to get on the right-of-way side of the wildlife exclusion fence. Mule deer were documented at all 11 monitored ramp locations across the project area in Year 3, suggesting that there were multiple points of entry into the fenced right-of-way in different portions of the project area.

Overall, there was a large variation in mule deer activity ( $n=1-135$ ) and intercept rates (0-100%) by location. Ramps without perpendicular rail fence had a higher intercept rate (61%) than ramps with perpendicular rail fence (36%), while ramp slope appeared to have less influence on mule deer intercept rates. As elk were not detected at most ramps and were only present in high numbers at one escape ramp, ramp location relative to elk presence in the landscape appears to be the greatest factor influencing intercept rates for elk.

Mule deer and elk escape rates off the ramps were comparatively low, and results were mixed with respect to the two different slope designs and the presence of perpendicular rail fences. The presence of perpendicular rail fence regardless of ramp slope did not have a discernable influence on escape rates for mule deer as both ramps with and without rail fence had escape rates of 13%. However, in the paired ramp analysis, both intercept rates and escape rates for

mule deer were higher at the two new 3:1 slope ramps without rail fence than at the two older 2:1 slope ramps with rail fence. Overall, these preliminary results suggest that multiple variables may influence both intercept rates and escape rates, including 1) species; 2) species activity in the landscape; 3) ramp location; 4) landscape situation relative to the roadway; 5) ramp slope; and 6) presence or absence of perpendicular rail fence. These variables will continue to be evaluated through this research.

The number of times mule deer and elk used the monitored escape ramps to escape to the habitat side of the wildlife exclusion fence, ( $n=53$ ), was a small fraction of the total number of times they were photographed at the ramps in the right-of-way ( $n=816$ ). These results are typical of other study results (Cramer, unpublished data; Arizona Game and Fish Department, unpublished data). As time goes on, mule deer and elk may adapt to the ramps and use them more often, but the best result would be a lowered number of deer in the right-of-way.

In addition to mule deer and elk, bighorn sheep, moose and white-tailed deer were documented by the cameras on the habitat side of the fence line. The high number of parallel movements by these species indicate that animals had many opportunities to breach the wildlife exclusion fencing by jumping up from the back side of a ramp, but no such attempts were made, suggesting that the ramp height of six feet is sufficient in discouraging a jump up attempt by deer or elk. However, given the low escape rates even at ramps with higher intercept rates, the six-foot ramp height may be too high to encourage successful escapes.

#### South Fence End

Mule deer and elk movements captured by the cameras at the fence end indicate there may still be a problem with animals moving into the fenced right of way section of the highway, and with animals in this area finding and using the wildlife crossing structures farther to the north. The total number of ungulate movements at the south fence end increased 40% from Winter 2016-17 to Winter 2017-18. While the total number of ungulate movements into the fenced right-of-way were low in Winter 2017-18 ( $n=34$ ), in Winter 2016-17 there were only nine such movements, representing a 278% increase. More mule deer were documented entering the fenced right-of-

way than were captured exiting it, although some of these movements in both directions appear to have been made repeatedly by the same individuals.

As in the previous year, the vast majority of ungulate movements at the south fence end occurred beyond the fence end (91%); that is animals that approached and potentially crossed the highway at-grade without entering into the fenced right-of-way. Most of these movements were made by mule deer ( $n=619$ ), although elk were also photographed beyond the fence end ( $n=95$ ). In several cases, the cameras documented a group of animals approaching the road and repelling several times before either finally making a successful at-grade highway crossing or completely repelling from the highway.

Ongoing and increasing ungulate activity at the south fence end may indicate that wildlife-highway mitigation is not fully capturing the wildlife crossing zone on SH 9. These findings are consistent with CPW's understanding of wildlife movements in the lower Blue River valley prior to the mitigation construction; however, there was no obvious location for an additional wildlife crossing structure south of this location, so the design team opted to end the wildlife fence at MP 126.6 rather than risk blocking wildlife movements with additional wildlife exclusion fencing along this section of SH 9.

### Wildlife-vehicle Collisions

Each of the WVC carcass and accident datasets demonstrate a decreasing trend in WVC following the completion of mitigation construction in the SH 9 project area, although accident data through Winter 2017-18 are not yet available from CDOT Traffic and Safety. Within the project area, WVC carcasses decreased 89% in Winter 2017-18 compared to the five-year pre-construction average (based on BVR/CPW carcass data). This decrease is slightly greater than the 86% decrease reported the previous winter. These results support the assertion that wildlife crossing structures and other mitigation features have been effective in reducing WVC along SH 9, while also providing wildlife connectivity across the highway.

The BVR/CPW carcass reporting is the only source to document WVC carcasses inside the project area during Winter 2017-18. No WVCs were documented in either the CDOT

Maintenance carcass dataset or the CDOT Traffic and Safety accident database. However, as described in the Year 2 progress report (Kintsch et al. 2018), only 18% of the WVC carcasses recorded by BVR/CPW were captured in Traffic and Safety accident reports, and 68% were captured in the CDOT Maintenance carcass database.

The CDOT Maintenance carcass databased demonstrates that WVCs continued to occur beyond the fence ends, particularly south of the project area, but do not appear to be increasing. These results may suggest that wildlife-highway mitigation on SH 9 is not completely capturing the WVC hotspot. Still, there was no increase in WVC carcasses at the south fence end and terminating the mitigation at this location does not appear to have affected WVC rates south of the project area. Further analysis through the next two years of this research study will help to determine whether there are additional mitigation needs south of the project area.

As of Year 3 of this research, the wildlife-highway mitigation on SH 9 does not appear to be influencing WVC rates on US 40. Wildlife-vehicle collision carcasses on US 40 were relatively high in Winter 2010-11 and again in Winter 2015-16, the latter timeframe corresponding with construction of Phase 1 mitigation on SH 9. However, in Winter 2016-17 and Winter 2017-18 WVC rates on US 40 dropped again. These variations in WVC rates on US 40 may be due to a number of factors, such as annual weather and snow depths, traffic volumes and human activity in the landscape.

### Next Steps

The results from the first three years of monitoring on SH 9 are promising and several performance measures for the mitigation project regarding mule deer use of crossing structures have already been achieved. Other objectives, for example, regarding elk use of crossing structures or mule deer use of escape ramps, have not yet been achieved, but will continue to be monitored and evaluated. The research team will continue post-construction monitoring through Winter 2019-20 and will continue to provide recommendations to adaptively manage the mitigation as appropriate. The results of this study are expected to inform future wildlife-highway mitigation projects in Colorado and beyond.

## APPENDICES

### Appendix A: Monitoring Methods

Mitigation effectiveness was measured with two general types of measures: the number of movements made by mule deer, elk and other wildlife through the crossing structures and success vs. repel rates for each species; and the reduction in WVC. The research methods used to evaluate these measures are presented below.

#### Camera Monitoring

Monitoring locations are listed in Table 1; Figures 1 & 2 depict the locations of all monitoring sites across the project area. Monitoring was conducted in three discrete phases:

*Pre-construction:* From November 2014 to the onset of mitigation construction in April 2015. Pre-construction camera monitoring was conducted by CPW at all crossing structure locations. At each location, a camera was set up on either side of the highway.

*Pre-completion:* From the onset of this research study (December 2015) through the completion of Phase 2 construction (November 2016). Pre-completion monitoring involved the deployment of 40 cameras at 24 locations. Pre-completion monitoring was conducted by the ECO-resolutions team with support from CPW.

*Post-construction:* Following the completion of all construction activities (December 2016) through Winter 2019-20. During Year 3, post-construction monitoring involved the deployment of 62 cameras at 49 locations. Post-construction monitoring is being conducted by the ECO-resolutions team with support from CPW.

Monitoring was conducted using motion-triggered Reconyx Professional Series cameras (PC800 and PC900). Cameras were installed on T-posts using a U-bolt system and Reconyx security boxes. Where cameras were placed in areas with human activity or visible from the roadside, the cameras were mounted inside metal utility boxes to disguise the camera. All cameras were code-

locked and secured with master locks and/or cable locks. The cameras were motion-triggered and took photos day and night with a rapid-fire setting and no down time. Cameras were set to take burst of 10 photos per trigger and continued triggering as long as movement was detected. Exceptions were at wildlife guards with heavy traffic, where cameras were set to 3 or 5 photos per trigger and were scheduled to trigger only between before dusk to after dawn (from 4:30pm to 8am).

Fourteen pre-construction cameras documented species presence and relative abundance of non-mule deer species at future wildlife crossing locations during Winter 2014-15. At each future structure location, a camera was deployed on either side of SH 9 approximately 50' (15 m) from the highway. Prior to the construction of the wildlife crossing structures and wildlife exclusion fence, wildlife could cross SH 9 at any point along the highway rather than at discrete crossing locations. Therefore, pre-construction monitoring could only capture a snapshot of this dispersed wildlife activity near the roadway. The objective of pre-construction monitoring was to compare species that were present near the roadway prior to mitigation construction with their relative abundance post-mitigation construction. Accordingly, species presence for all non-mule deer species was tallied without a categorization of animal behavior. Movements across SH 9 or repel movements from the highway right-of-way were not captured in pre-construction monitoring.

For post-construction monitoring, cameras were set up at each monitoring location to maximize capture rates and wildlife responses to the mitigation features. At crossing structures, cameras were placed to capture wildlife behavior at the entrance of the structure to distinguish success movements (passage through a crossing structure) from repels and parallel movements. Two cameras were placed at each arch underpass, at opposite corners. In addition, a habitat camera was placed on one side of each underpass, 50-100 feet from the structure entrance, directed toward the habitat facing away from the road (Fig. A-1). The two overpass structures have steep entrance slopes leading to the top of the structures, so in addition to the two cameras on top of each structure, additional cameras were placed at the bottom of the slopes on either side of the structure. These 'entrance' cameras were more likely to capture repels and parallel movements, while the structure cameras could be used to confirm through-passage. Habitat cameras were placed on each side of the overpass facing outward to capture wildlife movements in the adjacent habitat.

*Figure A-1.* Two cameras were positioned at each underpass at opposite corners (left). Habitat camera placed 50-100 feet in front of a structure, facing out into the adjacent habitat (right).

Cameras at other monitoring locations were positioned to capture specific wildlife behaviors. At wildlife guards and pedestrian walk-through gates, cameras were placed to capture wildlife behavior in front of the guard or walk through gate (e.g., approaches, repels and breaches). All wildlife guard cameras were set to 5 pictures per trigger and locations with high vehicular traffic were programmed to be off from 8am – 4:30pm Mountain Standard Time year-round.

Cameras were deployed at 13 wildlife guard locations for varying amounts of time. Flat bar guards were installed at all locations during Phase 1 construction. In Phase 2, round bar guards were installed at five locations, including replacement of two flat bar guards that had been previously installed in the Phase 1 segment. Flat bar guards were installed at all remaining sites. Four round bar wildlife guards were installed at locations in close proximity to flat bar wildlife guards. These pairings will help in evaluating wildlife responses to the wildlife guards where the motivations for breaching or repelling from the guards are expected to be similar, thereby helping to minimize confounding factors that may influence guard effectiveness. Wildlife guards are just under 16' long with the bars spaced 4" apart, and of varying widths, corresponding to the width of the road or driveway. The size of the wildlife guards and the spacing between bars is the same for both the flat bar and round bar designs.

Two cameras were set up at each monitored escape ramp, one at the base of the ramp to capture wildlife approaching the ramp or walking around the ramp; and one on the habitat side to capture

wildlife at the top of the ramp, including successful jump downs as well as jump up attempts from the habitat side onto the ramp. Through Year 3, 13 escape ramps have been monitored for varying lengths of time. In the Phase 1 (north) segment, all ramps were constructed with a 2:1 slope and perpendicular rail fence, except for the North Overpass Escape Ramp, on which rail fence was not constructed. Based on preliminary observations and recommendations by the research team, during Phase 2 construction all ramps were constructed with a 3:1 slope instead of a 2:1 slope (Fig. 24). In general, ramps were constructed with perpendicular rail fence, except for select locations where rail fence was omitted per the request of the researchers, who wanted to evaluate the effectiveness of ramps with and without perpendicular rail fence. In addition, two new 3:1 slope escape ramps were constructed in the Phase 1 segment near existing 2:1 slope ramps. These two ramps are also situated at lower topographic positions relative to the roadway, while the 2:1 slope ramps are at higher topographic positions above the roadway. All of the ramps built in both construction phases are six feet high at the jumping off point, with a 16' wide fence gap.

*Figure 30.* Example of an escape ramp with a 2:1 slope with perpendicular rail fence (left) and a ramp with a 3:1 slope with no rail fence (right).

At the south fence end, cameras were positioned to capture both wildlife movements into and out of the fenced right-of way, as well as movements that occurred beyond the fence end.

## Photo Analysis

Cameras were visited every 4-5 weeks during the winter months and every 6-8 weeks the rest of the year to exchange memory cards and batteries. Photo data were systematically processed to identify movement events every time a camera is triggered. Events are defined by the movements of individuals or groups at crossing structures, wildlife guards, escape ramps, pedestrian gates, and the fence end. Events were defined as 15-minute time periods based on the methodology developed by Cramer (2012) because animals typically leave the camera area within 15 minutes. For each 15-minute timeframe, if an animal approached a structure multiple times without crossing, this was considered a single event until the animal crossed, repelled, or the 15-minute period ended, in which case a new event would be recorded. Events at all monitoring locations were recorded in a SQL database created for this research.

All events were categorized by time of day according to three time periods: day, night, and dawn/dusk. To account for the changes in the timing of dawn and dusk throughout the year, time of day was determined by the images themselves – color photos are taken during the day; black and white photos are taken at night; and black and white photos taken at dawn and dusk appear with a lighter background.

For each event at a crossing structure, the researchers identified, by species, the number of individuals and their gender (if possible), the direction of the movement, and their response to the crossing structure: through passage (success), repel or parallel movement. These were defined as follows:

*Success* – Movement all the way through the crossing structure.

*Repel* – Initial movements near the entrance to the crossing structure that resulted in the animal turning away from the structure rather than passing through.

*Parallel* – Animals moved near the structure but were either headed in a direction beyond the structure entrance or were grazing on vegetation, with behaviors that were not indicative of attempts to use the structure.

Total Movements were calculated for each wildlife crossing structure as,

$$\text{Total Movements} = \text{Success Movements} + \text{Repel Movements} + \text{Parallel Movements}$$

Unique movements by individual deer were tallied only once, even when two cameras recorded the movement. Individual repel and parallel movements were tallied only once when the same deer moved in front of a camera multiple times in a 15-minute event period.

Numbers for all non-mule deer species were tallied at the habitat cameras directed toward the habitat facing away from the road. Tallying species presence at habitat cameras allows comparisons of species composition and abundance in the habitat near a crossing structure with the species successfully using the crossing structure. Since these cameras are only meant to document species presence and abundance, the photos are analyzed without a categorization of animal behavior.

Three small culverts were monitored, including two 8' x 8' box culverts and one 8' diameter concrete pipe culvert. The pipe culvert also had an open-top concrete trench at the outlet, effectively increasing the structure length. One camera was placed at either the east or west entrance of each culvert. Success movements at small culverts were tallied when an animal entered and did not reemerge from the culvert within 15 minutes, or when an animal emerged from the culvert without previously having entered it.

At wildlife guards, animal movements were categorized as a breach, repel or parallel movement. A breach movement occurred when an animal jumped or walked over the guard or, by another method, was able to move from the habitat side of the guard into the highway right-of-way or vice versa. At escape ramps, four different types of movement were recorded, 1) animals walking along the fence line inside the right-of-way that did not ascend (intercept) the ramp, but instead walked around the base of the ramp; 2) animals that ascended the ramp and then turned back down the ramp inside the right-of-way; 3) animals that ascended the ramp and jumped down (escaped) to the habitat side; and 4) animals that attempted to climb or jump up to the top of the ramp from the habitat side. At the fence end, individual movements were categorized as movements into the fenced right-of-way, movements from the fenced-right-of way out to the adjacent habitat, or movements that occurred beyond the fence end.

The following indices were calculated for each monitoring location, as applicable. These indices were then used to evaluate performance as described below under *Performance Measures*.

- **Success rate** – For each species at a given crossing structure location, the total number of individual movements of the species that were recorded moving through the structure divided by the total movements by that species.
- **Repel rate** – For each species at a given crossing structure location, the total number of individual movements of the species that were recorded being repelled at a structure divided by the total movements by that species. Repel rate was also calculated for deer and elk at wildlife guards, pedestrian walk-through gates and fence ends. In these cases, a repel movement is the desired wildlife behavior response to the mitigation features, i.e., the total number of times deer/elk were repelled divided by the total number of times deer/elk approached the mitigation feature.
- **Parallel rate** – For each species at a given monitoring location, the total number of individual movements of the species that were recorded moving parallel to the mitigation feature divided by the total movements by that species. This metric is calculated for crossing structures, escape ramps, and pedestrian walk-through gates.
- **Intercept rate** – This metric is calculated for deer and elk at escape ramps. It is the total number of times deer/elk were recorded ascending an escape ramp divided by the number of times deer/elk approached an escape ramp.
- **Escape rate** – This metric is calculated for deer and elk at escape ramps. It is the total number of times deer/elk were recorded successfully jumping down from an escape ramp divided by the number of times cameras captured deer/elk walking up the escape ramp.
- **Breach rate** – This metric is calculated for deer and elk at wildlife guards, escape ramps, pedestrian walk-through gates, and fence ends. It is the total number of times individual deer/elk breached the mitigation feature divided by the total number of times deer/elk approached that mitigation feature. For example, at a wildlife guard, breaches occur when animals cross over the guard; at escape ramps, breaches occur when animals jump up onto an escape ramp from the habitat side of the wildlife exclusion fencing; at a pedestrian walk-through gate, breaches occur when animals pass through the gate; at the fence end, breaches occur when animals enter into the fenced right-of way from beyond the fence end.

- **Average deer per day** – The total number of unique deer movements (not individuals) observed at the structure divided by the sampling effort. Sampling effort is calculated as the number of days a camera was in operation (or the average number of days for locations with two cameras) and is useful for standardizing the number of mule deer photographed when there is variation in the number of days that cameras were in operation at different monitoring locations. Deer per day may also be calculated for wildlife guards.
- **Average successful deer passages per day** – The total number of times deer successfully used a structure divided by sampling effort.

### Wildlife-Vehicle Collision Data Analysis

Wildlife-vehicle collision rates were analyzed using three independent datasets – WVC carcass data compiled by BVR and CPW; WVC carcass data recorded by CDOT maintenance patrols; and WVC accident reports compiled from law enforcement by CDOT Traffic and Safety. Blue Valley Ranch staff have recorded WVC carcass data north of Spring Creek Road (MP 128.5) to the town of Kremmling (MP 138) since 2005 and will continue to report these data through the duration of this research study; however, the 2005 data do not include month or day, and these data were excluded from further analysis. To complement these data, in 2013 CPW also began collecting carcass data south of Spring Creek Road to the southern end of the project area (MP 126). Carcass data were collected daily from November through April, when WVC are most common, with incidental reports compiled through the remainder of the year. Data collection included all species, with a focus on ungulates and large and medium-sized animals.

CDOT maintenance patrols have been recording carcasses due to WVC since 2005. Carcass reporting by maintenance personnel is non-compulsory. It is likely that reporting effort in the first years of the program was inconsistent. As the program became more established, reporting effort is believed to have become more consistent. WVC carcass pickups are reported year-round for all species, although the majority of carcass reports are deer and elk.

The study is also examining WVC accident reports compiled by CDOT Traffic and Safety. Wildlife-vehicle collision crashes, while underreported, are reported statewide and offer a useful standard for comparing WVC accident rates inside the project area with those outside of the

project area pre- and post-mitigation construction. The Year 3 progress report includes WVC accident data analysis through April 2017, as data for late 2017 and 2018 were not available at the writing of this report.

Winter was defined as the months of December through April for all analyses. Analyses of all three datasets focused on the winter timeframe; however, non-winter months were included in the analysis of reported WVC accidents to demonstrate the seasonality of WVC in the project area. Each WVC dataset was analyzed with respect to the date and location of WVC, and the species involved in these collisions. For this progress report, the researchers compared the five-year pre-construction WVC averages (Winter 2010-11 through Winter 2014-15) for each dataset with post-construction WVC rates.

Because CDOT maintenance reports are collected statewide, this dataset was selected for additional analyses of SH 9 one mile north and south of the project area and on a nearby segment of US 40 to identify a potential influence of the project on WVC rates beyond the project area. Both segments of highway are maintained by the same CDOT patrol eliminating potential data collection variations that may occur between patrols. Comparing WVC rates inside the project area with those beyond the project area, but within habitat used by the same ungulate herds and affected by the same weather patterns, helped the researchers to generalize reasons for potential changes in WVC in time and space, and the extent to which these changes may be due to the mitigation project. An increase in WVC from an annual baseline outside of the project area with a corresponding decrease in the mitigated area may suggest a shift in wildlife movement around the mitigated segment.

### Performance Measures

Performance measures allow an evaluation of how well the wildlife mitigation accomplishes stated objectives of a highway improvement project. These measures help agencies take adaptive management actions to increase the effectiveness of the mitigation, or to inform future mitigation projects in other locations. It is essential to define measurable performance measures at the outset of a project to objectively evaluate project success. The wildlife mitigation system on SH 9 is evaluated with respect to wildlife connectivity and traffic safety. Specifically, wildlife

connectivity performance measures address how well the crossing structures allow wildlife populations to access habitat on both sides of the highway; and traffic safety performance measures address how well the mitigation reduced WVC. Performance measures were generated by the researchers in conjunction with the research Study Panel.

The research team and study panel re-evaluated the performance measures following the first winter of post-construction monitoring (Winter 2016-17) in light of preliminary research results and recently published reports from comparable studies. No alterations were made to success thresholds established in Year 1 of the study. The team considered adding a measure evaluating intercept rates at escape ramps, but ultimately declined to do so; however, the team will report on intercept rates and escape rates at escape ramps. Performance Measure #12, which evaluates pedestrian walk-through gates, was eliminated as the walk-through gates were closed off with swing gates in Fall 2017. The research team observed deer breaching the gates – in some cases moving back from the ROW side to the habitat side, as well as breaches into the ROW – and CPW determined that these gaps should be closed. No additional changes to the performance measures will be made for the duration of the study to ensure that the measures remain unbiased by the study results.

#### Wildlife Connectivity Performance Measures

Wildlife connectivity is assessed for large and meso mammal species. To evaluate how well the wildlife crossing structures facilitate species' use, performance measures are based on two rates: 1) success rates, and 2) the number of movements recorded through or over structures per year for each species (movements/year).

#### *Success Rates*

*1. Mule deer success rate at each structure will be a minimum of 60%, and have a goal of 80% success during the final year of the study (based on Montana - Cramer and Hamlin 2016; Utah – Cramer 2014, 2016; Wyoming – Sawyer et al. 2012).*

*2. Elk success rate at each structure will be a minimum of 60%, and have a goal of 75% success during the final year of the study (based on Arizona – Gagnon et al. 2011).*

3. *Success rate for all meso to large mammal species (other than deer and elk) detected near each structure will be a minimum of 60%, and have a goal of 80% success for each structure during the final year of the study (based on Montana – Purdum 2013).*

#### *Movements per Year*

4. *By the end of the study, male and female mule deer movements through all crossing structures will be in the same male:female proportions as are estimated for the local population (based on population estimates as determined by CPW).*

5. *By the end of the study, male and female elk movements through all crossing structures will be in the same male:female proportions as estimated for the local population (based on population estimates as determined by CPW).*

6. *By the end of the study, the number of elk success movements at all structures annually, will be at least 50% of the number of elk movements captured at associated habitat cameras (i.e., documenting animals in the vicinity of the structures, but not necessarily using structures), irrespective of season (based on Arizona – Gagnon et al. 2011).*

7. *Each year there will be an increase in the number of mule deer movements at wildlife crossing structures annually until an overall equilibrium/plateau is reached (based on Arizona – Gagnon et al. 2011; Dodd et al. 2012; Utah – Cramer 2016; Montana – Cramer and Hamlin 2016).*

8. *Each year there will be an increase in the number of elk movements at wildlife crossing structures annually until an overall equilibrium/plateau is reached (based on Arizona- Gagnon et al. 2011; Dodd et al. 2012; Utah - Cramer 2016; Montana - Cramer and Hamlin 2016).*

9. *Each year, there will be at least one to several successful movements through or over crossing structures for every one of the less common species of large ungulates and carnivores in the study area that are documented by the habitat cameras. This may include bighorn sheep, pronghorn, moose, white-tailed deer (*Odocoileus virginianus*), mountain lion, black bear, bobcat, and other species (Utah – Cramer 2016; Montana – Cramer and Hamlin 2016).*

10. *By the end of the study, at least 80% of the individual mule deer, elk and other ungulate approaches to each wildlife guard will be deterred from entering the road right-of-way (based on Utah – Cramer and Flower 2017; Flower 2016).*

*11. By the end of the study, 50% of the individual mule deer and elk that ascend an escape ramp will escape to the habitat side, and no animals will jump up onto the ramp from the habitat side. (based on Arizona – Arizona Game and Fish Department, unpublished data; Colorado – Siemers et al. 2015).*

*12. By the end of the study, 100% of the individual mule deer and elk approaches to each pedestrian walk-through gate will be deterred from entering the road right-of-way. This performance measure will no longer be evaluated. In Year 2, breach rates for mule deer at the pedestrian walk-through gates ranged from 5-21% (Kintsch et al. 2018). In total, 32 breaches were made by mule deer and 2 by elk out of total of 304 and 47 movements, respectively. CPW determined that these breaches – and potential WVC – could be eliminated entirely with the installation of swing gates across the gate openings. By September 2017, all of the pedestrian walk-through gates in the project area were equipped with swing gates to block ungulate movements and monitoring activities ceased at these locations.*

*13. By the end of the study, the proportion of ungulate movements at the south fence end that enter into the fenced right-of-way will decrease to 20% or less (based on Utah – Cramer unpublished data, 2016).*

#### Traffic Safety Performance Measures

Traffic safety performance measures evaluate how well the wildlife mitigation reduced wildlife-vehicle collisions. This is measured with reported crashes and carcasses.

*14. The annual average number of WVC reported crashes (CDOT Traffic and Safety data) within the mitigated area of the study will decrease by at least 80% during the final two years of the study when compared to the five-year pre-construction average (based on Alberta, Canada – Clevenger and Barrueto 2014; Wyoming – Sawyer et al. 2012; compiled study – Huijser et al. 2009).*

*15. The annual average number of wildlife carcasses reported by Blue Valley Ranch and Colorado Parks and Wildlife within the mitigated area of the study will decrease by at least 80% during the final two years of the study when compared to the five-year pre-construction average (based on Alberta, Canada - Clevenger and Barrueto 2014; Arizona – Gagnon et al. 2015; Washington – McAllister et al. 2013).*

16. *By the last year of the study, the average annual number of WVC reported crashes within one mile south of the south fence end will not increase over the five-year average annual pre-construction crash rate for this section of road (based on Arizona – Gagnon et al. 2015; Wyoming – Sawyer et al. 2012).*

## Appendix B: Pre-Construction Monitoring Results

Mule deer were observed at all locations during pre-construction monitoring. Given their pervasiveness in the project area, mule deer presence and abundance was not tallied. Of all other wildlife species, elk and coyote were the most commonly documented species (Table B-1). Elk were most common in the southern portions of the project area, at the future sites of Williams Peak Underpass and the South Overpass. In the northern portion of the project area, bobcat was the most commonly documented species (other than mule deer) and occurred only at the future North Underpass site. Other species detected during pre-construction monitoring included red fox, American badger, hare/rabbit, striped skunk, and domestic dogs and cats.

**Table B-1.** Wildlife presence by species other than mule deer during pre-construction at future wildlife crossing structure locations. Pre-construction monitoring was conducted at all locations from November 2014 – March 2015. Additional pre-construction monitoring was conducted in the Phase 2 (south) segment during Winter 2015-16.

Monitoring Location	Elk	Moose	Pronghorn	Mountain Lion	Bobcat	Coyote
<b>Phase 1 (North) Segment</b>						
MP 136.0 – North Underpass	1	0	0	0	26	10
MP 134.3 – North Overpass	0	0	0	0	0	0
MP 132.5 – Middle Underpass	0	0	0	0	0	0

**Abstract:** *One potential contributor to the worldwide decline of bird populations is the increasing prevalence of roads, which have several negative effects on birds and other vertebrates. We synthesized the results of studies and reviews that explore the effects of roads on birds with an emphasis on paved roads. The well-known direct effects of roads on birds include habitat loss and fragmentation, vehicle-caused mortality, pollution, and poisoning. Nevertheless, indirect effects may exert a greater influence on bird populations. These effects include noise, artificial light, barriers to movement, and edges associated with roads. Moreover, indirect and direct effects may act synergistically to cause decreases in population density and species richness. Of the many effects of roads, it appears that road mortality and traffic noise may have the most substantial effects on birds relative to other effects and taxonomic groups. Potential measures for mitigating the detrimental effects of roads include noise-reduction strategies and changes to roadway lighting and vegetation and traffic flow. Road networks and traffic volumes are projected to increase in many countries around the world. Increasing habitat loss and fragmentation and predicted species distribution shifts due to climate change are likely to compound the overall effects of roads on birds.*

**Keywords:** bird populations, roads, road mortality, roadway lighting, surface transportation, traffic noise

Efectos de las Redes de Caminos sobre Poblaciones de Aves

**Resumen:** *El incremento en la prevalencia de caminos, que han tenido varios efectos negativos sobre aves y otros vertebrados, es un potencial contribuyente a la declinación mundial de poblaciones de aves. Sintetizamos los resultados de estudios y revisiones que exploran los efectos de los caminos sobre las aves, con énfasis en caminos pavimentados. Los bien conocidos efectos directos de los caminos sobre las aves incluyen la pérdida y fragmentación de hábitat, mortalidad causada por vehículos y envenenamiento. Sin embargo, los efectos indirectos pueden ejercer una mayor influencia sobre poblaciones de aves. Estos efectos incluyen ruido, luz artificial, barreras al movimiento y bordes asociados con caminos. Más aun, los efectos indirectos y directos pueden actuar sinérgicamente para causar decrementos en la densidad poblacional y en la riqueza de especies. De los muchos efectos de los caminos, parece que la mortalidad y el ruido del tráfico tienen los efectos más significativos sobre las aves en relación con otros efectos y grupos taxonómicos. Las medidas potenciales para mitigar los efectos perjudiciales de los caminos incluyen estrategias de reducción de ruido y cambios en la iluminación y vegetación de los caminos y en el flujo de tráfico. Se proyecta que las redes de caminos y los volúmenes de tráfico incrementen en muchos países en el mundo. Es probable que el incremento en la pérdida y fragmentación de hábitat y los cambios pronosticados en la distribución de especies debidos al cambio climático compliquen los efectos de los caminos sobre las aves.*

**Palabras Clave:** caminos, iluminación en caminos, poblaciones de aves, mortalidad en caminos, ruido de tráfico, transportación terrestre

## Introduction

Bird populations are declining around the world (BirdLife International 2008a). In North America the abundances

of at least 20 species previously categorized as common have declined more than 50% in the last 40 years (Butcher & Niven 2007; BirdLife International 2008b). Additionally, abundances of over half the species of Neotropical

‡email [angela.kociolek@coe.montana.edu](mailto:angela.kociolek@coe.montana.edu)

Paper submitted March 16, 2010; revised manuscript accepted August 6, 2010.

migrants have declined substantially. The reasons for these declines are not fully understood (Butcher & Niven 2007; BirdLife International 2008c). One likely contributor is the expansion of paved roads, mostly in terms of widening (National Research Council 2005), and corresponding increases in the speed and volume of vehicles on those roads (Ritters & Wickham 2003). We synthesized these effects on birds to balance the much greater attention that has hitherto been paid to the effects of roads on mammals and to examine the potentially negative effects of roads on birds worldwide.

Reduced breeding success is correlated with proximity of birds to roads and road density for species ranging from passerines (Catchpole & Phillips 1992; Reijnen & Foppen 1994) to vultures (Donazar et al. 1993). In some cases, avian communities adjacent to roads differ from nearby avian communities (Glennon & Porter 2005), presumably because of some combination of the direct and indirect effects of roads on animals in general (Forman & Alexander 1998; Trombulak & Frissell 2000; Fahrig & Rytwinski 2009).

There is a little understanding of whether declines in persistence of birds are more affected by direct or indirect effects. If this could be determined in urban areas, it may be possible to increase bird abundance and species richness. It is also important to identify and mitigate any negative road effects in protected areas, which are assumed to buffer populations of wild animals from human activities.

Many of the negative effects of roads on other vertebrates (e.g., mortality, habitat fragmentation, and audiovisual disturbance, chemical pollution) also apply to birds (Forman et al. 2003; Jacobson 2005). There are a few ways roads can benefit birds. For example, roads retain heat that can reduce metabolic costs for birds that rest on road surfaces (Whitford 1985), associated road infrastructure (e.g., poles and bridges) can create nesting sites (Forman 2000), and verges increase availability of food sources (Lambertucci et al. 2009) and link patches of habitat (Meunier et al. 1999; Huijser & Clevenger 2006; Reijnen & Foppen 2006). We reviewed recent reports and peer-reviewed articles focused primarily on direct and indirect negative effects of roads on bird populations and identified some potential forms of mitigation. Much of the literature we reviewed concerns paved roads because they have been the subject of more study and because their ecological effects are assumed to be greater than gravel, dirt, or ice roads (Forman et al. 2003; National Research Council 2005).

## Direct Threats Posed to Birds by Roads and Traffic

For bird populations the most visible direct negative effects of roads are habitat loss and mortality due to collisions

with vehicles. Because the effects of habitat loss on birds have been comprehensively reviewed elsewhere (Andren 1994), we did not focus on this effect here. Nonetheless, roads have other effects that are related to habitat loss. For example, maintenance activities in the right-of-way can further reduce habitat quality and destroy nests, which may reduce population viability for rare species (e.g., Burrowing Owl [*Athene cunicularia*]) (Catlin & Rosenberg 2006). We focused on the negative effects associated with vehicular traffic.

### Vehicle-Caused Mortality

For individual birds and other vertebrate groups, a direct threat of roads is death due to collisions with vehicles (Erritzoe et al. 2003). In the United States, vehicles are estimated to cause approximately 80 million bird fatalities each year (Erickson et al. 2005). Despite the high number of mortalities each year, vehicle-caused mortality has been assumed to have less of an effect on persistence than some indirect effects of roads (Forman & Alexander 1998; Reijnen & Foppen 2006). Only three bird species found in the United States appear to suffer population declines as a result of them: Florida Scrub-Jay (*Aphelocoma coerulescens*) (Mumme et al. 2000; IUCN 2008), Audubon's Crested Caracara (*Polyborus plancus audubonii*), and Hawaiian Goose (*Branta sandvicensis*) (Huijser et al. 2007; IUCN 2008). A greater understanding of what makes some species more susceptible to vehicle collision and population decline as a result of vehicle-caused mortality is needed, but some generalities emerge from the literature.

First, birds are more likely to collide with vehicles if they forage, roost, or nest near roads (Erritzoe et al. 2003; Huijser et al. 2007). Collision frequency can increase near watercourses (Erritzoe et al. 2003; Ascensao & Mira 2006) and houses (Ascensao & Mira 2006). Collisions are also more likely to occur at lower elevations (Clevenger et al. 2003) and in open areas than in forests (e.g., Clevenger et al. 2003; Ascensao & Mira 2006; Ramp et al. 2006).

Several other factors have less consistent effects on vehicle-induced bird mortality. For many species, vehicle-induced mortality increases during breeding and migration (Fulton et al. 2008; Gryz & Krause 2008), but for other species it increases during winter (Loos & Kerlinger 1993; Boves 2007). Collisions can increase (Jackson 2003) or decrease as roadside lighting increases (Hernandez 1988). Roadside trees, hedgerows, and other features that cause birds to fly higher across roads typically decrease collision frequency (Pons 2000; Bard et al. 2002; Clevenger et al. 2003; Erritzoe et al. 2003; Taylor & Goldingay 2004; Orłowski 2005), but they can also increase it (Ramp et al. 2006; Varga et al. 2006). Birds also vary in their responses to roads. Some individuals appear to learn to avoid vehicles (Mumme et al. 2000), whereas others do not (Loos & Kerlinger 1993; Jackson 2002).

It is difficult to measure the true extent of vehicle-induced mortality because estimates are typically far lower than the actual number of birds killed (Erickson et al. 2005). Estimation accuracy is reduced by variation in searcher efficiency, scavenger bias (Erickson et al. 2005; Boves 2007), and incorrect attribution of cause of death (Kerlinger & Lein 1988). Even long-term studies in which 100% of individuals are marked, researchers can fail to detect all instances of vehicle-caused mortality (Mumme et al. 2000). Vehicle collisions may also cause nonfatal injuries that increase the probability birds will die from other causes (Orlowski & Siembieda 2005). In addition, inaccurate estimates of vehicle-induced mortality can result if only carcasses are studied in the absence of data on species abundance (Hernandez 1988; Aebischer et al. 2005). Missing information about population size makes it difficult to compare rates of mortality in different areas, especially on different continents (Erritzoe et al. 2003).

### Pollution and Poisoning

Deicing agents, petroleum-based organic compounds, nutrients, sediments, agricultural chemicals, and other substances regularly run off paved roads during construction, maintenance, and use (Buckler & Granato 1999). Road salt is a common deicing agent that attracts birds. Its ingestion can lead to death, which dispels the notion that road salt has a negative effect only because it attracts birds to the road surface, making them subject to collisions with vehicles (Mineau & Brownlee 2005). Dust on unpaved roads can change the composition of vegetation (Walker & Everett 1987), which can affect birds (Kalisz & Powell 2003). Gravel roads are frequently treated with dust suppressants, the environmental and toxicological effects of which are not well understood (Fay & Kociolek 2009). Despite the ubiquity of road contaminants from vehicles and maintenance activities, toxic effects of roads appear to be rare, even in areas with high traffic volumes (Buckler & Granato 1999), and pollution appears to have fewer effects on birds than other road-related effects (Reijnen & Foppen 2006).

### Indirect Threats Posed to Birds by Roads and Traffic

Even in the absence of direct deleterious effects, many bird species appear to avoid roads purposely (e.g., Bollinger & Gavin 2004; Balbontin 2005; Gavashelishvili & McGrady 2006). Some species may be present near roads for a time, but they are more likely to abandon nests near roads (Gorog et al. 2005). For birds, road avoidance appears to be associated with the physical barrier to movement roads present, noise, artificial light, and edge effects.

### Physical Barriers

Of the indirect threats of roads, the barriers to movement roads present may have the greatest effect on vertebrates (Forman & Alexander 1998). Several forest-dwelling bird species are unlikely to cross gaps in forest cover  $\geq 50$  m in areas dominated by agriculture (Desrochers & Hannon 1997), timber harvesting (Awade & Metzger 2008), and urban infrastructure (Tremblay & St. Clair 2009). Some species exhibit reluctance to cross dirt roads that are 10–30 m wide (Develey & Stouffer 2001). Nonetheless, the barriers caused by roads may be a simple function of the width of the gap they create in the surrounding habitat, unless the roads are also noisy (St. Clair 2003; Tremblay & St. Clair 2009) or are associated with tall features such as power lines (Pruett et al. 2009).

### Noise

Traffic noise probably has the most widespread and greatest indirect effect on birds (Reijnen et al. 1995 (Table 1). Noise likely causes reductions in population densities that have been reported for several bird species that are present near roads (Reijnen & Foppen 2006; Patricelli & Blickley 2006). In grasslands the effects of noise appear to extend farther from roads than in forests (Forman et al. 2002), perhaps because grasslands have less vegetation to absorb sound. In addition to the effects of traffic volume and its associated noise, there may be synergistic effects of noise, habitat loss and fragmentation (Forman & Deblinger 2000), and edge effects (Habib et al. 2007).

Birds may be affected by anthropogenic noise because they rely extensively on acoustic communication (Table 1). Chronic industrial noise can reduce species richness, alter population age structure, and change avian predator-prey dynamics (Francis et al. 2009). Like industrial noise, chronic traffic noise appears to produce younger age structures and reduces population densities in several bird species (Reijnen & Foppen 2006). These effects may occur because anthropogenic noise masks the frequencies of calls used to attract mates (Rheindt 2003; Pohl et al. 2009), communicate with flock members (Lohr et al. 2003; Slabbekoorn & Ripmeester 2008) or offspring (Leonard & Horn 2005), defend territories (Habib et al. 2007; Mockford & Marshall 2009), and detect predators (Slabbekoorn & Ripmeester 2008; Francis et al. 2009) (Table 1). Effects of noise on both birds and anurans seem to depend on the frequencies and amplitudes of species-specific signals (Lengagne 2008; Slabbekoorn & Ripmeester 2008; Hu & Cardoso 2009). Some species seem unaffected by roads or traffic (Kaselloo 2005; Reijnen & Foppen 2006), and others may not come near roads when traffic volume is high (Bautista et al. 2004). Several urban-dwelling songbird species appear to counteract the masking effects of traffic noise (Table 1) by singing at a higher pitch (Slabbekoorn & Peet 2003), increasing song amplitude (Brumm 2004b), or singing

**Table 1. The effects of anthropogenic noise on avian communities and communication.**

<i>Category</i>	<i>Effect</i>	<i>References</i>
Community		
species richness	reduced as noise increases	Stone 2000
density & abundance (all species)	reduced as noise increases	Reijnen et al. 1995, 1996; Kuitunen et al. 1998; Bayne et al. 2008
	no overall reduction	Peris & Pescador 2004
densities & abundance (specific species)	reduced as noise increases	Reijnen & Foppen 1994; Reijnen et al. 1995, 1997
	dependent on species	Kuitunen et al. 1998; Peris & Pescador 2004
	higher abundance of birds with higher song pitch near roads	Rheindt 2003
age structure	younger at noisy sites	Reijnen & Foppen 1994; Habib et al. 2007
physiology	increased stress at higher noise levels	Campo et al. 2005
	no stress difference at higher noise levels	Byers et al., unpublished data
Breeding cycle		
pairing and mate retention	decreased time devoted to courtship behavior	Goudie & Jones 2004
	reduced pairing success	Habib et al. 2007
	reduced mate preference	Swaddle & Page 2007
territory and nest-site selection	farther from noise sources	Francis et al. 2009
nest success	increased as noise increases for some species	Francis et al. 2009
Foraging		
begging calls	reduced parental discrimination in noisy locations	Leonard & Horn 2005
prey location and probability of predation	predator reduction increases nest success in noisy locations	Francis et al. 2009
	potential alterations to interspecies interactions	Slabbekoorn & Halfwerk 2009
	increased vigilance as noise increases	Quinn et al. 2006
Communication		
temporal adjustment	sing more at night in noisy locations	Fuller et al. 2007
amplitude increase	sing louder as noise increases (Lombard effect)	Cynx et al. 1998; Brumm 2004a, 2004b; Brumm et al. 2009; Osmanski & Dooling 2009
	louder begging calls in noisy locations	Leonard & Horn 2005
pitch modification	increased pitch in noisy locations	Slabbekoorn & Peet 2003; Fernandez-Juricic et al. 2005; Slabbekoorn & den Boer-Visser 2006; Wood & Yezerinac 2006; Parris & Schneider 2009; Kirschel et al. 2009; Nemeth & Brumm 2009
redundancy	no correlation between pitch and road noise	Skiba 2000
detection of con- and heterospecific vocal signals	more repetition in noisy locations	Brumm & Slater 2006
	reduced detection probability of signals in noisy locations	Langemann et al. 1998; Lohr et al. 2003
response to signals	strongest response to played-back signals when ambient noise levels are similar to local environment	Mockford & Marshall 2009
reviews	effects of noise and implications	Patricelli & Blickley 2006; Slabbekoorn & Ripmeester 2008; Barber et al. 2010
Brain response		
gene activation	immediate early-gene ZENK expression in the neural pathway of the avian brain not modified by noise playback	Vignal et al. 2004

during periods of low traffic noise (Fuller et al. 2007). Other species may be unable to adapt their songs to accommodate chronic noise (Slabbekoorn & Ripmeester 2008; Barber et al. 2010), and pairing success of birds with relatively high amplitude songs is reduced when they are exposed to high levels of chronic noise (Habib et al. 2007).

### Artificial Light

Light from roadways can have negative effects on many animals (Rich & Longcore 2006), including birds (Ogden 1996; Van De Laar 2007). Some lighting structures attract migrating bird species, which increases the probability they will be preyed on or collide with structures and often causes them to redirect flight paths and thus deplete energy stores (van de Laar 2007). Artificial lighting can also affect avian patterns of nestling development, singing, breeding, molting, and migration (De Molenaar et al. 2006). There is some evidence that roadway lighting may reduce habitat quality and change the timing of breeding for the Black-tailed Godwit (*Limosa limosa*), a species associated with grasslands in Africa, Europe, and Asia (De Molenaar et al. 2006). American Robins (*Turdus migratorius*) sing earlier in the morning in areas with more anthropogenic light (Miller 2006), but this response may be difficult to disentangle from the associated effect of road noise, which is more important than light for explaining nocturnal singing by European Robins (*Erithacus rubecula*; Fuller et al. 2007).

### Edge Effects

Positive and negative effects of edges on breeding birds have been documented in many studies (Stephens et al. 2003). The edge effects of roads may be particularly acute when introduced species, such as rats (*Rattus rattus*), prey on ground-nesting birds (Delgado et al. 2001) or parasitic species, such as Brown-headed Cowbirds (*Molothrus ater*), target the nests of species of conservation concern (Chace et al. 2003). In some cases, these edge effects are contradictory (Bergin et al. 2000; Lariviere 2003).

### Mitigation

Paved roads are a pervasive feature across much of North America, and existing roads are being widened, new roads are being built, and, and traffic volume is increasing (Forman et al. 2003; National Research Council 2005) throughout the world (Urban Land Institute 2007; Bhattacharya 2008). Efforts to mitigate road effects are most likely to increase probabilities of persistence of birds when applied across extensive areas (Stutchbury 2009).

New information about the ubiquity of the effects of noise on birds suggests reducing road noise may be

cost-effective because it can benefit both birds and humans (Bluhm et al. 2007; Slabbekoorn & Ripmeester 2008; Barber et al. 2010). Promising measures to reduce road noise include temporal adjustments to traffic flow (Reijnen & Foppen 2006) and increased reliance on mass transit (Barber et al. 2010). The unvegetated area created by light-rail train tracks is more permeable to bird movement than roads of equivalent sizes, perhaps because they are quieter (Tremblay & St. Clair 2009). New tire designs (Carstens 2003) and noise-absorbing porous asphalt (Piepers 2001) can substantially reduce levels of highway noise (Elvik & Greibe 2003). Other noise-reducing strategies include the use of earth berms and vegetation that, unlike walls (Varga et al. 2006), do not create vertical barriers to animal movement, although this may depend on the animal. These features typically also increase quality of life and property values for human residents.

Changing roadway lighting may also benefit both birds and people through reductions in energy consumption and increases in safety (De Molenaar et al. 2006). Replacing red or white lights with green lights greatly reduces the negative effect of artificial lights on oil platforms on birds (van de Laar 2007). Such lighting could be used on highway (Poot et al. 2008).

Edge effects might be partially mitigated with vegetation management and restoration. Poisoning and non-point source pollution can be mitigated, in part, by policy aimed at encouraging use of nontoxic agents to maintain safe driving conditions. A practice that would reduce vehicle-induced bird mortality would be to refrain from planting along roadsides fruit-bearing vegetation that attracts birds.

### Future Implications

In the United States road area is expected to increase by 27,900 km<sup>2</sup> by 2030, and lanes added to existing roadways to accommodate increased traffic volume is projected to increase road area by an additional 94,100 km<sup>2</sup> (Theobald 2010). Exponential increases in the road network and traffic volume are anticipated to occur in large, densely populated, countries such as China and India (Bhattacharya 2008). Among the factors studied to date, it appears that traffic noise has the greatest potential to reduce population abundance and species richness of birds (Reijnen & Foppen 2006; Barber et al. 2010). Although vehicle-caused mortality does not appear to affect persistence for most populations, it is a problem for some species (Huijser et al. 2007) and may exacerbate other anthropogenic threats to birds (Erickson et al. 2005). Given global traffic projections and in light of losses due to collisions, road-induced mortality of birds should be examined more systematically and comprehensively. Other road-related disturbances such as light and chemical

pollution appear to have minor effects at the population level, but their spatial extent may still generate a large collective effect on birds. Finally, increasing habitat loss and fragmentation, in addition to predicted species distribution shifts due to climate change, are likely to compound the overall effect of roads (Heller & Zavaleta 2009).

## Abstract

Riparian habitats have been frequently identified as priority areas for conservation under climate change because they span climatic gradients and have cool, moist microclimates relative to surrounding areas. They are therefore expected to act as dispersal corridors for climate-induced species range shifts and to provide microclimatic refugia from warming. Despite recognition of these values, rigorous methods to identify which riparian areas are most likely to facilitate range shifts and provide refugia are currently lacking. We completed a novel analysis across the Pacific Northwest, USA, that identifies potential riparian corridors featuring characteristics expected to enhance their ability to facilitate range shifts and provide refugia. These features include large temperature gradients, high canopy cover, large relative width, low exposure to solar radiation, and low levels of human modification. These variables were used to calculate a riparian climate-corridor index using a multi-scale approach that incorporates results ranging in scale from local watersheds to the entire Pacific Northwest. Resulting index values for potential riparian corridors in the Pacific Northwest were highest within mountainous areas and lowest within relatively flat, lowland regions. We also calculated index values within ecoregions, to better identify high-value riparian climate corridors within the relatively flat, degraded areas where they may most contribute to climate adaptation. We found that high-value riparian climate-corridors are least protected in flat, lowland areas, suggesting that such corridors should be high priorities for future conservation effort. Our analysis provides critical information on valuable riparian climate-corridors to guide climate adaptation efforts (and riparian management and restoration efforts) in the Pacific Northwest, while offering a novel approach that may be applied to similar efforts in other geographies.

## Introduction

As climate change progresses and concern grows over the ability of species and ecosystems to adapt [1–2], considerable effort has been devoted to identifying areas on the landscape expected to promote biological resilience to change [3–5]. Riparian areas have been frequently

design, data collection and analysis, decision to publish, or preparation of the manuscript.

**Competing interests:** The authors have declared that no competing interests exist.

identified as important features to conserve for climate adaptation [6–9], because they span the climatic gradients species are likely to follow as they track shifting areas of climatic suitability [10–12] and contain microclimates that are significantly cooler and more humid than immediately surrounding areas [13]. For these reasons, they are expected to provide dispersal corridors for species undergoing climate-induced range shifts [7,9] and microclimatic refugia from warming for species with limited movement capacities [14,5–6]. Riparian areas may also offer especially effective conservation umbrellas under climate change, because they disproportionately contribute to regional species richness [15–16], provide habitat for many upland species as well as riparian specialists [15–16], and directly contribute to the climate resilience of adjacent freshwater aquatic habitats [17–18]. Despite this recognition, few methods have been proposed for identifying priority riparian areas for climate adaptation.

Riparian areas are frequently prioritized in conservation planning efforts (e.g., [19–20]), but there are few examples of approaches aimed at identifying those that are most likely to promote climate adaptation. Available approaches for identifying riparian corridors to promote climate-induced range shifts include a conservation planning analysis for South Africa that included riparian corridors constructed by applying a fixed buffer around rivers connecting coastal to inland habitats to promote elevational species range shifts [21]. Similarly, riparian areas associated with 2<sup>nd</sup> order streams linking the Pacific Ocean to high elevations were prioritized in a climate adaptation analysis for California, USA [22]. In another analysis, a land facet corridor analysis aimed at promoting species range shifts in Arizona, USA, connected large blocks of natural habitat using riparian corridors identified by applying a fixed buffer around expert-identified streams and riparian habitats [23]. Most of these analyses used rivers as coarse proxies for riparian habitat, and none rigorously accounted for variability in riparian area quality, which we argue strongly influences the degree to which riparian areas may facilitate range shifts and provide refugia.

To address the need for a rigorous approach to identify priority riparian areas for climate adaptation, we completed a novel analysis that identifies potential riparian corridors expected to promote the ability of biodiversity to respond to climate change. Specifically, we developed a riparian climate-corridor index to quantify the degree to which riparian areas may promote range shifts and provide refugia, identifying those riparian areas that: 1) span large temperature gradients, 2) have high levels of canopy cover, 3) are relatively wide, 4) have low solar insolation, and 5) exhibit low levels of human modification. These variables were derived from the theoretical and empirical literature on species' responses to observed and projected climatic change. For example, riparian corridors that span large climatic gradients may help promote climate-induced range shifts from warmer to cooler areas [11–12]; riparian areas are already used as movement corridors for both riparian and upland species [24–26], and those spanning climatic gradients may offer particularly effective conduits for range migration, particularly across flat, degraded landscapes [27]. The effectiveness of such corridors would be further enhanced by high levels of canopy cover and greater riparian area width, features that have been shown to increase wildlife use of riparian areas as movement corridors [25], and to help moderate temperatures within riparian areas and promote the resilience of neighboring aquatic systems [17, 28]. Riparian corridors with lower exposure to solar insolation may also feature cooler temperatures and greater moisture [13, 29], increasing their value as microclimatic refugia [30–32]. Finally, riparian corridors with lower levels of human modification are likely to be more permeable to wildlife movement [33], while also being less vulnerable to exotic species invasion and other stressors that may inhibit species movements and reduce refugia quality [34].

Because these characteristics are likely to vary by the scale of analysis, and because scales of climate-induced range shifts and microclimatic refugia are likely to vary among species and

over time [35,14], we developed a multi-scale approach to calculating riparian climate-corridor index values that incorporates results ranging in scale from local watersheds to the entire Pacific Northwest, USA. We also evaluated the protected status of riparian climate-corridors to help inform potential conservation action for maintaining riparian climate-corridor networks. Our analysis may thus provide critical information for guiding riparian management and climate adaptation efforts in the Pacific Northwest, while offering a novel approach that may be applied to similar efforts in other geographies.

## Materials and methods

### Study area

We completed our analysis for the Pacific Northwest, USA (USGS Water Resource Region 17; Fig 1). The Pacific Northwest includes a relatively cooler, moister region between the Pacific Coast and Cascade Range that is dominated by evergreen temperate forest; and a relatively drier region between the Cascade Range and Rocky Mountains that experiences more pronounced seasonality in temperature and features more diversity in vegetation types, from mixed forest at higher elevations to sagebrush-steppe in more arid lowlands.

**Fig 1. Analysis extent.** We completed our analysis for the Pacific Northwest hydrologic region (Water Resource Region 17, in dark gray).

<https://doi.org/10.1371/journal.pone.0205156.g001>

### Analysis inputs

To identify high value riparian climate-corridors, we used a map of potential riparian areas identified by Theobald et al. [36], rather than a map of riparian vegetation. The potential riparian area map identifies the physical template where the dynamics of riparian vegetation are expected to occur, based on hydrological (stream discharge) and geomorphological (valley bottom shape) information rather than the (current) presence of riparian vegetation [36]. This 30 m data layer thus provides a comprehensive and consistent estimate of potential riparian area while avoiding many of the data gaps and inconsistencies [37] associated with existing maps of riparian vegetation derived from land cover (e.g., US LANDFIRE, US Fish & Wildlife Service National Wetland Inventory), which often have difficulty distinguishing riparian from non-riparian vegetation at 30 m resolution [37]. The potential riparian area dataset also provides key additional data layers (e.g., flow direction; see below) required by our analysis.

Our analysis aimed to identify the extent to which riparian corridors span large temperature gradients, have high levels of canopy cover, are relatively wide, have low exposure to solar radiation, and exhibit low levels of human modification. Our analysis thus included the following five variables (Table 1): mean annual temperature, canopy cover, riparian area width, potential relative radiation, and landscape condition.

We calculated mean annual temperature ( $T$ ) as the 30-year mean of mean annual temperatures from 1961–1990, using a 90 m digital elevation model and the ClimateWNA tool [38], which extracts and downscales PRISM [39] monthly data and calculates climate variables for specific locations based on latitude, longitude, and elevation. For canopy cover ( $C$ ), we used the percent tree canopy cover dataset for 2011 from the National Land Cover Dataset [40, 41]. We calculated potential riparian area ( $A$ ), a measure of the width of potential riparian areas, directly from the 30 m potential riparian area data layer from Theobald et al. [36]. We used the 30 m National Elevation Dataset [42] to calculate potential relative radiation ( $R$ ), a unitless measure of solar radiation that takes into account temporal changes in solar orientation as well as topographic shading from adjacent landforms [43]; such shading has been shown to contribute to lower temperatures in complex terrain [13–14]. We used the landscape condition ( $L$ ) model [44] as a measure of the degree to which potential riparian areas have been affected by human activities. Although a more recent and higher-resolution dataset on human modification was available [45], we used  $L$  to be consistent with the Western Association of Fish and Wildlife Agencies Crucial Habitat Assessment Tool [46].

Table 1. Analysis variables and source data.

Analysis Variable	Base Layer	Base Layer Resolution	Year Represented by Base Layer	Base Layer Sources
Mean Annual Temperature ( $T$ )	PRISM Mean Annual Temperature (downscaled using Climate WNA)	90 m	1961–1990 (mean historical temperature)	Daly et al. [39] ( <a href="http://prism.oregonstate.edu/">http://prism.oregonstate.edu/</a> ), Wang et al. [38] ( <a href="http://climawna.com/">http://climawna.com/</a> )
Canopy Cover ( $C$ )	NLCD Percent Canopy Cover	30 m (resampled to 90 m using bilinear interpolation)	2011	National Land Cover Dataset [40]
Riparian Area ( $A$ )	Potential Riparian Area	90 m	2009 (digital elevation model)	Theobald et al. [36]
Potential Relative Radiation ( $R$ )	Potential Relative Radiation (calculated using digital elevation model)	30 m (resampled to 90 m using bilinear interpolation)	2009 (digital elevation model)	This study, following methods of Pierce et al. [43], and using a digital elevation model from the National Elevation Dataset ( <a href="http://ned.usgs.gov/">http://ned.usgs.gov/</a> ).
Landscape Condition ( $L$ )	Landscape Condition	270 m (resampled to 90 m using bilinear interpolation)	2010 (roads); 2006 (development); 2001 and 2006 (landcover)	Western Association of Fish and Wildlife Agencies Crucial Habitat Assessment Tool [46], based on the NatureServe Landscape Condition Model [44]

### Calculating a riparian climate-corridor index

We calculated an index of riparian climate-corridor quality for individual, ecologically-relevant spatial units that we call “potential riparian corridors,” which we define as the potential riparian area that runs longitudinally along a stream/river from the stream outlet (or mouth) up through the hydrologic network of a watershed, ending at the stream initiation point (or headwater). For each potential riparian corridor, we calculated a riparian climate-corridor index using three main steps.

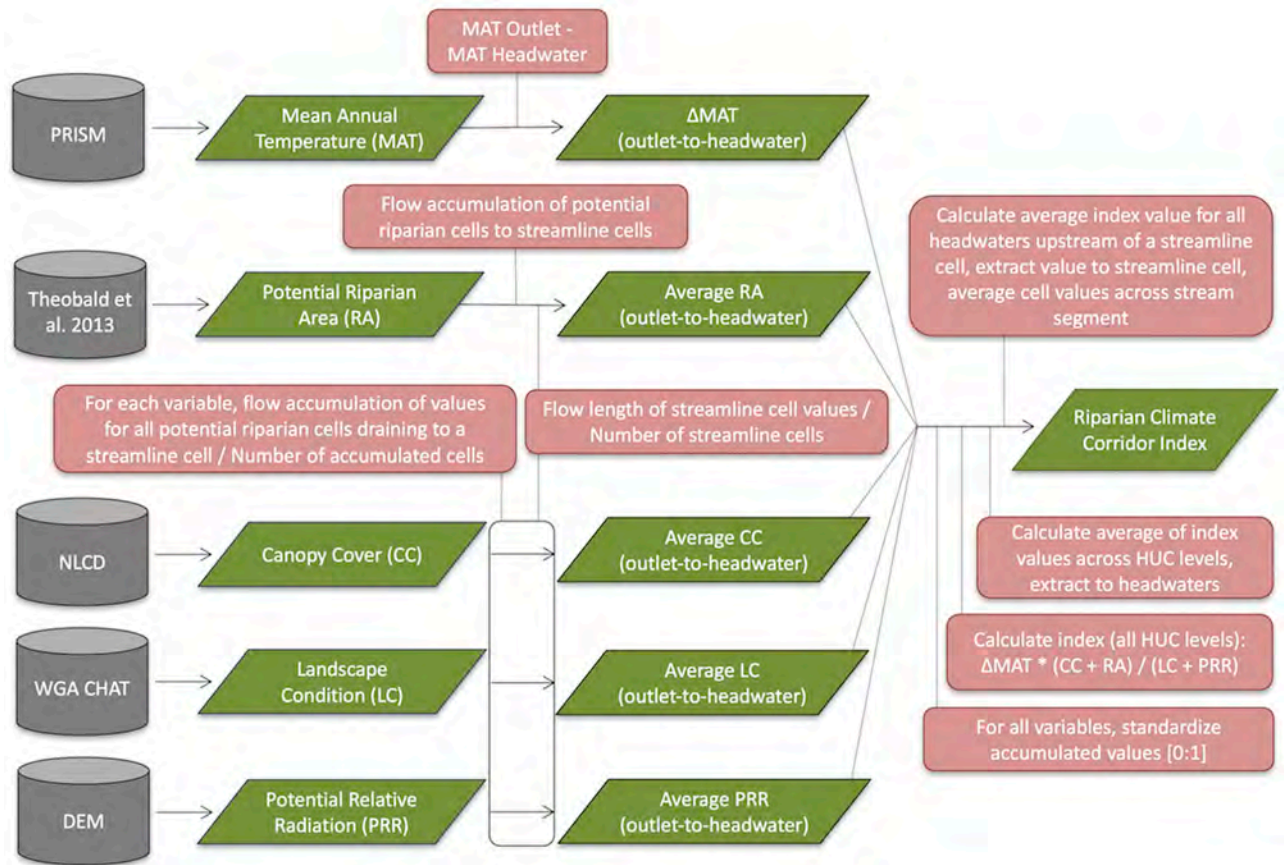

First, we accumulated the values of four variables (*C, A, R, L*) from locations (cells) within potential riparian areas laterally (i.e., orthogonal to the neighboring stream) to the nearest cell along the central flow path that follows the mid-line of streams/ivers (Fig 2a).

Second, we accumulated the values longitudinally along the central flow path within the stream/river, from its outlet to its headwater (Fig 2b). We accumulated values upstream rather than downstream to simulate the process of upward range movement along riparian corridors, from watershed outlets toward higher-elevation headwaters. Accumulating upstream also allowed us to calculate index values for individual riparian corridors adjacent to a stream/river reach running between its headwater and watershed outlet, because accumulating downstream would result in a single accumulated index value for an entire watershed. Third, we used these accumulated variable values to calculate an index of climate adaptation quality for the riparian climate-corridor from the outlet to headwater. Representing potential riparian corridors using a raster representation (rather than stream line vectors) allowed us to account for subtle gradients and variations within potential riparian areas—vital information lacking in previous

**Fig 2. Using Flow Direction, Flow Accumulation, Flow Length tools to calculate the riparian climate-corridor index for a potential riparian corridor.** a) For all potential riparian cells draining into a given cell in the streamline (outlined in bold, with it and all cells draining into it shown in the same color), we calculate, for each variable (*C, R, L*), the average value across the cells that contribute (accumulate) to the stream flow cell, and attribute this average value to the streamline cell (or the midline cell, for larger water bodies) using the Flow Direction and Flow Accumulation tools in ArcGIS. We calculate *A* as the number of potential riparian cells draining into the streamline cell. b) We then calculate, for each variable (*C, R, L, A*), the average value across all streamline cells from the outlet (*O*) to the headwater (*H*), and attribute this average value to the headwater using the Flow Length tool in ArcGIS. We also attribute a value for *T*, calculated as the absolute difference in temperature between the outlet and headwater cells. We then standardize (0–1) the average value for each variable (for equal weighting) and calculate the index, attributing this index value to the headwater cell. This is repeated for each downstream outlet until reaching the ocean, each time attributing the index value to the headwater cell. Each streamline cell is then given the average index value attributed to its upstream headwaters.

**Fig 3. Summary of modeling approach, including key inputs, outputs, and analysis steps.** Data sources are shown in gray, processing steps in pink, and inputs and outputs in green.

<https://doi.org/10.1371/journal.pone.0205156.g003>

studies. For rivers wider than 90 m, we excluded water cells when calculating variable values. Note that we represented spatial features, such as elevation and land cover, at 30 m resolution, but accumulated the up-scaled data at 90 m for computational purposes. A more detailed description of our analysis is provided below, and summarized in Fig 3.

### 1. Accumulate values within potential riparian corridors laterally to the stream line.

We clipped the *C*, *R*, and *L* rasters to the extent of the potential riparian area. We then accumulated *C*, *R*, and *L* values along flow paths for all potential riparian cells draining into a given cell that represents the center of the stream line (i.e. the central flow path). That is, each cell located along the central flow path was attributed with the sum of the values for that variable for all the potential riparian cells that drain into it, using hydrologic tools in ArcGIS v10 software [47]. We then divided the accumulated value for each variable by the number of accumulated cells, so that, for each variable, each central flow path cell in the adjacent stream/river was ultimately attributed with the average variable value for its contributing potential riparian cells. The flow-accumulated area for the potential riparian area (*A*) was calculated in a similar manner, by accumulating the number of potential riparian cells draining into each central flow path cell in the adjacent stream/river. In cases where no potential riparian area cells drained into a central flow path cell, values for each variable were measured for only the central flow path cell itself, which was given an *A* value of 1.

**2. Accumulate values for each variable longitudinally from stream/river outlet to headwater.** We accumulated values along individual streamlines running from the watershed outlet to a stream's headwater, for each of the four variables ( $C$ ,  $A$ ,  $R$ ,  $L$ ). These accumulated values were then extracted to the central flow path cell at the stream/river's headwater, and divided by the number of contributing central flow path cells, to provide an average value for each variable for the associated potential riparian corridor. Mean annual temperature ( $T$ ) was also extracted at each watershed outlet (or sink, in the case of closed basins) and for each headwater, and the difference between the two calculated and extracted to each stream/river's headwater. The average value for each variable was then divided by the largest value for that variable within the full study region, to standardize values to the range 0:1.

**3. Calculate riparian climate-corridor index for each watershed-scale riparian corridor.** We used the averaged, standardized values for each variable to calculate a Riparian Climate-Corridor Index for each watershed-scale riparian corridor, using the following formula:

$$\text{Riparian Climate - Corridor Index} = \Delta T \times [(C + A)/(R + L)]$$

Index values will thus be highest for those riparian corridors with the largest change in temperature ( $T$ ) from outlet to headwater, highest percent canopy cover ( $C$ ), greatest width ( $A$ ), lowest exposure to solar radiation ( $R$ ), and lowest level of human modification ( $L$ ). Where  $\Delta T$  was negative (indicating a higher temperature at the headwater than at the outlet), the index value was set to 0, to maintain higher index values for corridors leading from warmer to cooler areas across scales (see description of multi-scale approach, below). Our analysis is thus similar to other climate-gradient corridor approaches [11–12] in that it prioritizes corridors connecting warm areas to cool (in this case, headwater and outlets) using pathways that follow monotonic gradients (i.e., moving along gradients in only one direction, from warm to cool). All index values were extracted to the headwater associated with each potential riparian corridor.

**4. Account for scale effects.** We calculated a multi-scale, riparian climate-corridor index using the above procedure for riparian corridors within 6<sup>th</sup>, 5<sup>th</sup>, 4<sup>th</sup>, 3<sup>rd</sup>, 2<sup>nd</sup>, and 1<sup>st</sup> field HUCs (i.e., nested watersheds, from smallest to largest, respectively). HUCs are hierarchical hydrologic unit codes (HUC) assigned to all watersheds in the US [48]; the watershed cataloging system nests watersheds into progressively larger units, similar to Pfafstetter codes that are also used globally. Our method should thus be applicable to any similar watershed cataloging system in other countries. This procedure resulted in up to six index values being extracted to each headwater, corresponding to the index values of progressively longer downstream potential riparian corridors adjacent to each stream/river from its headwater to its outlet for progressively larger watersheds, eventually terminating at the ocean (or sink, in the case of closed basins). We scaled each of these nested index values to the range (0:1) and averaged them (equally-weighted), so that the final index value extracted to each headwater would reflect the climate adaptation value of all of its downstream riparian corridors. Finally, we calculated, for each individual central flow path cell within streams/ivers, the average of the index values attributed to all of its upstream headwaters. The final index values for each flow path cell within streams/ivers thus reflect the degree to which its adjacent potential riparian area cells are expected to help facilitate range shifts and provide refugia, from local to regional scales.

We also calculated a measure of riparian climate-corridor quality for entire watersheds by calculating the average of index values for all riparian climate-corridors within a given HUC. To account for differences in index values among ecoregions, and to more easily identify the highest quality riparian climate-corridors within each ecoregion, we binned all index values into 5 equal-area quintiles within each Level III ecoregion [49].

## GAP analysis and sensitivity testing

We evaluated the degree to which high-value riparian climate-corridors identified by our analysis fall within currently designated protected areas by measuring the GAP status of riparian climate-corridors within 1) the top quintile of index scores, 2) the top two quintiles, and 3) all quintiles, for both the entire Pacific Northwest and within ecoregions. GAP status codes are provided by the US Geological Survey's Gap Analysis Program (GAP), and measure the degree to which lands in the US are managed for conservation [50]. Code 1 and 2 denote the highest degree of management for conservation (and meet the IUCN definition of protected), while Code 3 is given to lands that support multiple uses, including resource extraction. Code 4 lands are unprotected or have unknown management intent.

We also tested the sensitivity of the riparian climate-corridor index to the inclusion of individual input variables by removing individual variables one at a time, re-calculating the index, and measuring resulting differences across the study area. We also calculated correlation coefficients among these index values, as well as correlation coefficients among individual variables, to aid in interpretation of results.

## Results

### Riparian climate-corridor index values

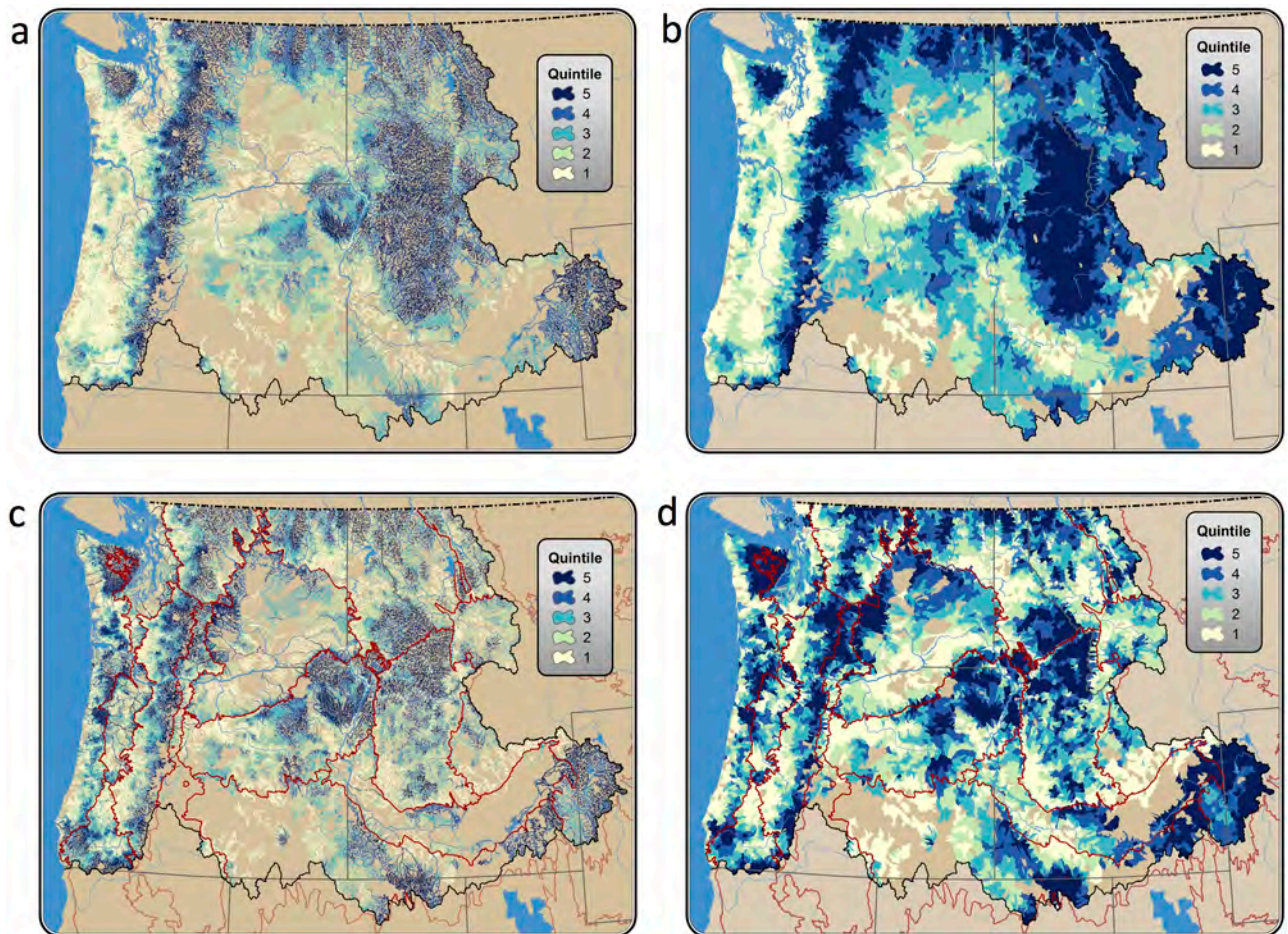

We found that the climate adaptation potential of riparian corridors varies considerably, both across the Pacific Northwest (Fig 4) and within individual watersheds (Fig 5). Index values ranged from 0 to 0.83 (Fig 6), with the highest index values found in mountainous areas (e.g., the Cascade Range), and the lowest index values found in relatively flat, lowland regions such as the Columbia Plateau. Mountainous areas exhibited higher  $\Delta T$  scores, on average, as well as higher canopy cover ( $C$ ), solar insolation ( $R$ ), and landscape condition (S1–S4 Figs). These effects were amplified by positive correlations among all input variables but riparian area (S5 Fig): relatively flat areas with low  $\Delta T$  tended to also have lower canopy cover ( $C$ ), were in poorer landscape condition ( $L$ ), and had higher solar insolation ( $R$ ). Indeed, removing  $\Delta T$  from the index calculation resulted in a spatial pattern similar to that seen when the calculation included  $\Delta T$  (Fig 7); including  $\Delta T$  generally reinforced the pattern of lower values in areas with gentler topographic relief (often near outlets) and higher values in mountains (often near headwaters).

Most potential riparian corridors had relatively low index values (Fig 6). The relatively high number of potential riparian corridors with index values equal to 0 is due in large part to the relatively cool temperatures of the Pacific Northwest coast; many interior headwaters have warmer mean annual temperatures than their streams' coastal outlets. Because negative  $\Delta T$  values were converted to zero and  $\Delta T$  is multiplied by the rest of the index, such potential riparian corridors receive a zero value, though they may otherwise be of high quality (Fig 7). For example, the low index scores received by otherwise high-quality riparian areas in the western Olympic Peninsula were due to negative or relatively low  $\Delta T$  between coastal stream outlets and headwaters (Fig 7, S1 Fig).

Areas with no headwaters (and thus no index scores) were seen in regions lacking surface water due to high aridity and/or high soil permeability (Fig 4).

## GAP analysis and sensitivity testing

We found that riparian climate-corridors varied regionally in their level of protection (Fig 8). For riparian climate-corridors with the highest 20% of index scores, 35.5% were fully protected (GAP status 1–2) and 50.4% were partially protected (GAP status 3) across the Pacific

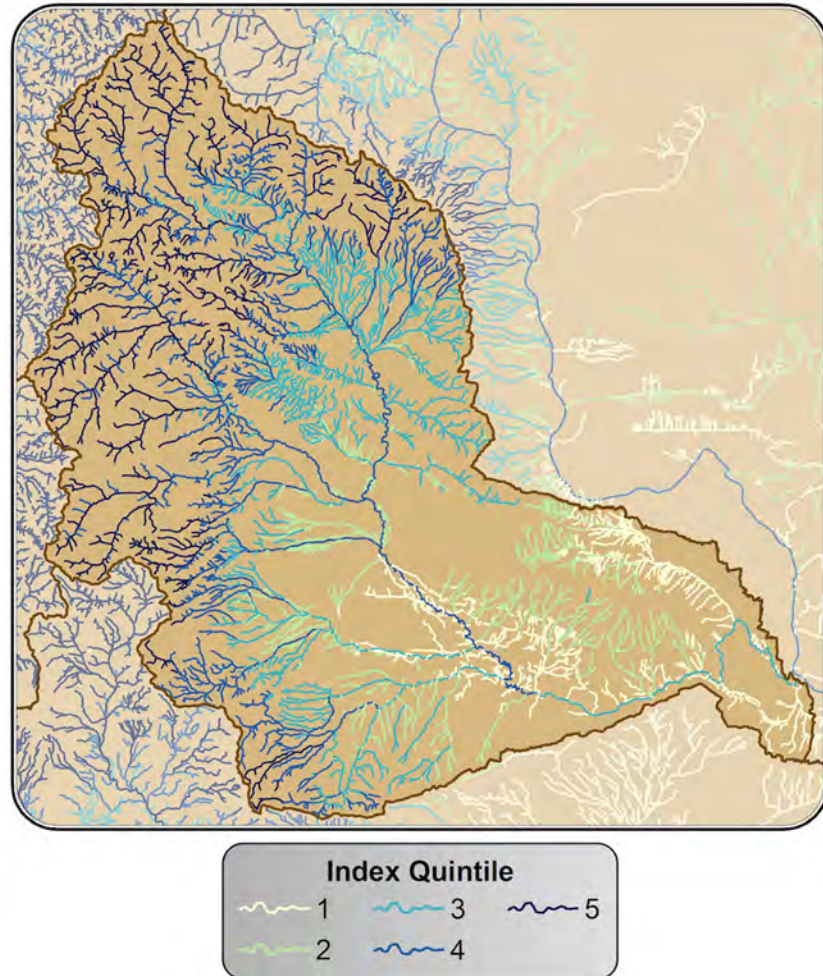

**Fig 4. Riparian climate-corridor index values for the Pacific Northwest.** Values are averaged across nested watershed scales (6<sup>th</sup> to 1<sup>st</sup> field HUCs), attributed to streamlines associated with potential riparian corridors. Values are shown by quintile for the Pacific Northwest, USA (panels a and b), and within ecoregions (panels c and d); and for both individual riparian corridors (panels a and c) and averaged across 6<sup>th</sup> field HUCs (panels b and d).

<https://doi.org/10.1371/journal.pone.0205156.g004>

Northwest. Within ecoregions, GAP status of riparian climate-corridors with the highest 20% of index scores varied from 83.8% fully protected and 14.6% partially protected in the North Cascades, to 1.3% fully protected and 18.8% partially protected in the Columbia Plateau.

We found that riparian climate-corridor index values were relatively insensitive to individual input variables (Fig 7). Removal of individual variables from the index calculation resulted in little change to index scores across the study area, resulting in an average change in index values of -0.0126 for removal of mean annual temperature ( $\Delta T$ ), +0.0051 for landscape condition ( $L$ ), -0.0168 for canopy cover ( $C$ ), -0.0607 for riparian area ( $A$ ), and -0.1154 for potential relative radiation ( $R$ ). Given the strong correlations among index variable values and elevation (i.e., that relatively flat areas with low  $\Delta T$  also have lower canopy cover ( $C$ ) and landscape condition ( $L$ ), and higher solar insolation ( $R$ )), variable exclusion generally resulted in decreased values in mountainous areas and increased values in lower-elevation areas. Exclusion of  $R$  had a slightly stronger effect on index values in mountainous areas (lowering index values), and exclusion of  $T$ ,  $C$ , and  $L$  had a slightly stronger effect on lower-elevation coastal areas (increasing values).

**Fig 5. Riparian climate-corridor index values shown for an individual watershed.** Values are shown by quintile and attributed to streamlines associated with potential riparian corridors.

## Discussion

Our analysis identified potential riparian corridors that span climatic gradients, have high canopy cover, low levels of solar exposure, low levels of human modification, and are relatively wide—characteristics expected to facilitate climate-induced range shifts and provide micro-climatic refugia. Not surprisingly, we found that potential riparian corridors in mountainous regions—which tend to be steep, forested, topographically shaded, and have low levels of human modification—had the highest riparian climate-corridor index values. We also found that potential riparian corridors in lowland areas—which tend to be flat and have low canopy cover, less topographic shading, and high levels of human modification—had the lowest values (Fig 4a and 4b). Because of the correlations of temperature with other variables, change in temperature—which we had expected to be a key variable for identifying riparian corridors with strong climatic gradients—in fact had a relatively modest impact on index scores (Fig 7), generally reinforcing the pattern of lower index values in areas with gentler topographic relief and higher values in mountains. The index is thus robust to our coarse approach to measuring temperature gradients along riparian corridors.

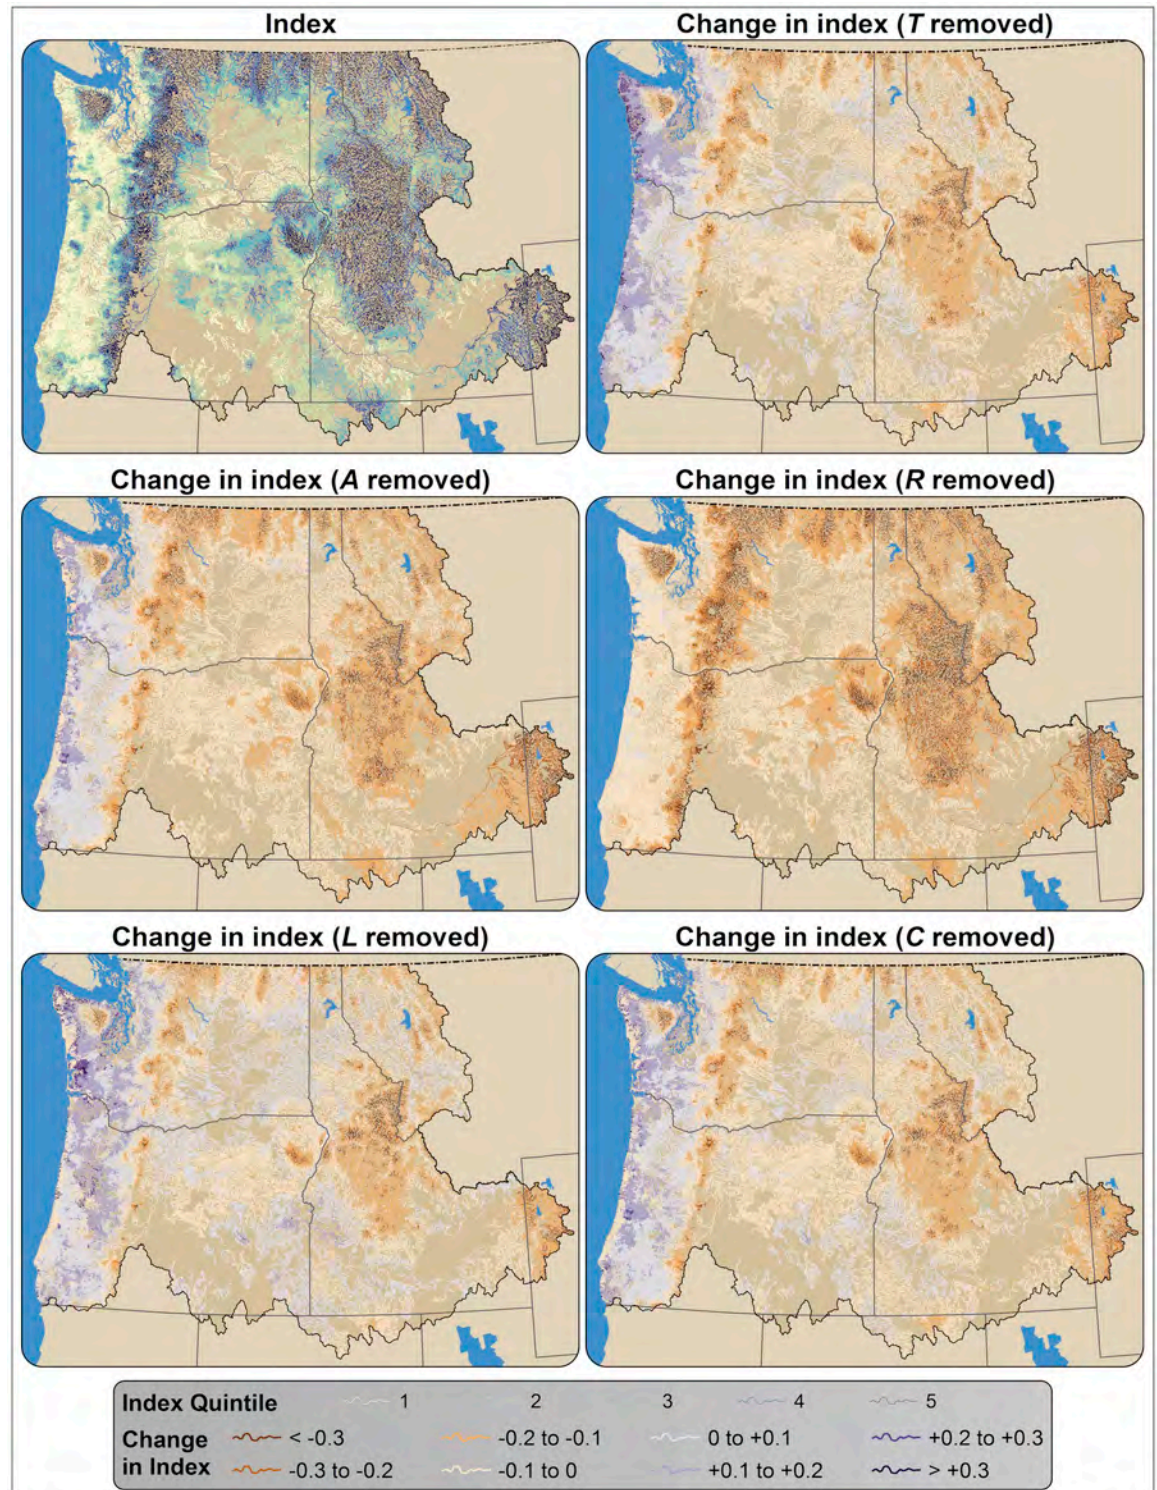

**Fig 6. Distribution of riparian climate-corridor index values.** Shown for all watershed-scale riparian corridors in the Pacific Northwest.

<https://doi.org/10.1371/journal.pone.0205156.g006>

We also found that relatively flat and highly modified ecoregions (e.g., the Columbia Plateau and Puget Lowlands ecoregions; Fig 4c and 4d) had the least protected high-scoring riparian climate-corridors among Pacific Northwest ecoregions (Fig 8). High-scoring riparian climate-corridors in these areas thus suggest immediate priorities for conservation action (e.g., protection or restoration), as they may provide some of the best adaptation opportunities in flat, highly modified landscapes that may limit species range movements and persistence in microclimatic refugia. We also found that a large number of otherwise high-quality potential riparian corridors along the coast received low index scores, because their interior headwaters have warmer mean annual temperatures than their streams' cooler, coastal outlets. These results emphasize that our index is designed to identify riparian climate-corridors expected to promote species range shifts from warmer to cooler areas, which may in some cases result in low scores for corridors that have high conservation value under static or current climates.

Index values for riparian climate-corridors along large rivers (e.g., the Columbia River) often had higher values than corridors within nearby lower-order streams (e.g., headwater streams). This is because higher-order streams frequently have tributaries at higher elevations; riparian climate-corridors associated with these higher-elevation tributaries tend to have relatively high index values, and the index values of riparian climate corridors along higher-order streams incorporate these upstream values. The high index values of riparian climate-corridors along higher order streams thus reflect their connectivity to high-scoring upstream corridors, and thus their capacity to promote range shifts and provide access to climatic refugia at a regional scale. Indeed, shorter riparian corridors, such as those that would be found along headwater streams, have been shown to be more effective at promoting species movements [51]. Thus, the trade-off of this multi-scale approach—designed to accommodate diverse

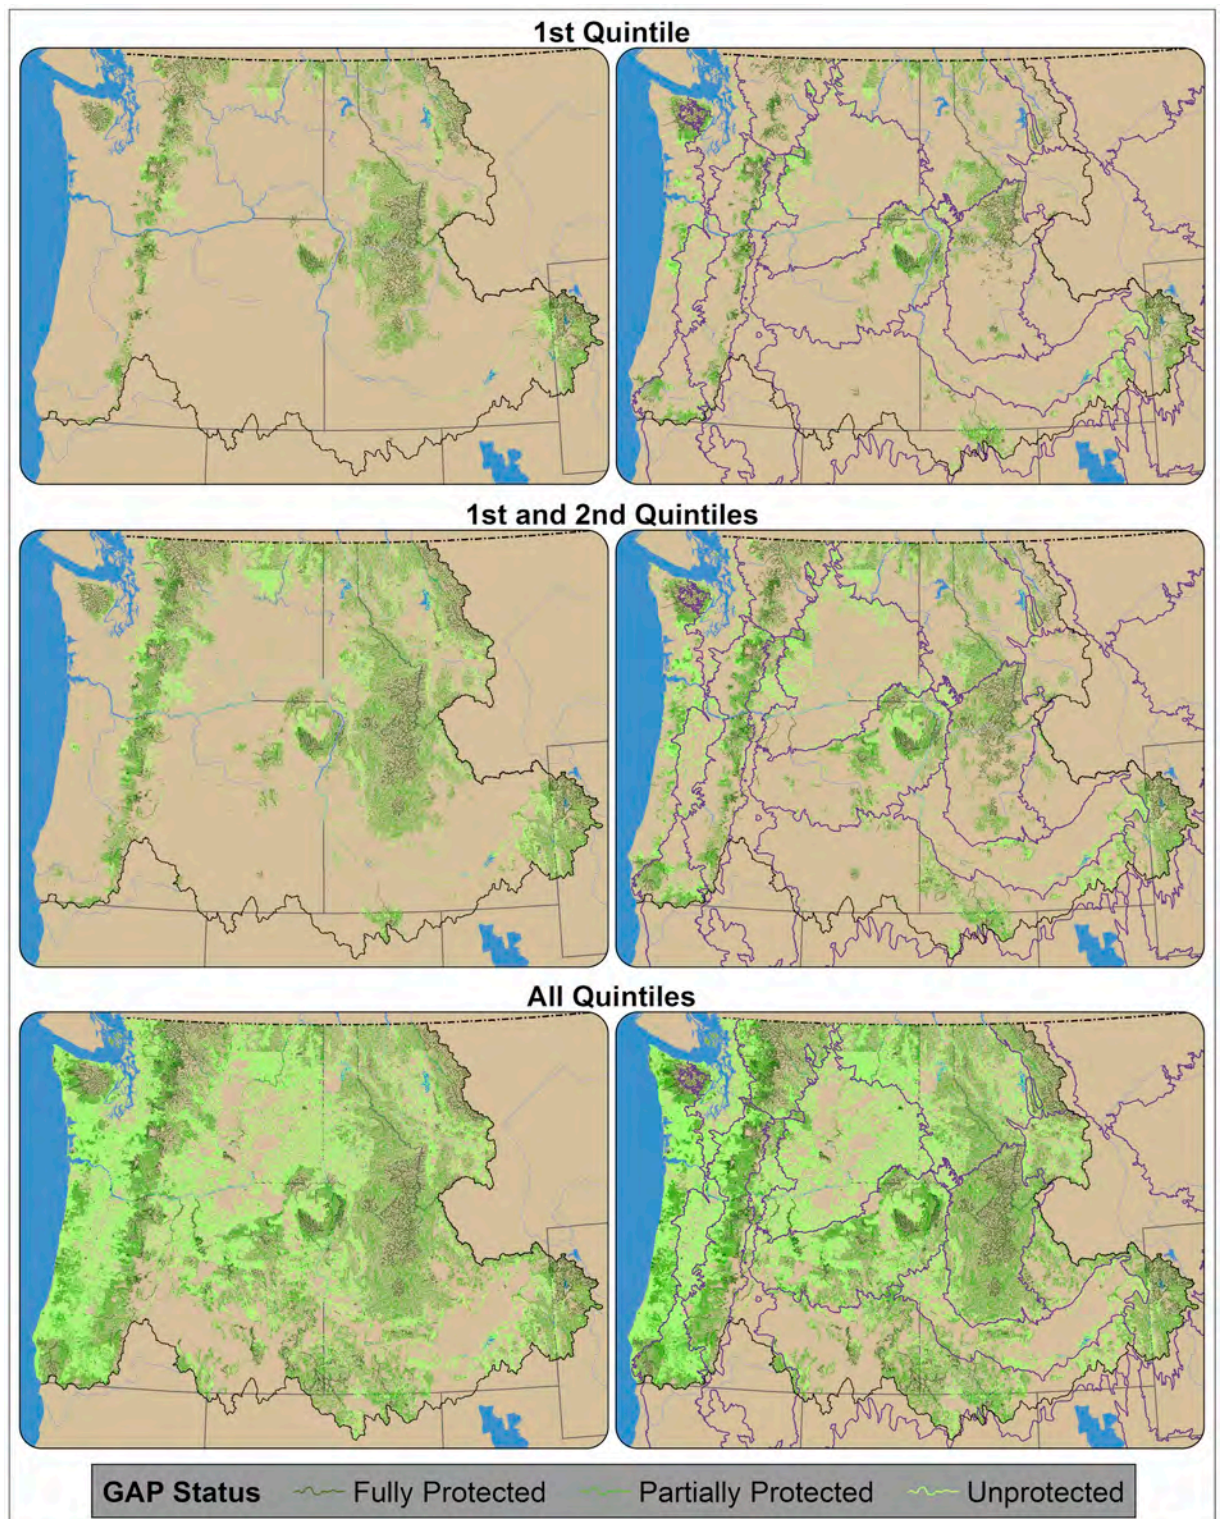

**Fig 7. Sensitivity of riparian climate-corridor index values to individual analysis variables.** Panels show the index with all variables included (top left), and the index with change in mean annual temperature (*T*) removed, with riparian area (*A*) removed, with potential relative radiation (*R*) removed, with landscape condition (*L*) removed, and with canopy cover (*C*) removed.

<https://doi.org/10.1371/journal.pone.0205156.g007>

**Fig 8. GAP status of riparian climate-corridors.** GAP status is shown for riparian corridors within the top quintile of riparian climate-corridor index values (top row), top two quintiles (middle row), and all quintiles (bottom row); by both the entire Pacific Northwest (left column) and within ecoregions (right column). GAP status is shown for fully protected (GAP status 1 and 2; forest green), partially protected (GAP status 3; kelly green), and unprotected (GAP status 4; lime green) riparian climate-corridors.

<https://doi.org/10.1371/journal.pone.0205156.g008>

species with needs for movement and refugia at a range of scales—is its potential to overlook riparian climate-corridors that may be valuable at a more local scale, but do not meaningfully contribute to broader-scale, regional adaptation. Identifying riparian climate-corridors with high index values within ecoregions (Fig 4c and 4d) or local watersheds (S6–S10 Figs) may help address needs for more local-scale prioritization.

We recommend considering several caveats when applying the riparian climate-corridor index. First, this approach only indirectly accounts for connectivity along riparian corridors; while index values will decrease with increasing human modification along a corridor, the effect of local but severe movement barriers (e.g., towns, cliffs) on index values could be muted if human modification is low elsewhere along the corridor, particularly at broader scales. The analysis could thus be improved by incorporating explicit connectivity measures that sufficiently penalize high-resistance, local barriers that could sever connectivity; a range of connectivity modeling approaches could be adapted for this purpose (e.g., [52]). The analysis could also be improved by further validating analysis inputs and assumptions, such as empirically measuring canopy cover and solar insolation across riparian areas and testing their influence on temperature, and, ultimately, range shifts and refugia. Future comparison of our index to other indices of riparian quality (e.g., [53]) would also aid in interpretation of results. Thus, we recommend using this analysis as a means of identifying priority riparian areas for additional evaluation (e.g., field validation, comparison with other data sets, integration with other conservation values) before making decisions regarding conservation action.

We also recognize the scaling challenges in mapping riparian vegetation and modeling potential riparian areas. Our analysis provides estimates of potential riparian climate-corridors at (>90 m) due to data resolution and computation limitations. Future work can apply our approach using high resolution data that have (or will likely) become available. An additional caveat is the risk of unintended negative consequences (e.g., spread of invasive species or disease) by protecting or restoring riparian climate corridors to promote species movements. Our analysis reduces this risk by prioritizing those riparian areas that are in good condition, and therefore expected to be less vulnerable to invasion. Further, previous research has shown that the benefits of corridors outweigh potential negative effects [54], including potential risks related to climate-induced range shifts [55]. Indeed, the synergistic threats of habitat loss, fragmentation and climate change present an urgent need to restore landscape features such as riparian corridors that have historically provided natural conduits for species movement.

Although riparian areas are expected to provide critical movement corridors and refugia under climate change [6–7,9], they are also among the most threatened habitats in many regions [56]. Our analysis offers a first step toward identifying, for large regions, those riparian areas most likely to promote species' ability to respond to climate change, as well as those that may be most vulnerable to climate change and in need of restoration measures. Such information may offer valuable guidance for future investments in riparian protection and restoration as part of climate adaptation efforts.

## Abstract

Urbanization can result in the fragmentation of once contiguous natural landscapes into a patchy habitat interspersed within a growing urban matrix. Animals living in fragmented landscapes often have reduced movement among habitat patches because of avoidance of intervening human development, which potentially leads to both reduced gene flow and pathogen transmission between patches. Mammalian carnivores with large home ranges, such as bobcats (*Lynx rufus*), may be particularly sensitive to habitat fragmentation. We performed genetic analyses on bobcats and their directly transmitted viral pathogen, feline immunodeficiency virus (FIV), to investigate the effects of urbanization on bobcat movement. We predicted that urban development, including major freeways, would limit bobcat movement and result in genetically structured host and pathogen populations. We analysed molecular markers from 106 bobcats and 19 FIV isolates from seropositive animals in urban southern California. Our findings indicate that reduced gene flow between two primary habitat patches has resulted in genetically distinct bobcat subpopulations separated by urban development including a major highway. However, the distribution of genetic diversity among FIV isolates determined through phylogenetic analyses indicates that pathogen genotypes are less spatially structured—exhibiting a more even distribution between habitat fragments. We conclude that the types of movement and contact sufficient for disease transmission occur with enough frequency to preclude structuring among the viral population, but that the bobcat population is structured owing to low levels of effective bobcat migration resulting in gene flow. We illustrate the utility in using multiple molecular markers that differentially detect movement and gene flow between subpopulations when assessing connectivity.

## Introduction

Habitat loss and degradation are the leading causes of species declines around the world (<http://www.iucnredlist.org/>). Urbanization, an extreme form of habitat degradation, results in immediate displacement of

wildlife from developed areas, followed by the increasing isolation of groups of animals confined to shrinking natural areas (McKinney 2002; McDonald *et al.* 2008). A common effect of urbanization is the fragmentation of once contiguous landscapes into smaller patches of non-contiguous habitat.

Maintaining functional connectivity, the extent to which organisms and genetic material move between

Correspondence: Justin S. Lee, Fax: (970) 491 0603; E-mail: jlee337@colostate.edu

habitat patches, can be essential for population persistence in fragmented landscapes (Crooks & Sanjayan 2006). Reduced functional connectivity between habitat patches can result in physically and genetically isolated subpopulations prone to inbreeding and to the loss of genetic diversity through genetic drift (Frankham 2006). However, measuring functional connectivity can be difficult, especially for cryptic solitary species such as large carnivores (Crooks 2002). One commonly used method of evaluating functional connectivity involves characterizing patterns of gene flow using molecular markers to evaluate the distribution of genetic diversity within and among groups of individuals (Frankham 2006; Balkenhol & Waits 2009; Ruell *et al.* in press). Populations with high connectivity should exhibit homogeneous distributions of genetic diversity. Populations with low connectivity will be genetically structured, exhibiting localized variations in genetic diversity as a consequence of reduced gene flow among isolated groups of individuals.

Microsatellites are neutral heritable molecular markers commonly used to evaluate genetic structure, and hence connectivity, among natural populations (Avice 2004; Hedrick 2005a). These polymorphic, codominant markers provide a powerful means for assessing gene flow. However, microsatellite markers only reflect individual movement within structured populations if a migrant is sampled or if a migrant successfully reproduces and at least one offspring is sampled. Transient movements between subpopulations, or migrants that do not reproduce, may not be detected by analysing microsatellites (Riley *et al.* 2006). Therefore, while powerful, host genetic markers may not accurately characterize connectivity when individual movements do not result in gene flow.

Because directly transmitted obligate pathogens are inextricably linked to their hosts, pathogens can serve as alternative or additional markers for studies of wild-life population dynamics (Nieberding & Olivieri 2007; Liu *et al.* 2008). Feline immunodeficiency virus (FIV), a retrovirus that naturally infects many felid species (Troyer *et al.* 2005; Vandewoude & Apetrei 2006), has many characteristics that render it potentially useful as a marker of population dynamics in wild cats. First, the mutation rate of FIV is significantly faster than that of host genetic markers (approximately  $\mu = 1\text{--}3\%$  every 10 years in mountain lions) (Biek *et al.* 2003). Also, infection with FIV is life-long because an obligatory step in viral replication involves the permanent insertion of a copy of the viral genome into the host's chromosomal DNA. Therefore, FIV genotypes have the capacity to serve as life-long molecular markers for each infected individual. Furthermore, the virus cannot be transmitted by insect vectors, nor is it stable in the envi-

ronment, and thus, transmission events are indicators of direct contact between individuals.

Finally, the strains of FIV, which infect domestic cats, are genetically distinct from the strains isolated from wild felids. The domestic cat strains have never been documented to infect nondomestic felids in the wild, and therefore, the genetic diversity of FIV among nondomestic felids is only influenced by the distribution, movement and contact rates among conspecifics across the landscape.

Indeed, previous studies have demonstrated that patterns of FIV relatedness closely reflect the geographical distribution of bobcats, mountain lions and African lions at various geographical scales (Biek *et al.* 2006; Franklin *et al.* 2007a; Antunes *et al.* 2008). Specifically, Franklin *et al.* (2007a) demonstrated that the FIV isolates infecting bobcats north and south of Los Angeles, CA are genetically distinct, having diverged since the isolation of the two host populations. Because of these characteristics, viral genetic analyses may provide novel and powerful techniques for assessing connectivity and population structure with improved resolution, supplementing that which is currently possible using host genetic markers.

Bobcats (*Lynx rufus*), with large home ranges and high resource requirements, are susceptible to the effects of habitat loss and fragmentation in urbanizing systems (Crooks 2002; Riley *et al.* 2003, 2006, 2010). We investigated patterns of genetic diversity among bobcats and FIV isolates from a fragmented landscape in southern California to evaluate how urbanization affects connectivity among bobcats in this region. We specifically evaluated the extent to which several large freeways, and the developed areas surrounding them, are barriers to gene flow and pathogen transmission between habitat patches. We predicted that decreases in connectivity would lead to significant genetic structure among both host and pathogen populations. We performed standard population genetics analyses using 16 unlinked microsatellite loci from 106 bobcats. We also constructed phylogenetic trees to assess patterns of relatedness among FIV isolates from 19 of these individuals infected by the virus.

Our findings, presented below, demonstrate that two spatially structured, genetically distinct bobcat subpopulations exist. However, the pathogen phylogeny revealed no association between FIV relatedness and bobcat population structure, suggesting movements, contacts and disease transmission between subpopulations continue despite very low levels of host gene flow. This finding was inconsistent with our hypothesis that decreased gene flow among bobcats would lead to similar genetic structure among the virus population. However, these results are consistent with other studies that have found major roads and urban development to

be more permeable to transient bobcat movements than to effective migration, allowing for the potential movement of pathogens in the absence of gene flow (Riley *et al.* 2006; Ruell *et al.* in press). We illustrate the utility in using multiple molecular markers, each with different determinants of movement throughout populations, to assess complex questions of connectivity.

## Methods

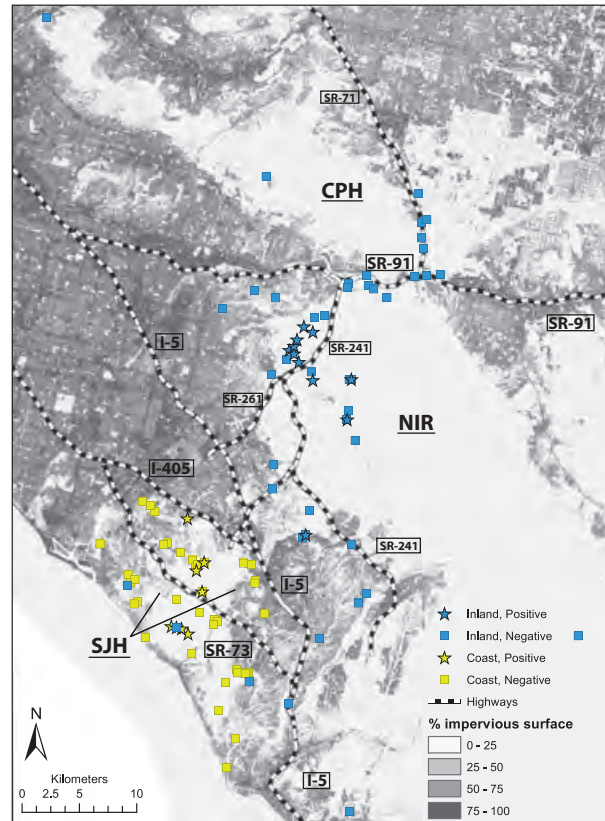

### *Location and field sampling*

This study was located south and west of Los Angeles, CA and included four habitat patches divided by three large freeways—Interstate-5 (I-5), the Riverside Freeway (SR-91) and the San Joaquin Hills Transportation Corridor (SR-73) (Fig. 1). I-5 through this region was constructed from 1944 to 1958 and has an average annual daily traffic volume (AADT) of ~262 000 cars per day (California DOT 2009). SR-91 was originally completed in 1971 and underwent a major expansion in 1995. The AADT of this freeway is ~264 000 cars per day (California DOT 2009). SR-73 was constructed in 1996 and has an AADT of ~73 000 cars per day (California DOT 2009). Aside from these roads and adjacent urban development, the only potential natural barrier to bobcat movement is the Santa Ana River, which flows about 100 m to the north of SR-91. No other natural barriers to gene flow (i.e. major mountain ranges) exist between these habitat patches, which are primarily characterized by chaparral, coastal scrub and grassland vegetative communities.

A total of 106 bobcats were included in this study. The majority of bobcats ( $n = 75$ ) were live-captured between December 2002 and March 2009 using wire cage traps baited with visual and odour attractants (Lyren *et al.* 2006, 2008a,b). Animals were anesthetized, and blood samples were collected. Animals were captured, sampled and released with permission of cooperating agencies after approval by all appropriate animal care and use committees. The remaining individuals ( $n = 31$ ) were opportunistically sampled postmortem; when possible, heart blood clots, thoracic fluid, ear punch and hair samples were collected from these bobcats. Blood and tissues were stored at USGS facilities in Irvine, CA, and aliquots were sent to Colorado State University for analysis as described below.

### *Putative subpopulation assignments*

Bobcats were assigned to one of four putative subpopulations based on the GPS coordinates of the capture or road kill location relative to freeways I-5, SR-91 and SR-73 (Fig. 1). These three freeways were the focus of our

**Fig. 1** Map of study locations southeast of Los Angeles, California. GPS capture locations of 105 bobcats indicated by squares [feline immunodeficiency virus (FIV) negative] or stars (FIV positive). Blue or yellow fill of each symbol represents the genetic assignment of an individual to an inland (east of I-5) or coastal (west of I-5) subpopulation, respectively (see Fig. 2). The a priori assignment of individuals to putative subpopulations (SJH-W: San Joaquin Hills West; SJH-E: San Joaquin Hills East; NIR: North Irvine Ranch; CPH: Chino Puente Hills) was based on the capture location of bobcats relative to the focal roads SR-73, I-5 and SR-91, which were investigated as potential barriers to gene flow. Degree of urban development (% impervious surface) is represented by grey shading.

investigation because they completely traverse the study area (i.e. animals cannot move between habitat fragments without crossing one of these freeways), and these roads represent a gradient of permeability to bobcat movements based on previous studies [see discussion and also Lyren *et al.* (2008a,b)]. The San Joaquin Hills west subpopulation [SJH-west ( $n = 29$ )] was located between the coast and SR-73, which merges with I-405 to the north and I-5 to the south. The San Joaquin Hills east subpopulation [SJH-east ( $n = 20$ )] included individuals sampled between SR-73 and I-5. The North Irvine Ranch [NIR ( $n = 44$ )] subpopulation comprised individuals captured east of I-5 and south of SR-91, whereas the Chino Puente Hills [CPH ( $n = 12$ )] subpopulation consisted of individuals captured east of

I-5 and north of SR-91. One individual did not have a recorded capture location, and thus, it was not included in analyses that required the above subpopulation assignments. The following population genetics analyses were, except where noted, performed using this a priori assignment of individuals to putative subpopulations and the multilocus microsatellite genotype data for each individual.

#### Genotyping microsatellites

Bobcat genomic DNA was extracted from whole blood, peripheral blood mononuclear cells (PBMCs) or tissue using QIAamp® DNeasy blood and tissue kit (Qiagen Inc., Valencia, CA, USA). Seventeen microsatellite loci (Table 1) were amplified using primer pairs for polymerase chain reaction (PCR) developed by Menotti-Raymond *et al.* (1999): FCA008, FCA023, FCA026, FCA031, FCA043, FCA045, FCA077, FCA090, FCA096, FCA132, FCA149, FCA559; Menotti-Raymond *et al.* (2005): FCA740, FCA742; and Faircloth *et al.* (2005): BCE5T, BCD8T, BCG8T. Primers BCE5T and BCG8T were modified to contain the M-13 sequence instead of the CAG sequence as published. We selected these primer pairs from the above publications based on the following criteria: longer repeat units, efficiency of amplification and maximal heterozygosity. The 5' end of the forward primer of each primer pair was modified with a 16-bp tail comprising the M-13 sequence

(5'-GTA AAA CGA CGG CCA G-3'). Reverse primers were not modified. All microsatellite PCR products were fluorescently labelled using a second forward primer consisting of the above M-13 sequence with 6-FAM on the 5' end.

PCR methodologies were adapted from Boutin-Ganache *et al.* (2001) and Riley *et al.* (2006). PCR reaction conditions included 94 °C for 3 min followed by 22 cycles of (94 °C for 30 seconds; 59 °C for 30 seconds; and 72 °C for 45 seconds), followed by 10 cycles of (94 °C for 30 seconds; 53 °C for 30 seconds; and 72 °C for 45 seconds), and a final cycle of 72 °C for 10 min. Randomly selected PCR products as well as the negative control for each reaction were visualized under UV light using gel electrophoresis with ethidium bromide in 2% agarose gel to confirm the presence of amplicons of appropriate length. Precise PCR product fragment lengths were determined using an ABI 3730xl DNA Analyzer and Peak Scanner 1.0 software (Applied Biosystems, Foster City, CA, USA). PCR and genotyping were repeated in ten per cent of randomly chosen bobcat samples for each microsatellite locus to confirm genotypes and prevent scoring errors. All duplicated genotypes were consistent with the primary analysis, demonstrating a high degree of assay reproducibility and reducing the likelihood of genotyping errors owing to false alleles or allelic dropout.

**Table 1** Characterization of 17 microsatellite loci in 106 bobcats

### Validating and characterizing microsatellite data

Microsatellite data were screened for genotyping errors because of stuttering, null alleles and large allele dropout at all loci in MICROCHECKER 2.2.3 (Van Oosterhout *et al.* 2004). There was no evidence of errors because of stuttering or large allele dropout at any loci. The following three loci showed evidence of null alleles when testing across all individuals with no subpopulation information: FCA045, FCA090 and FCA132. The null alleles at these loci correspond to NIR (FCA045 and FCA090) and SJH-west (FCA132) when the same analysis was run with a priori subpopulation assignments.

Tests for linkage disequilibrium among loci were performed in GENEPOP 4.0 (Raymond & Rousset 1995; Rousset 2008). The results for linkage disequilibrium varied greatly between subpopulations with seven significant tests in SJH-west (120 total tests;  $\alpha = 0.009313$ ), four significant tests in SJH-east (120 total tests;  $\alpha = 0.009313$ ), two significant tests in NIR (136 total tests;  $\alpha = 0.009102$ ) and one significant test in CPH (104 total tests;  $\alpha = 0.009567$ ). Loci FCA077 and FCA043 were in linkage disequilibrium in all four putative subpopulations, and therefore, FCA043 was eliminated from further analyses.

Hardy-Weinberg equilibrium probabilities were calculated using GENEPOP 4.0 (Raymond & Rousset 1995; Rousset 2008). Three of four subpopulations significantly deviated from Hardy-Weinberg equilibrium at one unique locus: FCA023 in SJH-west (15 tests;  $\alpha = 0.015068$ ), FCA045 in NIR (16 tests;  $\alpha = 0.014790$ ) and BCE5T in CPH (16 tests;  $\alpha = 0.014790$ ). The remaining loci in each subpopulation did not deviate from HW equilibrium, and therefore, all subpopulations were assumed to be in HW equilibrium. Observed and expected heterozygosity and the polymorphic information content (PIC) for each locus were determined using the program CERVUS 3.0 (Table 1) (Kalinowski *et al.* 2007).

### Assessment of population structure

Population differentiation based on allele frequencies was calculated for each pair of putative subpopulations using GENEPOP 4.0 (96 tests;  $\alpha = 0.0097$ ) (Raymond & Rousset 1995; Rousset 2008). Allelic richness, estimated using rarefaction to avoid bias caused by differences in sample size (Leberg 2002), was calculated for each putative subpopulation using FSTAT 2.9.3.2 (Goudet 1995). Allelic richness results were confirmed to be normally distributed using a Ryan Joiner Test in Minitab Student Version 14.11.1 (Ryan Joiner test;  $P > 0.1$ ). Analysis of variance (ANOVA) was used to determine whether allelic richness differed significantly between subpopulations

( $\alpha = 0.05$ ). Estimates of subpopulation differentiation ( $D_{est}$ ) were calculated using the online program Software for Measurement of Genetic Diversity (Jost 2008; Crawford 2010).  $F_{ST}$  values were calculated in FSTAT (Goudet 1995). The use of  $F_{ST}$  values as measures of population differentiation has recently been criticized (Hedrick 2005b; Jost 2008). Therefore, we include them here as supplemental information only to allow a general comparison among similar, previously published studies (Table S1, Supporting information).

Bayesian clustering in program STRUCTURE 2.3.3 was used to infer the number of genetically distinct subpopulations ( $K$ ) and to assign each individual to the subpopulation with which they share the highest genetic similarity. Parameters were set to include 50 000 burn-in and 500 000 Markov Chain Monte Carlo iterations (Pritchard *et al.* 2000). Data were first analysed without a priori source population information for individuals. Independent allele frequencies among subpopulations and genetic admixture were included as parameters so as not to introduce an upward bias in the estimation of  $K$  (Pritchard *et al.* 2000). This analysis was repeated five times for each  $K$  to verify the consistency of likelihood values between runs.  $K$  was varied from  $K = 1$  to 5, representing a range of greater than expected  $K$  values to ensure our analysis included all ecologically plausible values of  $K$ .

This was followed by additional analyses with the data set divided into two groups: coastal animals (SJH-west and SJH-east) and inland animals (NIR and CPH) to more closely evaluate possible substructure within each of these two groups (Pritchard *et al.* 2010). The parameters of this model were the same as above, with each analysis repeated five times for each  $K$  from  $K = 1$  to 3 for each group. For all of the above analyses, posterior probability values were computed for each  $K$  according to Pritchard *et al.* (2010). Additionally,  $\Delta K$  values, which have been shown to accurately reflect the actual number of genetic clusters, were calculated according to Evanno *et al.* (2005).

Structure was also used to identify individuals that were captured in one subpopulation but genetically assigned to another and thus represent migrants. The parameters for this analysis were the same as described above except subpopulation assignments were included in the analysis with the migration prior set to 0.05. Individuals with a probability of assignment to their source population  $\leq 0.01$  were considered migrants. Individuals with ambiguous assignment probabilities were considered hybrids.

An individual pairwise relatedness test was performed after correction for null alleles using the program Maximum-likelihood (ML)-Relate (Kalinowski *et al.* 2006; Wagner *et al.* 2006; Carlsson 2008). The

average pairwise relatedness of each subpopulation was compared using a *t*-test.

#### Detection of FIV infection

All bobcats for which serum samples were available ( $n = 91$ ) were screened for antibodies to FIV by Western blot as previously described (Franklin *et al.* 2007b). Of these, 24 (26.4%) were scored as 'weak positive' or 'positive' for FIV antibodies. PCR was used to confirm FIV infection in these samples (two to four PCR attempts per seropositive individual) using DNA extracted from whole blood or PBMCs. We used a set of degenerate nested primers, which was previously shown to amplify a region of the *RT-pol* gene from a diverse set of FIV isolates (Troyer *et al.* 2005). All bobcats that were not screened by Western blot ( $n = 15$ ) were screened for FIV infection by the PCR method only. In total, 19 individual bobcat FIV isolates were amplified by PCR and included in the FIV genetic analyses.

#### FIV *pol* and *env* PCR amplification and sequencing

Two gene regions were analysed to evaluate viral phylogeny using both a highly conserved region (*RT-pol*, encoding the essential viral polymerase) and a region that is less evolutionarily constrained (*env*, encoding the surface envelope protein) (Pecon-Slattery *et al.* 2008). PCR amplification of a region of the *RT-pol* gene was performed using degenerate primers as previously described (Troyer *et al.* 2005). Primers to amplify a region of the *env* gene were designed by first performing an alignment of two previously published FIV sequences: PLV-14 [GeneBank (accession no. U03982)] isolated from a Florida panther (*Puma concolor coryi*) and PLV-1695 [GenBank (accession no. DQ192583)] isolated from a puma (*Puma concolor cougar*) in British Columbia. Degenerate nested primer pairs were designed from regions of homology including first-round primers mJLenvF1 (5'-GTG CAI GTC ATI AGA TGT AGA G-3') and mPLVenvR7 (5'-GGG GTG TCA TTA TAA IIA GTA AAA TT-3'), amplifying a fragment of ~700 bp, and second-round primers mPLVenvF8 (5'-GGG TGC ATT IGT IAA AGA ICC ATT TTT AG-3') and mPLVenvR6 (5'-GGT GCI TTG AAI GGA CAC ATT CC-3'), which amplified a 570-bp product. Underlined bases indicate 5' tail sequences added to the primers to lengthen primers and increase strength of primer binding to the template DNA.

Fifty microlitre PCR reaction mixtures contained 25  $\mu$ L iQSuperMix (Qiagen), 400 nM of each primer and 10  $\mu$ L DNA. DNA concentrations varied among samples resulting in a range of ~100–500 ng template per reac-

tion. PCR reaction conditions for both rounds included a hot start at 94 °C followed by 20 cycles of melting at 94 °C for 30 seconds, touchdown annealing temperatures ranging from 55 to 46 °C decreasing by 1 °C every 2 cycles for 30 seconds, extension at 72 °C for 30 seconds, followed by 25 cycles of melting at 94 °C for 30 seconds, annealing at 52 °C for 30 seconds and extension at 72 °C for 30 seconds with a final extension at 72 °C for 3 min. This protocol successfully amplified proviral *env* fragments from three FIV-positive bobcats.

The resulting sequences were aligned, and the regions of highest homology were used to develop the following nested primer pairs that successfully amplified *env* fragments from all remaining bobcats with amplified *pol* sequences ( $n = 16$ ). First-round primers were envfw201 (5'-TTT CTC ATG TTC CTT GAA TGG TAC-3') and envrv202 (5'-CAC ATT CCA CTT AAT TGG TAT TG-3'), resulting in approximately a 450-bp amplicon. Second-round primers were envfw202 (5'-TGG TAC ATT CTG GGT GTT TAA ATC-3') and envrv201 (5'-CTA TTT TGG TCA CTC TCT GAT GC-3'), resulting in approximately a 400-bp product. PCR reagents and reaction conditions were the same as above with the exception that touchdown annealing temperatures ranged from 58 to 49 °C and the annealing temperature for the last 25 cycles was 54 °C. PCR products were visualized under UV light using gel electrophoresis with ethidium bromide in 2% agarose gel to confirm the presence of product bands.

PCR products were purified using the QIAquick PCR Purification Kit (Qiagen Inc.) prior to sequencing. Forward and reverse sequences were aligned using BLAST (National Center for Biotechnological Information, Bethesda, MD, USA), and a single consensus FIV sequence was produced for each infected bobcat. All sequences were verified manually. All sequences are available in the NCBI GenBank under accession numbers JN383436–JN383465.

#### Genetic alignments and phylogenetic analyses

Sequences were trimmed at the 5' and 3' ends resulting in all sequences having the same length (*pol* = 427 bp, *env* = 347 bp). Trimmed consensus sequences for each gene fragment ( $n = 19$  *pol* & *env*) were converted to coding frame using an online DNA translator tool (Swiss Institute of Bioinformatics; <http://www.isb-sib.ch/>), prior to alignment in CLUSTAL X2 (Larkin *et al.* 2007). Alignments were input into jMODELTEST (Posada 2008) to estimate the best-fit model of nucleotide substitution, which was the TPM2uf model with among-site rate variation for both gene segments (Kimura 1981). The estimated model parameters used for *pol* were [Lset base = (0.4030 0.1312 0.1592) nst = 6 rmat = (7.3755

50.7381 7.3755 1.0000 50.7381) rates = gamma shape = 0.2280 ncat = 4 pinvar = 0]. The model parameters for *env* included [Lset base = (0.3707 0.1869 0.1840) nst = 6 rmat = (4.2249 11.3706 4.2249 1.0000 11.3706) rates = gamma shape = 0.2250 ncat = 4 pinvar = 0].

Maximum-likelihood phylogenetic analyses were conducted in Phylogenetic Analysis Using Parsimony (PAUP) (Sinauer Associates, Sunderland, MA, USA) (Swofford 2003). The corresponding *pol* and *env* gene regions from an FIV isolate sequenced from a Florida panther in 1994 were included to provide a root for each tree (Langley *et al.* 1994). ML trees were constructed using an NJ starting tree, followed by a heuristic search using the tree-bisection-reconnection branch-swapping algorithm. The *pol* and *env* trees were found to be congruent, and therefore, a single *pol-env* concatenated sequence was used to construct the final phylogenetic tree for analysis. Bootstrap analyses were performed with 100 iterations for all trees. Viral isolates were divided into four 'FIV Groups' based on clusters of related isolates arising from a basal node supported with an ML bootstrap value of 70 or greater.

We estimated the number of FIV migration events between coastal and inland bobcat subpopulations by calculating the *s* statistic for the observed ML phylogenetic tree in Mesquite 2.75 (Maddison & Maddison 2011). The *s* statistic reflects the minimum number of parsimony steps that explain the discord between subpopulations as monophyletic groups on the tree (Slatkin & Maddison 1989).

To estimate the timeline of past virus transmissions within and between subpopulations, the concatenated viral sequence data were analysed in the coalescent framework as implemented by the program BEAST 1.6.2 (Drummond & Rambaut 2007). The SDR06 substitution model was used with a relaxed uncorrelated lognormal molecular clock (Drummond *et al.* 2006). The tree model included a piece-wise linear Bayesian Skyline prior with five groups and a randomly generated starting tree (Drummond *et al.* 2005). An initial run of 10 000 000 Markov chain Monte Carlo (MCMC) iterations, sampled every 1000 runs, was performed to estimate model parameter values. The first 10% of logged values were discarded as burn-in. From this analysis, the following model parameter priors were changed from default settings: (i) the relative rate parameters were set to vary from 0 to 10; (ii) the Bayesian Skyline population size was set to vary from 0 to 500; and (iii) the mean rate for the uncorrelated relaxed molecular clock was set to vary from 0 to 10.

The final analysis included the above settings with 50 000 000 MCMC iterations sampled every 1000 runs. The first ten per cent of logged values were again dis-

carded as burn-in. The estimated values and associated effective sample size (ESS) for each model parameter were viewed in TRACER 1.5 (Rambaut & Drummond 2007). ESS values for all parameters were >500. The maximum clade credibility tree was produced in TREEANNOTATOR 1.6.2 (Rambaut & Drummond 2002). The resulting tree was viewed in FIGTREE 1.3.1 (Rambaut 2006), and the mean posterior probability heights with 95% highest posterior density (HPD) intervals were labelled on internal nodes.

## Results

### *Bobcat population structure*

*Distribution of alleles.* An analysis of population differentiation performed in GENEPOP indicated that the distribution of alleles among bobcats from the two coastal subpopulations, SJH-west and SJH-east, differed significantly ( $P = 0.0064$ ) at only the FCA008 microsatellite locus. Therefore, the coastal bobcats, regardless of whether they were captured east or west of SR-73, had a similar distribution of alleles at 15 of the 16 microsatellite loci examined. Similarly, the two inland subpopulations, NIR and CPH, significantly differed in allelic distribution at only FCA026 ( $P = 0.0025$ ) and FCA077 ( $P = 0.0048$ ). This finding demonstrates that bobcats captured north and south of SR-91 had a similar distribution of alleles at 14 of the 16 microsatellite loci we analysed. However, the distribution of alleles differed greatly between the coastal and inland subpopulations. SJH-west bobcats significantly differed from NIR and CPH bobcats at 13 and 10 microsatellite loci, respectively, and SJH-east bobcats differed from both NIR and CPH bobcats at 13 loci ( $P < 0.01$  all significant pairwise tests). These results indicate a high degree of genetic differentiation exists between bobcats separated by I-5 and its associated urban development.

*Genetic diversity.* No pairwise difference existed in allelic richness (Table S2, Supporting information) when comparing the two coastal subpopulations ( $F_{1,29} = 2.59$ ,  $P = 0.118$ ) or the two inland subpopulations ( $P = 0.982$ ,  $F_{1,30} = 0.00$ ). However, the coastal bobcats (combined SJH-W and SJH-E) had significantly lower allelic richness than the inland bobcats (combined NIR and CPH) ( $P < 0.001$ ,  $F_{1,62} = 12.62$ ). This further suggests that coastal and inland bobcats are genetically distinct and indicates that coastal bobcats have lower genetic diversity than inland bobcats. Interestingly, the BCD8T locus appears to have drifted to fixation in coastal bobcats as only one allele was sampled at this locus from all 49 coastal bobcats. Although the frequency of this allele was also high in NIR (0.82) and CPH (0.67), four and

five alleles, respectively, were present at this locus in these subpopulations.

*Departures from random mating.* The overall estimate of genetic differentiation among the four putative subpopulations,  $D_{est} = 0.11$ , indicates a moderate amount of genetic structure exists within this population. Pairwise  $D_{est}$  values were lowest when comparing the two coastal subpopulations ( $D_{est} = 0.008$ , SJH-west:SJH-east) or the two inland subpopulations ( $D_{est} = 0.014$ , NIR:CPH) and highest between the coastal and inland subpopulations ( $D_{est} = 0.11$ , SJH-west:NIR;  $D_{est} = 0.13$ , SJH-west:CPH;  $D_{est} = 0.14$ , SJH-east:NIR;  $D_{est} = 0.19$ , SJH-east:CPH). The estimated differentiation between the coastal bobcats (combined SJH-W and SJH-E) and the inland bobcats (combined NIR and CPH) was  $D_{est} = 0.14$ . Locus-specific  $D_{est}$  values are reported in Table S2 (Supporting information).

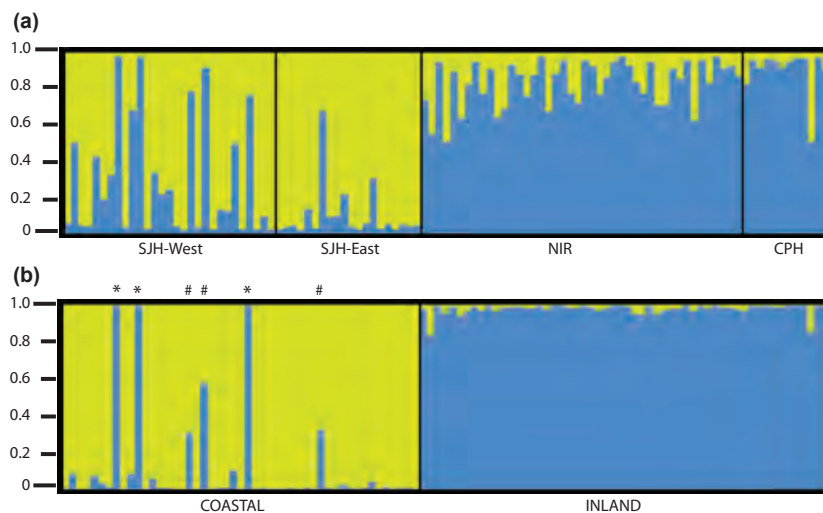

We found no evidence of inbreeding within the overall population ( $F_{IS} = 0.013$ ; 95% CI:  $-0.29$ – $0.065$ ), nor in any of the putative subpopulations [ $F_{IS} = (0.011, \text{SJH-W}; -0.045, \text{SJH-E}; 0.029, \text{NIR}; 0.034, \text{CPH})$ ].

*Individual assignment tests.* Bayesian clustering indicated the assumption of two genetically distinct subpopulations ( $K = 2$ ) best explained the variation in our microsatellite data (Fig. S1, Supporting information). This result was the same regardless of whether or not source population information was used as a prior in the anal-

ysis. All bobcats caught east of I-5 (NIR and CPH bobcats  $n = 56$ ) were assigned to one 'inland' subpopulation, while 46 of 49 bobcats caught west of I-5 (SJH-west and SJH-east bobcats) were assigned to a 'coastal' subpopulation (Fig. 2). Three individuals captured west of I-5 were genetically assigned to the inland subpopulation and thus represent possible migrants. However, no bobcats captured east of I-5 were genetically assigned to the coastal subpopulation. If any additional human development and/or freeways in this region (i.e. SR-91, SR-73, SR-241, SR-261) were causing genetic structure, a population model with  $K > 2$  should have had the highest support. Therefore, the I-5 corridor is the only human development in this region implicated as a cause of genetic structure among bobcats during our period of sample collection.

Three individuals were identified as first-generation migrants as they were captured in the coastal area but had assignment probabilities of 1.00 to the inland population when capture locations were included in the Structure analysis (denoted by \* in Fig. 2b). Three other bobcats captured in the coastal area had the genetic profile of hybrids with partial assignment to both subpopulations (denoted by # in Fig. 2b). No individuals sampled from the inland area were identified as migrants or hybrids from the coastal area.

*Relatedness of individuals.* The average relatedness of bobcats in the coastal population ( $R = 0.096$ ;  $SE = 0.0037$ )

**Fig. 2** Individual bobcat genetic assignments to each of two distinct subpopulations. Each vertical bar represents one individual. Values on the  $y$ -axis are the probability of assignment of each individual to one of the two genetic groups identified (Fig. S1). The shading of each bar corresponds to the probability of genetic assignment to either the coastal group (yellow) or the inland group (blue) of bobcats. (a) Results for simulation of  $K = 2$  without including a priori capture locations. The majority of individuals captured west of I-5 had strong assignment to one subpopulation (coastal—yellow), while all of the individuals captured east of I-5 had a high probability of assignment to a second subpopulation (inland—blue). (b) Three migrants (\*) and three hybrids (#) were identified in Structure using a priori assignments to coast or inland subpopulations based on capture locations. All gene flow was detected from the inland to the coastal subpopulation.

was significantly higher ( $t_{5634} = 7.23$ ;  $P < 0.001$ ) than in the inland population ( $R = 0.064$ ;  $SE = 0.0026$ ).

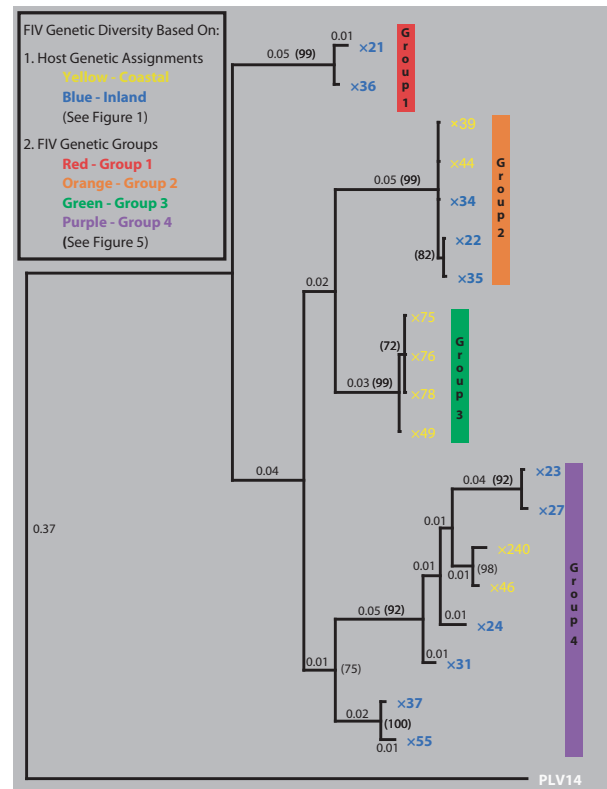

### FIV phylogenetic analyses

We amplified a 427-bp region of *pol* and 347-bp region of *env* by PCR from 19 bobcats (four in SJH-west, four in SJH-east and 11 in NIR) bobcats. These included 17 of the 24 (70.8%) bobcats putatively seropositive by Western blot, one bobcat that was negative by Western blot and one bobcat that was screened by PCR only. The inability to amplify FIV sequences from a subset of putatively seropositive bobcats is similar to the findings of previous studies (Troyer *et al.* 2005; Franklin *et al.* 2007b). This is probably the result of a difference in the sensitivity and specificity of these two assays and/or a relatively low FIV proviral load present in a subset of infected animals.

The demographic information for 18 of the 19 FIV-positive bobcats was known: 13 were adult males, one was a yearling male, two were adult females and two were yearling females. The age-specific prevalence of FIV was 14.2% (3/21) for yearlings and 23.8% (15/63) among adults.

The ML phylogenetic tree built from *pol-env* concatenated gene sequences (Fig. 3) shows no evidence of association between capture location (coastal vs. inland) and FIV relatedness (see also Fig. 4). The basal nodes have low bootstrap support, suggesting little overall genetic structuring within the virus population. The number of parsimony steps ( $s$  statistic) that best explains the discord of FIV relatedness between subpopulations indicates a minimum of three FIV transmission events have occurred between the coastal and inland subpopulations (Slatkin & Maddison 1989).

We estimated the past timeline of virus movement within and between bobcat subpopulations using a coalescent Bayesian model (Drummond *et al.* 2005; Drummond & Rambaut 2007). Figure 5 illustrates the maximum clade credibility tree with labels representing the estimated year of coalescence (mean posterior node ages) for each internal node. The age of the basal nodes is difficult to interpret because of large 95% HPD intervals (analogous to 95% confidence intervals). Therefore, it is impossible to reconstruct a precise timeline of ancestral divergence into the observed FIV groups. However, the more terminal nodes are insightful as they depict the estimated year of recent FIV coalescent events. FIV Group 4, the largest supported group of isolates, comprises six isolates from inland bobcats (x23, x24, x27, x31, x37 and x55) and two isolates from coastal bobcats (x240 and x46). The two coastal isolates in this group share a common ancestor with two of the

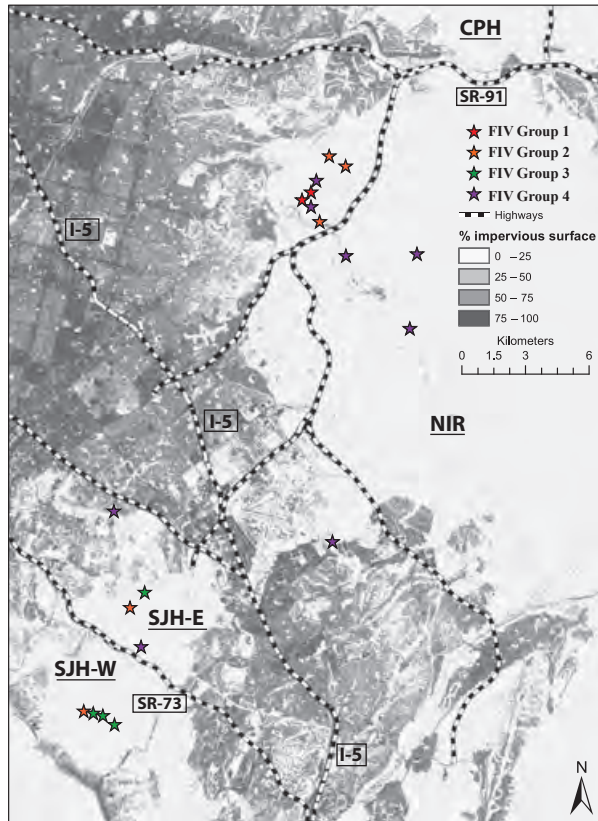

**Fig. 3** Maximum-likelihood phylogenetic tree of feline immunodeficiency virus (FIV) concatenated *pol-env* sequences from 19 infected bobcats. The tree was constructed using a single 774-bp sequence (427 bp from *pol*, 347 bp from *env*) of proviral DNA from each individual. All sequences are in coding frame. Bootstrap values  $>70$  are indicated in parentheses. Branch lengths  $\geq 0.01$  are also indicated. Individuals have been coloured to represent their genetic assignment based on the results of the *Structure* analysis (see Figs 1 and 2). Because no migrants were infected with FIV, the colour of an individual also represents whether an individual was captured west (yellow) or east (blue) of I-5. FIV isolates were assigned to groups based on the four most basal supported nodes to illustrate the distribution of FIV genetic diversity across the landscape (See Fig. 4). The tree is rooted with PLV-14, a viral sequence from the same FIV clade, which was sequenced from a Florida panther in 1994.

inland isolates (x23 and x27) in *c.* 1990 (Fig. 5; 95% HPD: 1967–2003). Similarly, FIV Group 2, with 99% bootstrap support, contains nearly identical sequences from three inland bobcats (x22, x34 and x35) and two coastal bobcats (x39 and x44), which share a common ancestor in approximately the year 2000 (Fig. 5; 95% HPD: 1995–2003).

Feline immunodeficiency virus Group 3 contains four closely related viral isolates (Fig. 3; x75, x76, x78 and x49) from related coastal bobcats ( $r > 0.25$ ). To our knowledge, this is the first evidence of FIV familial transmission among bobcats. Familial transmission of

**Fig. 4** Geographical distribution of feline immunodeficiency virus (FIV) genetic diversity among inland and coastal bobcats. Each star indicates the capture location of one FIV-positive bobcat. The stars are coloured corresponding to which of the four groups of related FIV isolates was sampled from each bobcat (See Fig. 3). FIV Groups 1 (red) and 3 (green) contain isolates sampled only from inland or coastal bobcats, respectively. FIV Groups 2 (orange) and 4 (purple), containing both inland and coastal bobcats, resulted from the movement of FIV across Interstate-5. Degree of urban development (% impervious surface) is represented by grey shading.

FIV has been previously documented in mountain lions (Poss *et al.* 2008).

## Discussion

### *Bobcat population structure*

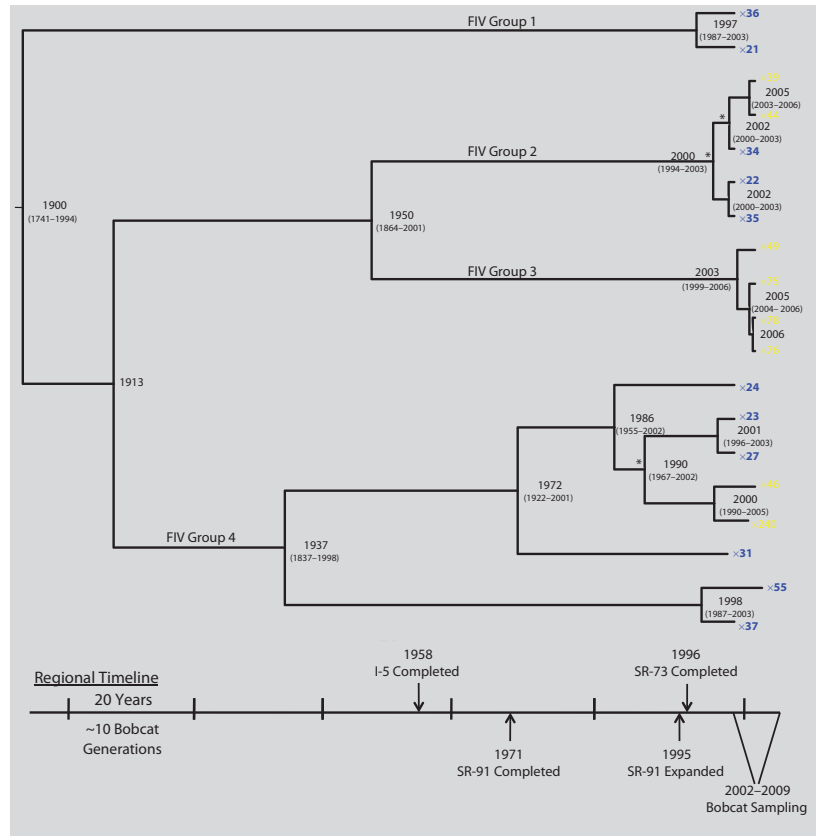

Understanding the degree of connectivity among populations in heterogeneous landscapes is an important goal of ecology, population genetics and conservation biology (Taylor *et al.* 1993; Crooks & Sanjayan 2006; Fischer & Lindenmayer 2007). We evaluated host and pathogen genetic markers to investigate connectivity among bobcats throughout a fragmented urban landscape in southern California. Our results indicate that two genetically distinct groups of bobcats existed in our

study area, defined as coastal and inland subpopulations, separated by urban development including Interstate-5 (Figs 1 and 3). This finding is in agreement with other analyses performed previously with a small subset of these bobcats and four of the 16 microsatellite loci utilized in this report (Ruell *et al.* in press).

Our results indicate that the coastal and inland bobcat subpopulations had a different distribution of alleles at most of the microsatellite loci examined and a low, unidirectional pattern of migration from the inland to the coastal area. We also observed reduced genetic diversity and increased relatedness among individuals in the coastal population. These findings suggest the observed genetic differentiation is because of decreased migration through the urban matrix between the inland and coastal habitat patches. We therefore conclude that urban development, including I-5, has been a physical barrier that has reduced bobcat movement and gene flow between isolated groups of individuals.

We did not detect substructure among bobcats separated by the two other freeways that we specifically evaluated, SR-91 and SR-73 and nor did we find evidence of genetic structure because of any other freeways (i.e. SR-241, SR-261) or human development in the region. The maintenance of gene flow across SR-91 and SR-73 is probably explained by the fact that these roadways are perforated by more functional wildlife underpasses and are bordered by more natural habitat than I-5. Therefore, the distance between habitat patches is shorter across SR-91 and SR-73 than across I-5, a factor that has been shown to be an important determinant in carnivore movement among habitat fragments in this region (Crooks 2002). It is possible that because SR-91 and SR-73 are newer roads, any isolation these may be causing has not yet resulted in detectable genetic structure.

Our findings, revealed by analyses of empirical genetic data, are supported by observations from remotely triggered cameras placed near underpasses of all three focal roadways. Cameras placed near the only potential wildlife corridor under I-5 that directly links SJH-E to NIR did not document any movement of bobcats between these habitat patches during 204 consecutive days of observation (Lyren *et al.* 2008a). Cameras, however, did not monitor another potential path across I-5 connecting NIR to SJH-W to the south; road kill carcasses and models of connectivity both suggest this path may be utilized by bobcats (Lyren *et al.* 2008a). In contrast to the lack of remote camera observations of bobcat movement across I-5, a similar duration of camera monitoring of potential wildlife corridors under SR-91 documented many successful movements between NIR and CPH (E. E. Boydston, unpublished data). Likewise, multiple bobcat movements between

**Fig. 5** The estimated timeline of viral coalescent events. Maximum clade credibility Bayesian phylogenetic tree of *pol-env* concatenated sequences constructed using dated tips. Internal node labels correspond to the highest mean posterior probability estimate [with 95% highest posterior density (HPD) interval] for the year of coalescence. The estimated dates on basal nodes lack precision; therefore, it is impossible to accurately reconstruct the timeline of ancestral diversification into the current four-group structure of feline immunodeficiency virus (FIV). Estimates of recent coalescent events are more precise and depict contemporary FIV transmission within and between bobcat subpopulations. \*Indicates common ancestor to contemporary isolates sequenced from both inland and coastal bobcat isolates. Viral movement across I-5 has probably occurred since the estimated date of these coalescent events, resulting in the presence of related viral strains sampled in both subpopulations (See Fig. 4).

SJH-W and SJH-E were also recorded during 358 days of camera observations near SR-73 (Lyren *et al.* 2008b).

Interstate-5 and the surrounding urban matrix have greatly increased in size over time since the original construction was completed in 1958. While it is difficult to know when I-5 became a 'barrier' to bobcat movement, Crooks (2002) estimated that the coastal San Joaquin Hills might have become effectively isolated from inland natural areas around 1980. Given the generation time of bobcats (*c.* 2 years) (Knick *et al.* 1985), between 12 (*c.* 1980) and 25 (*c.* 1958) generations have passed because the inland and coastal bobcat subpopulations became physically isolated.

#### *FIV phylogenetic analyses*

Directly transmitted pathogens are inextricably linked to their hosts, and therefore, the geographical distribu-

tion of pathogens reflects the movement and contacts of their hosts throughout the landscape. We analysed two gene sequences from FIV, a retroviral pathogen of bobcats, to evaluate whether the gene flow (transmission) of the virus revealed information about bobcat movement not discernable from traditional host genetic analyses. We hypothesized that urban development, which limits bobcat gene flow, would also limit viral transmission between bobcat subpopulations. Given that only one in five bobcats are infected with FIV, the expected virus migration rate is five times lower than the host migration rate. Thus, we expected each of the two bobcat subpopulations would be infected with a genetically distinct viral strain, divergent from one another owing to years of isolation, low viral migration rates and the high mutation rate of FIV.

This prediction is consistent with previous literature demonstrating that geographical or social barriers,

which prevent mixing between neighbouring host subpopulations, result in genetically structured retrovirus populations (Franklin *et al.* 2007a; Liu *et al.* 2008; see also Fig. S2, Supporting information—demonstrating clear divergence between FIVs isolated from bobcats north or south of Los Angeles). However, the phylogenetic trees constructed in this study from FIV gene segments demonstrated a pattern that differs from these previously published findings. The relatedness of FIV isolates is mixed among coastal and inland bobcat subpopulations, indicating that there is no association between FIV relatedness and the geographical/genetic structure of its host (Figs 3 and 4). While this finding differs from our prediction based on the ecology of FIV, it is consistent with previous studies of urban bobcats in southern California, which have found that individual movements (and thus opportunities for disease transmission) between fragmented habitat patches occur more frequently than predicted by observed levels of gene flow (Riley *et al.* 2006; Ruell *et al.* in press).

The topology of the ML phylogenetic tree (Fig. 3) illustrates that neither the coastal nor the inland bobcats are infected with a monophyletic cluster of viruses. Instead, we identified four groups of related FIV isolates but found no evidence to suggest these groups developed because of the population structure of bobcats. While two of the four groups contained only coastal or inland isolates (FIV Groups 1 and 3), these were the smallest groups sampled and the other two FIV groups did not follow this pattern. Instead, FIV Groups 2 and 4 contained closely related viruses arising from both bobcat subpopulations. The coastal isolates within each of these two groups shared recent common ancestry with inland viruses (Fig. 5), and thus, we conclude that FIV-infected bobcat migration events across I-5 are responsible for the observed mixing of isolates. Half of the viruses infecting coastal individuals (4/8) recently originated from, or were transmitted to, inland bobcats. The former is likely to have occurred in FIV Group 2 as suggested by the presence of multiple inland isolates basal to the two coastal isolates and evidence of a long Group 2 residence time within the inland subpopulation.

#### *Utilizing host and pathogen genetics*

The presence of related FIV strains on both sides of I-5 suggests that the intervening urban development is somewhat permeable to bobcat movement and disease transmission, despite the presence of distinct genetic structure among the host population. There may be several explanations for the discrepancy between the population structure of FIV and its host. One hypothesis is that a recent increase in bobcat migration across I-5 has

led to the observed mixing of viral genotypes, but not enough time has passed for this recent increase in migration to counteract previously established genetic structure among the bobcats. While possible, we consider this unlikely as human development along the I-5 corridor has increased over time, and no notable changes have been made in the area (e.g. underpasses, culverts) that would account for a recent increase in connectivity between the two subpopulations.

An alternative hypothesis is that FIV exchange between the two subpopulations is not necessarily linked to bobcat gene flow. Transient movements of individuals across a semi-permeable barrier such as I-5 may not result in the exchange of genetic material, but may involve sufficient contact between individuals to allow for disease transmission. Under this hypothesis, the contrasting patterns of population structure may reflect differences in the underlying ecology of the two molecular markers.

Microsatellite markers are useful for detecting host gene flow, the specific process involving animal movement which results in the exchange of genetic material from one group of individuals to another (Endler 1977). According to this definition, gene flow is dependent upon successful mating after migration. FIV transmission, however, can occur both vertically *and* horizontally, allowing FIV isolates to move between individuals and subpopulations in the absence of gene flow. For example, Biek *et al.* (2003) reported that for one population of mountain lions, horizontal transmission among adults resulted in the majority of new FIV infections and accounted for the observed increasing prevalence of FIV with age. Vertical transmission, resulting in a cohort of young individuals infected prior to adolescence, was equally important in explaining the dynamics of FIV in the population.

Given that bobcats and mountain lions share many life history characteristics, it is probably that similar FIV transmission dynamics occur in bobcats. Indeed, the relative prevalence of FIV in yearlings (14%) vs. adults (24%) in this study is similar to the age-prevalence relationship described in Biek *et al.* (2003). Young infected individuals may therefore play an important role in the maintenance and spread of FIV in this population. At adolescence, juvenile (usually male) bobcats often make transient movements during dispersal from their natal range while attempting to establish a new home range (Kitchings & Story 1984; Knick 1990; Hansen 2007). Young bobcats infected prior to dispersal therefore represent a potentially important mode of virus movement within and between subpopulations.

In fragmented landscapes such as southern California, where urban development and freeways act as boundaries limiting animal movement, bobcat home

ranges may shrink, and the amount of overlap between neighbouring home ranges may increase (Riley 2006; Riley *et al.* 2006). This pattern of 'home-range pile-up' has been described in other bobcat populations in California (Riley *et al.* 2006). This phenomenon decreases the probability that juveniles dispersing to a neighbouring subpopulation will successfully mate. Under these conditions, the actual rate of bobcat movements, contacts and opportunities for disease transmission between subpopulations would be higher than expected based on migration rates estimated from gene flow.

The low level of gene flow we detected across I-5 occurred in a unidirectional pattern from the inland area towards the coast. The coastal population, while reduced in overall genetic diversity, contains both migrants and hybrids from the inland population. This suggests that, while rare, inland bobcats can successfully migrate to and breed in the coastal population, while the reverse was not seen. However, inland FIV isolates do not form a monophyletic group; two of the three FIV groups infecting coastal bobcats also infect inland bobcats. There are two possible explanations to this pattern. One is that movement of FIV has occurred repeatedly one-way from the inland subpopulation to the coast, causing the diversity among coastal isolates to closely mirror that observed inland. This hypothesis is consistent with the one-way pattern of bobcat movement we detected from the microsatellite analysis.

The other possibility is that a coastal virus population diverged from inland viruses after the two groups were isolated by urban development and has since been transmitted back into the inland subpopulation multiple times via transient movements and contacts resulting in disease transmission but not gene flow. Tracking the movements of individual bobcats, evaluating FIV diversity in other neighbouring bobcat populations and utilizing spatially explicit phylogeographic analyses may help to distinguish between these alternatives.

In conclusion, our findings indicate that bobcats inhabiting this fragmented landscape in southern California are physically isolated and genetically structured. This pattern is consistent with decreased connectivity across urban development, resulting in low levels of migration and/or a low probability that migrants establish a home range and successfully mate. However, movements are apparently made, allowing for disease transmission between these habitat fragments. This conclusion carries with it conservation implications as populations with these characteristics are susceptible to decline as a result of a continued loss of genetic diversity from genetic drift and decreased individual fitness because of inbreeding depression (Frankham 2006). In addition, both subpopulations should be managed as a

unit when considering treatment and prevention interventions during future disease outbreaks. Habitat conservation and restoration as well as connectivity enhancements such as functional underpasses to better facilitate movement of bobcats under roadways may help safeguard their persistence in the face of substantial ongoing threats posed by humans in this region.

## Abstract

**Context.** Road mitigation to reduce animal–vehicle collisions (AVCs) is usually based on analysis of road survey animal carcass data. This is used to identify road sections with high AVC clusters. Large mammals that are struck and die away from a road are not recorded nor considered in these analyses, reducing our understanding of the number of AVCs and the cost–benefit of road mitigation measures.

**Aims.** Our aim was to develop a method to calculate a correction factor for large mammal carcass data reported through road survey. This will improve our understanding of the magnitude and cost of AVCs.

**Method.** Citizen scientists reported animal carcasses on walking surveys along transects parallel to the highway and reported observations using a smartphone application at three sites over a 5-year period. These data were compared with traditional road survey data.

**Key result.** We found that many large mammals involved in AVCs die away from the road and are, therefore, not reported in traditional road surveys. A correction factor of 2.8 for our region can be applied to road survey data to account for injury bias error in road survey carcass data.

**Conclusions.** For large mammals, AVCs based on road survey carcass data are underestimates. To improve information about AVCs where little is known, we recommend conducting similar research to identify a correction factor to conventionally collected road survey carcass data.

**Implications.** Identifying road mitigation sites by transportation agencies tends to focus on road sections with above-threshold AVC numbers and where cost–benefit analyses deem mitigation necessary. A correction factor improves AVC estimate accuracy, improving the identification of sites appropriate for mitigation, and, ultimately, benefitting people and wildlife by reducing risks of AVCs.

**Keywords:** animal vehicle collisions, citizen science, road ecology, road mitigation.

## Introduction

Animal–vehicle collisions (AVCs), particularly those involving ungulates, are increasingly recognised as a significant concern for traffic safety, socioeconomics, animal welfare and wildlife management in the United States, Canada, Australia and Europe (Groot Bruinderink and Hazebroek 1996; Huijser *et al.* 2008; Ward *et al.* 2011; Ang *et al.* 2019). In the USA alone, it is estimated that 1 million deer (*Odocoileus* sp.)–vehicle collisions occur annually, with an associated cost of more than US\$1 billion in vehicle damages and 29 000 human injuries (Conover *et al.* 1995). Similar patterns and growing concerns about vehicle collisions with large animals are found in Canada and Europe (Langbein *et al.* 2011; Vanlaar *et al.* 2012; Morelle *et al.* 2013; Rosell *et al.* 2013).

In an effort to reduce the frequency of AVCs, transportation agencies around the world have implemented road mitigation measures such as wildlife under- and overpasses, fencing, animal detection systems, and variable message signs (Huijser *et al.* 2008; van der Ree *et al.* 2015). AVC records are often used to locate optimal sites for these measures. For example, AVC data have been used solely, or in conjunction with, wildlife movement data to plan the location of mitigation measures on roads (Lenhert and Bissonette 1998; Van Manen *et al.* 2012; Gagnon *et al.* 2019). AVC data are also analysed together with landscape and road variables to identify where high AVC rates might occur, so as to help inform the underlying mechanisms leading to future AVCs (Ramp *et al.* 2005; Litvaitis and Tash 2008; Ward *et al.* 2011; Clevenger *et al.* 2015). For both

purposes, it is imperative that transportation agencies collect sound data to ensure that analyses provide strong inferences to inform decision making (Snow *et al.* 2015).

This includes systematically collected AVC information to avoid potential observation bias (Huijser *et al.* 2007; Santos *et al.* 2018). Common factors related to how the survey is conducted can affect the reliability and accuracy of AVC data. These range from speed at which surveys are conducted, the number and consistency of observers, to time of day when surveys are conducted (Slater 2002; Santos *et al.* 2011).

Animal–vehicle collision data collection can also be strongly biased if observers fail to detect road-kills along the survey (Ascensão *et al.* 2019). These biases may occur due to (1) carcass removal, for example, by scavenging animals or people, (2) detectability, as small road-killed animals are less likely to be observed than are large animals and (3) injury; that is, animals are not immediately killed by the collision but are injured and die some distance, out of sight of the road (Winton *et al.* 2018).

For many years, there has been speculation regarding a systematic discrepancy between reported or recovered numbers of AVCs and the actual numbers killed on roadways (Huijser *et al.* 2007). It is important to know the real road-kill rate to identify and prioritise road sections for mitigation planning (Lee *et al.* 2006; Polak *et al.* 2014; Sáenz-de-Santa-María and Tellería 2015). AVCs can be a significant cost to society and thresholds in the number of AVCs are used to identify what roads and segments are cost effective (Conover *et al.* 1995; Huijser *et al.* 2009). Having a more accurate estimate of AVCs will aid transportation agencies in selecting road segments where motorist safety is at high risk and benefits of mitigation outweigh costs.

Unreported AVCs include those collisions where animals are hit by vehicles, are injured and move well away from the road to die. These animals may not be observed during road surveys by road maintenance clean-up crews. We designed the present study to better understand injury bias in AVC data by comparing the relationship between AVC survey data obtained by a standard method of road survey (reported animal carcasses on the road by road maintenance clean-up crews) and data obtained by walking surveys using citizen scientists (detecting animal carcasses off the road to quantify the number of unreported animal carcasses). This will enable us to develop a correction factor for related landscapes in North America that can be applied to road survey carcass reports to both obtain a more reliable estimate of AVCs and to better understand the true societal costs of AVCs. Although the correction factor calculated in the present study may not be applicable to other landscapes with different habitats and species assemblages, our study outlines field-based methods for determining a road-kill correction factor.

## Materials and methods

### *The Crowsnest Pass region*

The Highway 3 transportation corridor is located in the Crowsnest Pass, Alberta, in the southern Canadian Rocky Mountains. The corridor is in a low-elevation, east–west aligned mountain pass bisecting the predominately north–south aligned Canadian Rocky Mountains. The elevation of the region ranges from 1113 m at the valley bottom to 2804 m at the mountain peaks and is

characterised by a rapid ecological transition from the prairie to alpine ecological zones. The complement of large mammals for the region includes grizzly bear (*Ursus arctos*), black bear (*Ursus americanus*), lynx (*Lynx canadensis*), cougar (*Puma concolor*), wolf (*Canis lupus*), wolverine (*Gulo gulo*), elk (*Cervus elaphus*), mountain goat (*Oreamnos americanus*), moose (*Alces alces*), mule deer (*Odocoileus hemionus*), white-tailed deer (*Odocoileus virginianus*), and Rocky Mountain bighorn sheep (*Ovis canadensis*).

In this region, Highway 3 is a 45 km long, two-lane paved road, supporting between 6000 and 9000 weighted average annual daily vehicle traffic. The highway connects six small settlements (ranging in size from 100 to 1500 people) and is a major trucking and commuter route between Alberta and British Columbia. Most of the region is managed for multiple values, including resource extraction, agriculture, human settlement, and tourism that includes both motorised and non-motorised recreation. The lower-elevation lands parallel to the highway are predominantly privately owned, with some government-owned crown land. The lower valley connects crown forest reserves and protected areas to the north and south. The Crowsnest Pass is recognised as a key wildlife linkage zone at a local and transboundary scale (Apps *et al.* 2007; Weaver 2013). Highway 3 bisects this critically important landscape for a variety of large mammal species (McKelvey *et al.* 2011; Proctor *et al.* 2012).

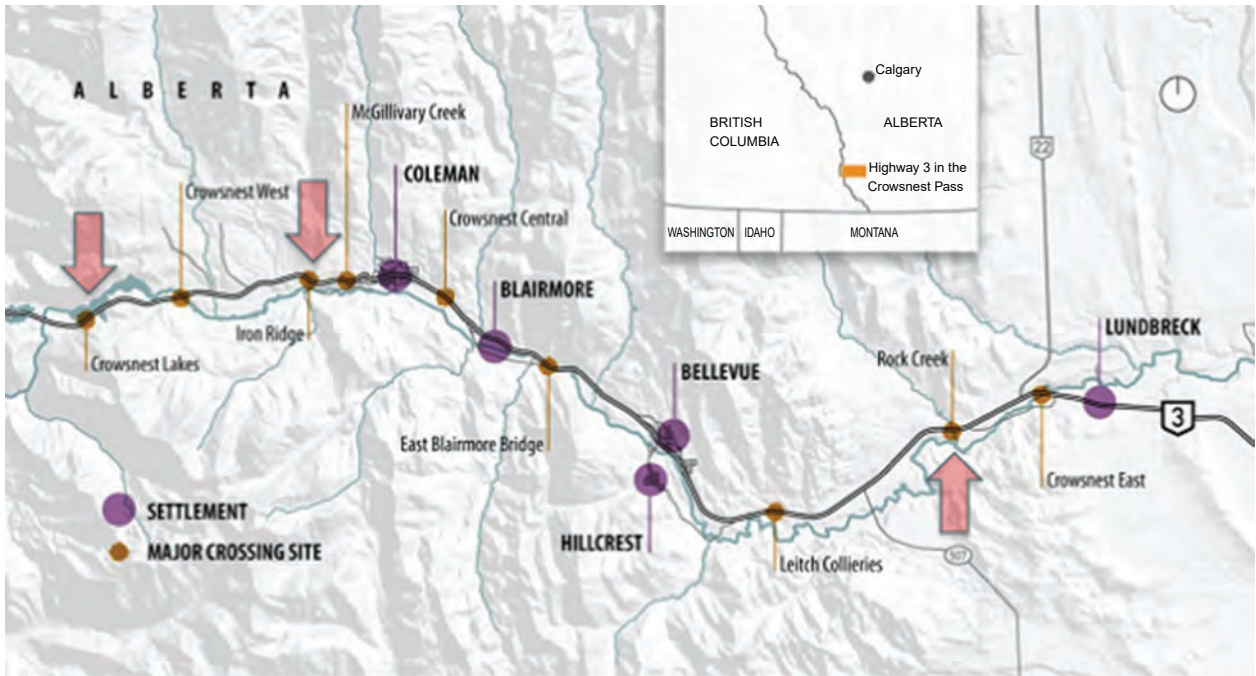

### *Site selection for road and walking surveys*

Animal–vehicle collisions are common along Highway 3 and involve a diversity of large-bodied mammals, with deer species being the most common. Road sections with a high number of AVCs (identified in Clevenger *et al.* 2010) and animal connectivity models were reviewed to identify nine mitigation emphasis sites (MES) where road mitigation measures would improve motorist and wildlife safety (Fig. 1; Apps 1997; Apps *et al.* 2007; Chetkiewicz 2008; Chetkiewicz and Boyce 2009; Clevenger *et al.* 2010). Two of the sites, Rock Creek and Emerald Lake MESs, have also been prioritised by Alberta Transportation for road mitigation. In addition to the two priority MESs, a third site, Iron Ridge, was selected as a control site where no road mitigation measures are being planned.

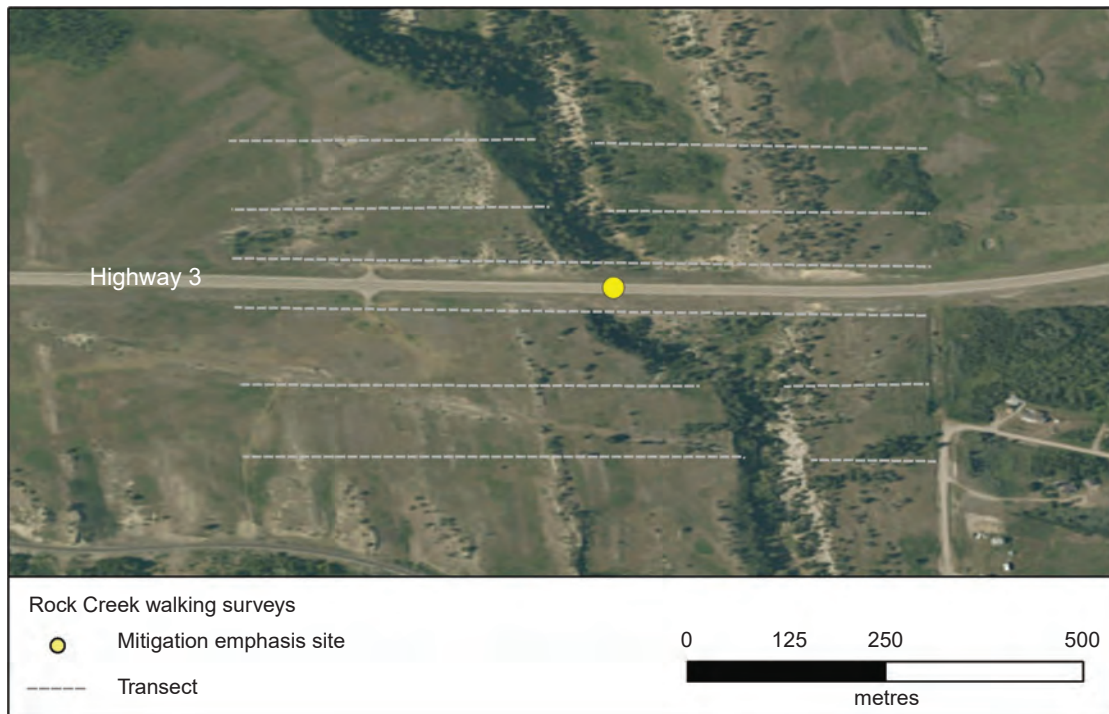

All three MESs occur in the montane natural subregion of Alberta, occurring in a lower-elevation valley consisting of moderately dry south- and west-facing slopes vegetated by open forests or grasslands. Open forests typically include lodgepole pine (*Pinus contorta*), Douglas fir (*Pseudotsuga menziesii*), trembling aspen (*Populus tremuloides*) and white spruce (*Picea glauca*) as pure or mixed stands. Grasslands are also common on moderately dry south- and west-facing aspects and include mountain rough fescue (*Festuca campestris*), Idaho fescue (*Festuca idahoensis*) and Parry's oatgrass (*Danthonia parryi*; Alberta Sustainable Development 2008).

At each MES (Rock Creek, Iron Ridge, Emerald Lakes), we established three walking transects, parallel to, but off the road surface, 1000 m long. Each transect was separated by 50 m to the north and south of the highway, except where limited by terrain (see Fig. 2 for Rock Creek transects). For example, on the northern side of Iron Ridge, we established only two walking transects (1000 m) separated by 50 m intervals. A third transect

**Fig. 1.** Highway 3 study area in Alberta, Canada. The study included nine mitigation emphasis sites (MESs) collected by road crews from vehicles (orange dots) and three MESs with walking surveys (red arrows).

**Fig. 2.** Example of walking transects along Highway 3 (white dashed lines) at the Rock Creek mitigation emphasis site (MES) on northern side of Highway 3, Alberta, Canada. Three parallel transects each 1000 m long and separated by 50 m.

was not included on the northern side because of dense tree cover that was inhospitable for surveying. An observer reported animal carcasses up to 10 m on either side of the transect by

using a visual scan. Areas with complex topography and tree patches caused some variability in line of sight along transects, potentially leading to missed animal carcass detections.

The majority of transects were difficult to see from the road, owing to terrain complexity and vegetation. Species presence for all three MESs was similar, including white tailed deer, mule deer, moose, elk, black bear, grizzly bear, wolf, cougar and coyote. The Emerald Lake MES also included bighorn sheep.

#### *Animal-carcass road and walking surveys*

Animal carcass data were acquired from two sources, namely, by road maintenance clean-up crews during regularly driven road surveys and by citizen scientists walking designated surveys at the three MESs.

Road maintenance clean-up crews reported animal carcass data during routine road surveys every weekday morning and late afternoon. From 1997 to 2017, animal carcasses were recorded on paper forms and then transcribed into a GIS environment by using local landmarks and distance to measurements (m). Local landmarks are consistently used by surveyors and were, on average, 250 m apart. It is, therefore, estimated that accuracy of animal carcasses collected by road maintenance clean-up crews is within 250 m of a landmark. For 2018, animal carcass data were reported using the Alberta Wildlife Watch (AWW) smartphone application using GPS for location information (Alberta Transportation 2017). There were no duplicate records in road survey data because animal carcasses were removed by road maintenance clean-up crews during the survey. To compare with walking surveys, AVC data were clipped to the spatial distribution of each MES. All three MESs occur at a local landmark used by road surveyors and, therefore, observed road survey animal carcasses are assumed to be accurately associated with each MES.

Citizen scientists reported animal carcasses during walked surveys at all three MESs. Animal carcasses were recorded using a smart phone application by 20 citizen scientists that walked transects once a week for approximately 5 years (2014–2018 inclusive).

For each animal carcass, citizen scientists reported species, date, time, and whether the carcass was visible from the road. Some animal carcasses had deteriorated beyond recognition and were classified as unknown species. A local project coordinator trained citizen scientists on data collection protocols, safety guidelines and the use of the smartphone application. The coordinator assigned transects to paired volunteers.

#### *Understanding error*

We acknowledge possible sources of error associated with multiple people reporting observations. Risk of error may increase as a result of multiple observers being involved in walking surveys, which can lead to double counting animal carcasses or species identification errors. To address this, participant groups (made up of two people for safety) walked the same transects reducing the number of people surveying at each MES. For example, Rock Creek south was surveyed by two groups who participated on alternate weeks. A series of rules were used to reduce possibility of duplicate records, animal carcasses reported during walking surveys were compared by species, date range (within month), and data were plotted spatially to ensure independent records. Citizen scientists were encouraged to report a species as unknown when not confident in

the identification. In some cases, photos were taken to aid species verification.

#### *Data analysis*

To determine the trend in AVCs along Highway 3, animal carcass data reported by road maintenance clean-up crews between 1997 and 2018 were summarised per year and linear regression was used to determine AVC trend over time.

Citizen science data collection started in April 2014 and was completed in December 2018. Walking survey data were verified to remove duplicate records and data were removed for the Emerald Lake MES after September 2016 because road mitigation measures were implemented there (including fencing tied into an existing underpass and jump-outs). In addition, from April through June 2014, animal carcass data reported as bones were excluded from the walking surveys to account for older animal carcasses that were likely to have occurred before the initiation of the project.

Through discussion with local biologists, we determined that walking surveys should occur at a minimum of once a week to ensure detection of carcasses before deterioration. However, surveys were missed sporadically during periods of heavy snow that prevented citizen scientists from parking safely in designated areas, or during periods of extremely high fire hazard, such as in the autumn of 2017 and winter of 2018. To account for differences in sampling effort among sites, walking surveys were standardised by multiplying the number of carcasses found per actual surveys walked with the expected number of surveys walked.

Previous research has indicated that driving surveys for large mammal detection should occur at a minimum of every 2 days (Santos *et al.* 2011). In our study, road maintenance crews surveyed the highway twice daily during weekdays, meeting the minimum survey requirements. In addition, because each method was designed for adequate carcass detection under the conditions, we did not standardise for sampling effort between survey types.

To calculate an injury-bias correction factor, animal carcasses reported by the road maintenance crews and walking surveys were both summed for each MES. The summed total was then divided by road survey data to determine the correction factor to apply to road survey datasets.

#### *Cost–benefit assessment*

We calculated the total cost of AVCs per 1 km road section with and without the correction factor for a 45 km section of Highway 3, by using a published cost–benefit model (Huijser *et al.* 2009). The model estimated the cost of an AVC for large-bodied ungulates such as a deer (US\$6617), an elk (US\$17 483), and a moose (US\$30 760) in 2007 US\$ values (Huijser *et al.* 2009). We compared this to the cost per kilometre of investing in road mitigation measures (i.e. underpass, jump-outs with fencing estimated to be US\$32 457 annually discounted at 7%) to reduce AVCs (Huijser *et al.* 2009). The authors calculated a 7% discount rate that was amortised into equivalent annual terms to account for the asymmetry between cost and benefit elements over time (Huijser *et al.* 2009).

To determine the cost of AVCs per 1 km road section per year, we used the number of animal carcasses reported during road surveys and calculated the average AVC for each species on the basis of a 5-year time-period (2014–2018). We included all large-bodied ungulates, namely, white tailed deer, mule deer, elk, moose and bighorn sheep. For each 1 km road section, we multiplied the cost of collisions of the specific species as provided by Huijser *et al.* (2009) to that species average number of AVCs and then summed among species to determine the total annual cost of AVCs. We applied the average cost of a collision of a deer to bighorn sheep as a conservative estimate of societal costs from collisions with bighorn sheep, because this species was not included in the study of Huijser *et al.* (2009). All other large-bodied species, such as carnivores recorded in AVCs, were not included in the model because collision costs for carnivore species are not currently available. Collision cost estimates are conservative because AVCs involving carnivore species are not included. So as to determine the difference in collision costs before and after applying the correction factor, we adjusted each species total per 1 km by multiplying the AVCs for each species by the correction factor, and then multiplying by the species estimated collision cost.

The resulting collision cost per 1 km was graphed to highlight the difference with and without the correction factor, and we then compared collision costs to the cost threshold for investing in an underpass, jump-outs and fencing, so as to document any change in the number of 1 km road sections where road mitigation is cost-effective.

## Results

### AVC trends and correction factor

Over the past 20 years, road maintenance clean-up crews have reported 2385 animal carcasses along Highway 3 resulting from AVCs. We found a significant increasing trend in annual AVCs in

**Fig. 3.** Total number of animal–vehicle collisions from 1997 to 2018 along Highway 3, Alberta, Canada, from Lundbreck, Alberta to the Alberta–British Columbia provincial border.

our study area from 1997 to 2018 ( $r^2 = 0.36$ ,  $P = 0.003$ ; Fig. 3). The species reported in the AVC data included white tailed deer, mule deer, elk, moose, bighorn sheep, black bear and grizzly bear.

The number of animal carcasses detected per year at each MES from road and walking surveys are shown in Tables 1–3. Animal carcasses recorded at MES during walking surveys include deer species, elk, cougar and bighorn sheep. Deer species were most common at Rock Creek and Iron Ridge, whereas bighorn sheep were most common at Emerald Lake. To account for the difference in walking survey sampling effort, we calculated the number of carcasses per MES standardised to walking survey effort (Table 4).

We determined a correction factor applied to road-surveyed carcass data for large mammals of  $2.8 \pm 0.74$  (Table 4), so as to account for injury bias in traditional road survey datasets. There was variability among the MESs, with a correction factor of 2.4 at Rock Creek, 3.5 at Iron Ridge and 2.1 at Emerald Lake.

### Cost–benefit of road mitigation with a correction factor

The total annual cost of AVCs for the 45 km stretch of Highway 3 from the Alberta–British Columbia border to Lundbreck, Alberta, is US\$1 045 417. With the calculated correction factor of 2.8, the annual cost increases to US\$2 927 168. To better understand the implications for cost–benefit of road mitigation, we compared the total cost of collisions per 1 km with and without the correction factor applied (Table 5). Without the correction factor, 10 km of road (representing 22% of the study area) exceeded the cost–benefit threshold for underpass, jump-outs and fencing on the basis of US\$32 457 annual cost (7% discounted rate) associated with the mitigation (Fig. 4). With the correction factor applied, 36 km of road (representing 80% of the study area) exceeded the cost–benefit threshold for mitigation of an underpass, jump-outs and fencing.

In addition, the correction factor increased the number of neighbouring road sections where road mitigation would be cost-effective. Without the correction factor, two road mitigation neighbourhoods (defined as a grouping of adjacent road sections where road mitigation is cost-effective) were identified. With the correction factor, six road mitigation neighbourhoods were identified, ranging from 4 to 10 km long (Table 5, represented in dark grey).

## Discussion

The Canadian road network supports continually increasing traffic volumes. Traffic on Canada’s National Highway System grew by 18% from 2005 to 2018, increasing the risk of AVCs (Transport Canada 2018). Along Highway 3 in Alberta, our results show a statistically significant increase in the number of AVCs over 20 years. Increasing AVCs are a concern to both motorist safety and maintaining healthy wildlife populations in this important landscape (Clevenger *et al.* 2010; Weaver 2013). In rural Alberta, 50% of collisions are due to AVCs, costing the province an estimated C\$280 million per year (Alberta Transportation 2017). Concern for motorist safety and the high cost of AVCs create strong socioeconomic incentives for transportation agencies to implement road mitigation strategies. Decision-making associated with road mitigation measures tends to be driven by identifying road sections with AVC clusters and where cost–benefit

**Fig. 4.** Annual costs of animal–vehicle collisions per road section (1 km) along Highway 3, Alberta, Canada (dark grey) and with correction factor applied (black). Threshold 1 represents the costs of wildlife underpass, fencing and jump-outs based on 3% discounted rate. Threshold 2 represents the costs of wildlife underpass, fencing and jump-outs based on a 7% discounted rate. The 1-km road sections run along the x-axis from Road section 1 (Alberta–British Columbia provincial border) to Road section 45 (Lundbreck, Alberta, Canada).

assessments justify road mitigation measures. Providing a more accurate assessment of the number of AVCs equips transportation agencies to implement effective road mitigation.

Our study demonstrated that AVCs involving large mammals are underestimated; more animal carcasses were reported during walking surveys off the road than were reported during road surveys. These animal carcasses represent error sources in traditional AVC datasets generated by road surveys, because of injury bias. In our region of the Rocky Mountains, we suggest that a correction factor of 2.8 can be applied to road survey datasets to account for undetected road-kills. Factors affecting sources of error are not likely to be consistent across sites, habitat types and/or species guilds and should, therefore, be assessed by region and species assemblage (Slater 2002). Our correction factor will not be appropriate for smaller species that

**Table 4.** Total number of animal carcasses for road surveys (RS) and walking surveys (WS; standardised WS carcass data to expected number of surveys) at each mitigation emphasis site to calculate the correction factor (CF)

MES	WS sample expected	WS carcass	WS sample actual	WS carcass standardised	RS carcass	CF
Emerald Lake	122	6	110	6.7	6	2.1
Iron Ridge	260	10	228	11.4	4	3.9
Rock Creek	259	38	250	39.4	28	2.4

are harder to detect and whose carcasses persist for shorter periods of time, for example, small mammals, amphibians and reptiles (Santos *et al.* 2011; Degregorio *et al.* 2011; Santos *et al.* 2016). We recommend that in regions with different habitat types and species guilds, similar studies be conducted to determine a correction factor for AVC data collection and cost–benefit analyses.

Although our correction factor is specific for our landscape, our general result that traditional roadside AVC counts are underestimates applies to other landscapes and species assemblages. Improving methods should improve existing systems to account for animal carcasses observed off the road right of way. Alternatively, in areas where animal carcass visibility from the road surface is limited, the survey methodology presented here could improve estimate accuracy.

We found some variability among the MESs in our study area, ranging from a correction factor of 2.1 to 3.5. This highlights the importance of including multiple study sites in correction factor assessments. All three sites offer limited visibility to the surrounding landscape from the road surface, occur in similar vegetation communities and have similar traffic volumes and speed limits. The variability could be partially attributed to differences in species diversity at each MES; although all three sites reported deer AVCs, bighorn sheep occur only at the Emerald Lake MES and elk occur most commonly at Iron Ridge MES. Although there is some species diversity among the MESs, our study was not able to assess species responses to AVC injury bias because of the low numbers of large mammal species (other than deer) reported during the study at all three sites.

Our analysis was dependent on detecting animal carcasses through systematic monitoring by using two different survey types, namely, walking and driving. Possible detection errors include carcass persistence rate (how long carcasses remain visible), overlooked carcasses, removal by predators and/or difference in survey protocols (Santos *et al.* 2011, 2016). In the present study, the two survey methodologies (road vs walking surveys) differed in temporal resolution; road surveys were undertaken twice daily, whereas walking surveys occurred at ~7-day intervals on the basis of assumed differences in carcass detection probabilities. Carcass detection while driving at 110 km h<sup>-1</sup> along a highway was estimated to be lower than at walking speed; thus, walking surveys were less frequent.

Carcass persistence is dependent on body size and habitat type or vegetative cover. A study by Santos *et al.* (2011) suggested a 2-day interval between surveys on the basis of large-mammal carcass persistence on road rights-of-way. Our road surveys took place twice daily and, therefore, occurred

more frequently than recommended, which further improves our confidence that carcasses on the road were accounted for. A week between walking surveys was deemed a minimum survey period appropriate on the basis of expert knowledge and deterioration rates that would enable species identification. However, many of the large carcasses reported by citizen scientists were no longer identifiable and were, therefore, recorded as an unknown species. In addition, the expected number of walking surveys did not occur because of inclement conditions such as wildfires and snow events. To address the concern that walking surveys occurred less frequently than recommended, we normalised walking survey data to the expected number of surveys across the three MESs.

In addition, predators occur at all three sites, including cougar, coyote, wolf, black bear and grizzly bear. All will scavenge road-killed animal carcasses. It is possible that the presence of predators may have resulted in an underestimate of animal carcasses during walking surveys. Our method is not able to account for this error, nor cases where injured animals had moved further from the roadway than our walking survey was designed to detect. Given these limitations, and the small area covered during walking surveys, we believe our correction factor is a conservative estimate of injury bias caused by AVCs.

Our results demonstrated how an injury-bias correction factor can affect cost–benefit models for road mitigation. Once the correction factor was applied, cost–benefit analysis suggested that 21 additional kilometres of road in our study area would qualify for road mitigation, including underpasses, jump-puts and fencing. Such road mitigation measures have proven to be effective in reducing AVCs, improving both motorist safety and animal survival, while enabling animal movement across roads (Huijser *et al.* 2008; Rytwinski *et al.* 2016).

In addition, the correction factor identified six road mitigation neighbourhoods, ranging in length from 4 to 10 km. A road mitigation neighbourhood represents longer stretches of highway where it is cost-effective to mitigate, and including longer road sections enables a more comprehensive road mitigation system to be designed. For example, long sections justify a series of crossing structures linked by fencing, further reducing the risk to motorists and wildlife and offering more opportunities for animal movement across the highway. A larger series of mitigations has cost efficiencies compared with single or multiple, isolated interventions. Without application of the correction factor, road mitigation measures along Highway 3 would remain focussed on few, isolated structures with wing fencing and have less overall impact on motorist and wildlife safety.

**Table 5. Average annual cost (US\$) of animal–vehicle collisions (AVCs) per 1 km road section (based on a 5-year average 2014–2018) with a correction factor (CF) of 2.8 being applied**

Road sections above the cost threshold are in light grey cells and road mitigation neighbourhoods are in dark grey cells

# Assessing Some Potential Environmental Impacts from Agricultural Anticoagulant Uses

Lorin L. Lima and Terrell P. Salmon

University of California Cooperative Extension - San Diego County, San Diego, California

**ABSTRACT:** This study was designed to give us a better understanding of the relationship between agricultural anticoagulant rodenticide uses and related occurrence of these materials in raptor tissues. The project utilized data from raptor carcasses collected, both in urban San Diego County and in largely agricultural Fresno, Kern, and Madera Counties, as part of the public health surveillance programs of the County Veterinarian(s) and/or Departments of Environmental Health. Most raptors contained detectible levels of second-generation anticoagulants, which are registered only for commensal rodent control in and around structures; very few contained first-generation anticoagulants, which are the only anticoagulants registered for use in agricultural production in California. This suggests that secondary hazards to raptors and other wildlife from anticoagulants stems primarily from retail sale of commensal rodent baits, particularly in residential areas, and not from anticoagulant rodenticide uses in agricultural regions.

**KEY WORDS:** agriculture, anticoagulants, California, nontarget hazard, potential environmental impact, raptor exposure, rodent control, rodenticides, secondary hazard, urban wildlife

## INTRODUCTION

Anticoagulant rodenticides are the most common baits used in agricultural and domestic areas to manage rodent pests (Litovitz et al. 1998, Maroni et al. 2000). They are generally classified as first- or second-generation anticoagulants based on their toxicity relative to the amount of bait a rodent must eat. The first-generation anticoagulants such as chlorophacinone, diphacinone, and warfarin usually require multiple feedings over several days to be lethal. The second-generation anticoagulants, such as bromadiolone, brodifacoum, and difethialone, are more persistent in animal tissues and in many situations can be lethal from only one feeding. In California, only first-generation anticoagulants are registered for agricultural uses. Almost 1 million pounds of formulated chlorophacinone and diphacinone baits are sold annually by California Agricultural Commissioners (CDPR 2007, CDPR 2009) to control agricultural ground squirrels, voles, and some other rodent pests. Additional first-generation anticoagulant bait is sold by commercial outlets for agricultural protection and some commensal use, but use data are not readily available. A much larger quantity of second-generation anticoagulants is sold to homeowners, structural pest control operators, and others for control of commensal rodents (Norway and roof rats, *Rattus norvegicus* and *R. rattus*, and house mice, *Mus musculus*) in and around structures (CDPR 2007). All of these uses have the potential of creating primary and secondary poisoning risks to pets, domestic animals, and wildlife including birds of prey.

Various predators and scavengers in California have tested positive for second-generation anticoagulants, while a much lower number of first-generation exposures have been detected (Redig and Arent 2008). However, without information on anticoagulant use patterns in the areas where these animals were collected, we cannot paint a complete picture of the exposure risks and impacts of anticoagulant use in agricultural production areas. Yet,

in the absence of such data, persons concerned about pesticide residues in wildlife often assume that anticoagulant rodenticides used in agriculture cause widespread risk to non-target wildlife, particularly predators and scavengers of rodents.

## OBJECTIVES

This study was undertaken to help understand the extent of raptor exposure to anticoagulants, particularly in relation to anticoagulant uses for protecting agriculture. Data were utilized from raptors that were collected as part of the public health surveillance programs of the County Veterinarian(s) and/or Departments of Environmental Health, as well as by submission from other organizations such as California Fish and Game and the United States Department of Agriculture – Wildlife Services. None of the raptors analyzed were initially suspected of having anticoagulant exposure or poisoning.

The ultimate goal was to determine possible raptor exposure to first- and second-generation anticoagulants by evaluating the relationship between the use of these materials in agricultural versus urban settings and the presence/absence of residues in raptor tissues collected from each region.

A second objective was to determine if wild rodents captured as part of a county Hantavirus surveillance program would show any signs of exposure to anticoagulants. While anticoagulant residues have been found in many carnivores, few reported data exist demonstrating the occurrence of residues in rodents found in areas where anticoagulant materials are used. The data that are available originates from rodents targeted by specific baiting programs. It is likely that some of these rodents survive baiting by consuming a sub-lethal dose. In turn, these survivors could have some anticoagulant residue remaining in their tissues, providing a possible exposure route for raptors and carnivores.

## METHODS

San Diego County has a robust public health surveillance program that includes testing of raptors and other birds found dead throughout the County. This provided a large number of raptors for potential analysis. Since San Diego County is fairly urban, we wanted to compare data from these birds with birds from more rural and agricultural counties. The top 5 agricultural counties with the highest quantity of total agricultural pesticide use in California in 2007 were Fresno, Kern, Tulare, San Joaquin, and Madera (Brooks 2008). Of these, Fresno, Kern, and Tulare Counties were selected because we have worked on extensive ground squirrel problems in these areas for the past 30 years. We sought to compare anticoagulant residue data from raptors collected in these counties to those from the more urban San Diego County, where we assume most rodenticides applied are used by homeowners for the control of commensal rodents.

### Anticoagulant Use

In order to better understand the information gathered, we estimated how much anticoagulant was used in each county. Table 1 provides the total amount of active ingredient of each of the 7 anticoagulants sold by all entities in counties comprising our study sites, in 2007. We assume that materials purchased would be used in the county of purchase within a 1-year period.

For example, 2.92 lbs of diphacinone (as active ingredient) reported for San Diego County would, when formulated at 0.005% a.i. in rodent baits, represents a total of 58,400 lbs of ready-to-use bait.

**Table 1. Pounds of anticoagulants (active ingredient) use for each included county as reported by rodenticide manufacturers or through the required applicator pesticide use reports (CDPR 2007).**

Active Ingredient (lbs)	San Diego County	Fresno County	Kern County	Tulare County
Chlorophacinone	0.0795	0.3927	0.8932	0.3235
Diphacinone	3.2941	1.8605	2.3378	3.523
Warfarin	0.1056	0.0903	0.0376	0.0024
Brodifacoum	0.0998	0.0647	0.045	0.0269
Bromadiolone	3.1664	0.8124	0.296	0.1553
Difethialone	0.2825	0.0378	0.0197	0.0159

### Raptor Tissue Collection

San Diego County has a robust public health surveillance program to detect the presence of West Nile virus in wild birds, and dead birds are routinely submitted to the County Veterinarian for testing. We partnered with the County Veterinarian to have the liver tissue removed and sent to UC Davis to test for the presence of anticoagulants. The Central Valley does not have a systematic raptor collection program. The birds that are submitted are generally obtained as a result of chance collection by members of the general public. Liver tissues from this region were provided by the Pesticide Investigations Unit of the California Department of Fish

and Game. Our project did not capture or handle raptors, nor did it cause any birds to be captured.

### Residue Analysis

Corresponding liver tissue samples from each animal were frozen and shipped to the California Animal Health & Food Safety Laboratory System at the University of California, Davis for anticoagulant residue analysis. If detected, the quantity in parts per million (ppm) was determined. When possible, the location where each bird specimen was found was entered into a GIS layer.

## RESULTS

Of 176 raptors available to us, 80 had no information on the specific site of collection, so we did not subject these to residue analysis. The remaining 96 were necropsied and liver tissues were sent for testing. Of these, 53 came from San Diego County and 43 from the three Central Valley counties.

The tested group consisted of 10 common raptor species: American kestrel, *Falco sparverius* (4); barn owl, *Tyto alba* (21); burrowing owl, *Athene cunicularia* (1); Cooper's hawk, *Accipiter cooperii* (12); great horned owl, *Bubo virginianus* (7); northern harrier, *Circus cyaneus* (1); red-tailed hawk, *Buteo jamaicensis* (22); red-shoulder hawk, *B. lineatus* (15); sharp shinned hawk, *A. striatus* (9); and Swainson's hawk, *B. swainsoni* (1).

Of the 53 birds tested from San Diego County, 92% ( $n = 49$ ) had anticoagulant detections. Some birds had multiple anticoagulant detections but all were of second-generation materials. Thirty-four of the 43 birds (69%) tested from the Central Valley counties also had anticoagulant detections. Detections included residues at levels above the limit of detection and residues in trace amounts (Tables 2, 3).

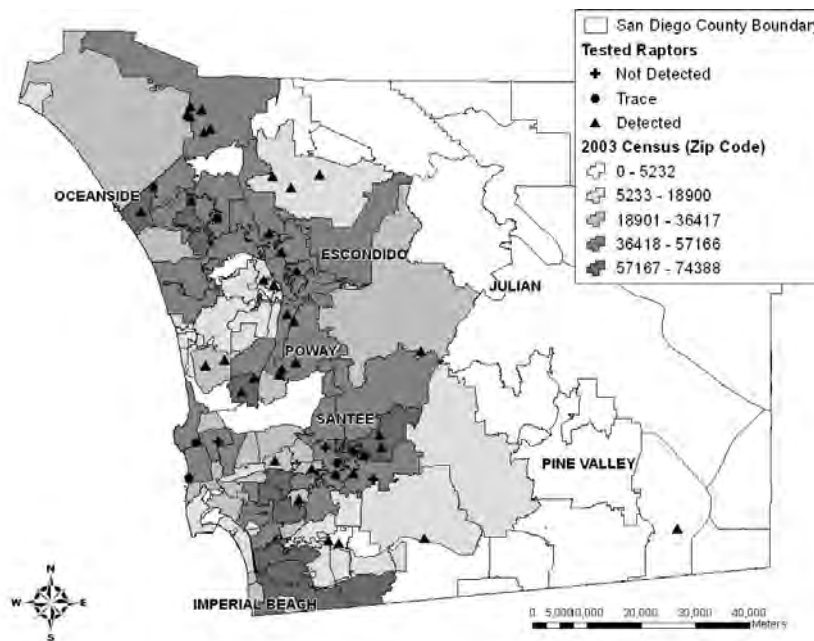

**Table 2. The reportable limit in parts per million for each anticoagulant included in this study.**

	Anticoagulant	Reportable Limit (ppm)
<b>First-Generation</b>	Chlorophacinone	0.25
	Coumachlor	0.05
	Diphacinone	0.25
	Warfarin	0.05
<b>Second-Generation</b>	Brodifacoum	0.01
	Bromadiolone	0.05
	Difethialone	0.25

For birds collected in San Diego Co., we plotted the pickup location (Figure 1). We define "rural birds" as those recovered within zip codes containing low human populations ( $\geq 36,417$  individuals), and "urban birds" were those occurring in highly populated zip codes ( $\leq 36,418$  individuals). Most birds came from "urban" areas, likely because more people were present and freshly dead birds were more likely to be seen and submitted. We see a trend of birds with detectable levels of anticoagulants occurring in the most highly populated areas, although this could be from a greater detection

**Table 3. Number of detections by chemical and location.**

		San Diego County		Central Valley	
		Detectable Level	Trace Amount	Detectable Level	Trace Amount
<b>First-Generation</b>	Chlorophacinone	0	0	0	2
	Coumachlor	0	0	0	0
	Diphacinone	0	0	0	0
	Warfarin	0	0	0	0
<b>Second-Generation</b>	Brodifacoum	44	5	5	1
	Bromadiolone	12	10	23	8
	Difethialone	5	3	0	0

**Figure 1. Locations of tested raptor carcasses within San Diego County in reference to human population.**

probability. No birds from San Diego Co., either “urban” or “rural”, contained any first-generation anticoagulants.

Of the 43 raptors submitted from the Central Valley, there were 34 individuals with anticoagulant residues. Only 2 birds contained residues of a first-generation anticoagulant (chlorophacinone), and in both cases it was present only in trace amounts. The other residues found were all second-generation anticoagulants.

**DISCUSSION**

Figure 2 shows the results of raptor collection site in relation to human population and agricultural commodity areas. It appears that raptors with detectable second-generation anticoagulants were more common in areas with higher population densities, although this could be the result of increased detection probability. This finding would make sense, because exposure to second generation anticoagulants is likely originating from commensal rodent pest control programs in and around buildings.

Due to the nature of the sample carcass collection in the Central Valley, we did not have specific collection location information for most of the birds. In these cases, the location was coded as the county where the bird was

collected. When evaluating the potential anticoagulant exposure of raptors in the selected Central Valley counties (see Figure 3), it appears that agricultural areas are much more dominant than urban areas. Because of the heavy agricultural production in these counties, we would expect more detection of first-generation anticoagulants in raptors collected in these counties if exposure simply relates to amount of material used. However, this is not supported by the data collected in this study. This finding could be from exposure rates but also could result for the shorter half-life of first generation anticoagulants in poisoned rodents.

**RODENTS**

**Methods**

As part of the Hantavirus surveillance program, San Diego County’s Department of Environmental Services set trap lines to capture wild rodents. The lines were set along fence lines radiating from urban areas into adjacent non-developed environments. A total of 131 rodent carcasses were obtained over several months, and all pickup locations were entered into a GIS layer. Due to limited resources, only 26 were selected for analysis to cover a variety of habitats. Necropsies were performed

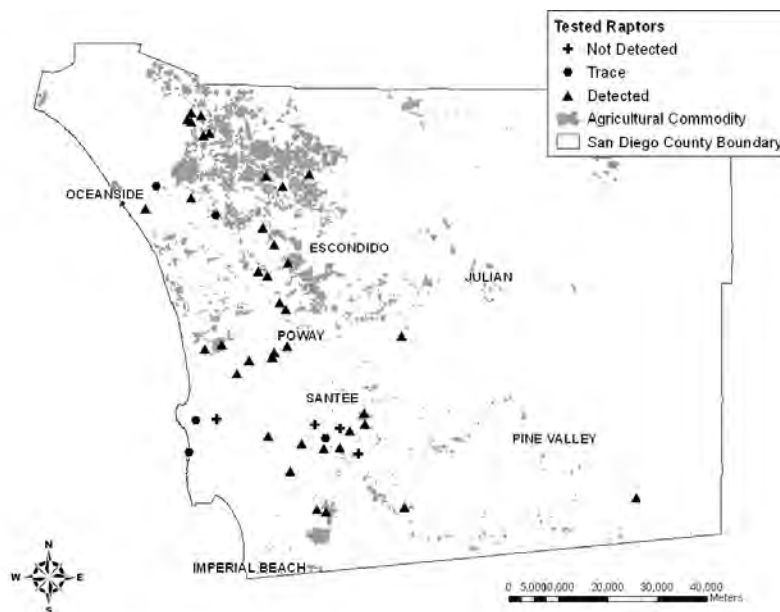

Figure 2. Locations of raptor carcasses in relation to human population and agricultural commodities of San Diego County.

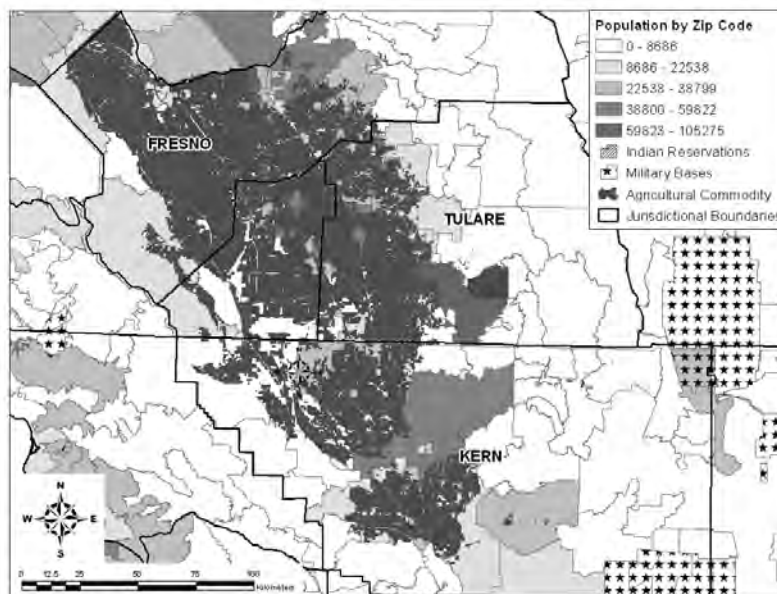

Figure 3. Human population and agricultural commodities in the Central Valley.

and liver samples were sent to the UC Davis laboratory for testing.

The tested specimens included: deer mouse, *Peromyscus maniculatus* (5); Baja mouse, *P. raterculus* (3); California mouse, *P. californicus* (6); and cactus mouse, *P. eremicus* (12).

Of the liver tissues submitted, 5 had trace detections of anticoagulants, only 1 of which was a first-generation anticoagulant. Unfortunately, we were unable to process a large enough sample of carcasses to show any real trends, but we were able to determine that measurable amounts of anticoagulants were present in “free-ranging” small rodents. Presumably, these rodents were exposed

to anticoagulants from a rodent control program, although none of these species are target animals of the second-generation anticoagulants. Since all of the detections were in trace amounts, the data should only be used to guide future research.

## CONCLUSION

With over a million pounds of anticoagulant baits sold annually in California for all target species, these are the most common rodenticides used in agricultural and domestic areas, and this creates potential primary and secondary risks to pets, domestic animals, and wildlife, including birds of prey. Anticoagulant exposure appears

to be relatively common, with the predominant anticoagulants detected in this study being the second-generation materials. In this study, 1 in every 1.17 raptors tested containing detectible levels of second-generation anticoagulants. Only 1 in 48 tested positive for first-generation materials. This difference could be from the higher persistence of second-generation materials in exposed animal tissue. Raptors with second-generation anticoagulants in their tissues were more commonly found in urban areas where commensal rodent control is presumably more common; however, this could be the result of more people to detect carcasses in the urban areas. In addition, it could be that the higher number of second-generation detections is from the greater half-life of these materials in carcasses of exposed animals, or because the detection levels for second-generation materials are generally much lower than for first-generation anticoagulants. Raptors were not commonly found in agricultural areas, but those that were tested did not usually contain any first-generation anticoagulant in their tissue.

While second-generation anticoagulant residues were found in many raptors we tested, there was no information available to us on the impact of these residues on the birds. No birds tested displayed symptoms of anticoagulant poisoning, so these levels were not indicative of anticoagulant poisoning. However, these residues could have had sublethal impacts on the birds or contributed to mortality from other causes. Clearly, more study is needed, particularly on the impacts of specific residue levels on raptors and other non-target wildlife.

**ABSTRACT** Roads have numerous direct and indirect ecological impacts on wildlife. Vehicle collisions are a top impact of roads on birds, with tens of millions of birds thought to be killed each year in the United States. However, currently available mortality estimates are extrapolated from a single study. We reviewed the literature and used 20 mortality rates extracted from 13 studies to systematically quantify data-driven estimates of annual U.S. mortality from bird-vehicle collisions. We generated 4 separate estimates along with uncertainty using different subsets of data deemed to be rigorous enough to contribute relatively little bias to estimates. All of our estimates of vehicle mortality are higher than previous U.S. figures. When averaging across model iterations, we estimated that between 89 and 340 million birds die annually from vehicle collisions on U.S. roads. Sensitivity analyses indicated that uncertainty about survey-related biases (scavenger removal and searcher detection of carcasses) contributes the greatest amount of uncertainty to our mortality estimates. Future studies should account for these biases to provide more accurate local estimates of mortality rates and to inform more precise national mortality estimates. We found relatively little information available to quantify regional, seasonal, and taxonomic patterns of vehicle collision risk, and substantial uncertainty remains about whether collisions contribute to large-scale impacts on bird populations. Nonetheless, the large magnitude of bird mortality caused by vehicle collisions combined with evidence that collisions can contribute to local population declines for some species highlights the need for implementation of conservation and management actions to reduce this mortality. Published 2014. This article is a U.S. Government work and is in the public domain in the USA.

**KEY WORDS** anthropogenic mortality, automobiles, birds, detection probability, roadkill, roads, scavenger removal, systematic review, United States, vehicles.

The global proliferation of road networks has led to a multitude of ecological impacts that affect biological diversity. In the United States, the greater than 6.5 million kilometers of roads (U.S. Department of Transportation 2012) ecologically affect at least 22% of the nation's land area (Forman 2000), causing loss and fragmentation of habitat; pollution with chemicals, light, and noise; alteration of animal movement and behavior; and direct mortality of wildlife from vehicle collisions (Forman and Alexander 1998, Trombulak and Frissell 2000, Forman et al. 2003, Coffin 2007). For birds, vehicle collisions are one of the greatest threats posed by roads (Kociolek et al. 2011), with as many as 80 million birds thought to be killed annually in the United States (Erickson et al. 2005) and roughly 13 million birds

estimated to be killed annually in Canada (Bishop and Brogan 2013). Moreover, roadkills have the potential to constitute the vast majority of total mortality for some bird species—most notably, barn owls (*Tyto alba*) (Moore and Mangel 1996, Newton et al. 1997). Roadkill mortality can also result in the creation of population sinks (Mumme et al. 2000, Boves and Belthoff 2012, Grilo et al. 2012) and may be an additive source of mortality that contributes to population declines (Bujoczek et al. 2011).

A large body of literature has identified numerous factors that influence bird-vehicle collision rates. Mortality rates have been found to increase with increasing traffic speed and volume (Case 1978) and rates are generally highest during spring and summer. Mortality rates are also greater for juvenile birds, in areas with favorable bird habitat in close proximity to the road, and where bird populations are abundant (Loos and Kerlinger 1993, reviewed by Erritzoe et al. 2003, Gunson et al. 2010, Boves and Belthoff 2012). In some cases, mortality rates have been found to increase with increasing width of the road corridor (Oxley et al. 1974) or to be greater along road segments that are elevated above the surrounding land (Baudvin 1997, Lodé 2000). Often, 2 or

<sup>2</sup>Present address: Department of Natural Resource Ecology and Management, Oklahoma State University, 008C Agricultural Hall, Stillwater, OK 74078, USA

Conflict of interest: The authors have no conflicts of interest to declare.

more of the above factors are strongly correlated—i.e., wider roads usually have a higher traffic volume than narrow roads—making it difficult to dis-entangle the relative impact of each factor. Furthermore, exceptions to the above relationships occur and are illustrative of how mortality rate correlates are often region-, taxa-, and habitat-specific. For example, several studies have found no link between traffic volume and mortality rates (Massemin et al. 1998, Lodé 2000, Coelho et al. 2008, Kambourova-Ivanova et al. 2012).

Current estimates of annual U.S. bird mortality from vehicle collisions—ranging from 60 to 80 million—are highly speculative, based on extrapolation of mortality rates from a single British study (Hodson and Snow 1965) to the entire U.S. road network (Banks 1979, Erickson et al. 2005). Comprehensive meta-analyses of studies that quantify bird populations have concluded that roads are consistently associated with reductions in bird abundance (Fahrig and Rytwinski 2009, Benitez-Lopez et al. 2010), but no clear evidence exists that vehicle collision mortality is a significant driver of these road-related declines. In addition, no such comprehensive analyses have been completed to assess bird-vehicle collision mortality in the United States. When compared to speculative or extrapolative estimates based on small samples of data, such systematic and quantitative reviews provide a more rigorous approach to estimating mortality, an improved understanding of the sources of uncertainty associated with estimates (Loss et al. 2012, 2013a, 2014; Machtans et al. 2013), and a more valid evidence base on which to prioritize policy and management strategies and to identify major research needs (Calvert et al. 2013, Machtans and Thogmartin 2014).

We reviewed the North American and European bird-vehicle collision literature and defined inclusion criteria to screen and remove studies likely to bias our estimates substantially. Based on data extracted from the remaining studies, we 1) systematically quantified the magnitude of bird mortality (along with uncertainty) caused by collisions with vehicles on U.S. roads by combining probability distributions of mortality rates, the length of U.S. roads, and biases associated with surveys for dead birds; 2) used sensitivity analyses to quantitatively investigate factors contributing to estimate uncertainty and to identify major research needs; and 3) summarized the available species-specific data on bird-vehicle collisions in the United States.

## METHODS

### Literature Search and Inclusion Criteria

We used Google Scholar and the Web of Science database to search for publications about bird-vehicle collisions on roads. The search terms we used were “bird-vehicle collision,” “bird-vehicle roadkill,” the previous terms with “bird” replaced by “avian” and “vehicle” replaced by “automobile,” “car,” and “truck.” We checked reference lists to locate additional sources, and we also referenced an annotated bibliography that included approximately 670 sources covering the impacts of roads on wildlife (Nietvelt 2002). For 5 North American studies (Nero and Copland 1981,

Decker 1987, Smith et al. 1994, Sutton 1996, Potvin and Bishop 2010), we were unable to access full-text articles and instead extracted the data as summarized in a review of bird-vehicle collisions in Canada (Bishop and Brogan 2013). Because of the large quantity of international studies—many that are published in languages other than English or inaccessible online or through North American libraries—we could not exhaustively review this literature. However, our review of the North American literature was comprehensive, and we likely located all studies that included a systematic sampling component. We may have overlooked some North American publications containing descriptions of incidentally found roadkill victims; however, these studies would have been excluded from analyses based on our inclusion criteria described below.

We defined several criteria for studies to be included in our estimation models. We designed inclusion criteria to remove studies that were not useful for generating mortality rate estimates or that were likely to substantially bias estimates. We excluded studies prior to in-depth review if they included no original data; were conducted in a region other than the United States, Canada, or Europe; or were published in a language other than English. In addition, because we sought to generate mortality estimates that were relevant to relatively modern road types and traffic patterns, we arbitrarily selected 1970 as the earliest date for which publications could be included in analyses (see also Bishop and Brogan 2013). Following in-depth review of the remaining 53 studies, we also excluded studies that 1) were retrospective, based on assessment of opportunistically collected data sets or recoveries of banded or radio-tagged birds, 2) focused on particular bird species or groups without sampling or presenting data for all species and groups, 3) included an experimental component without presenting control and treatment data separately, 4) were prospective but also included incidentally collected data without presenting it separately, 5) did not provide information about the proportion of the year covered by sampling, 6) did not present the length of road corridor sampled or a per kilometer mortality rate, 7) were based on a single survey or a series of surveys that covered less than 1 month, and 8) did not separately report fatalities from vehicle collisions and other collision sources (e.g., roadside fences). After implementing the above inclusion criteria, 16 of the 53 reviewed studies remained (9 U.S. and 7 European studies; Table 1; see Table S1 for excluded studies).

For the summary of species representation of mortality, we included data from U.S. studies meeting criteria 1–4 and 7–8 above. We considered criteria 5 and 6 unnecessary for producing unbiased species summaries. We used 7 of the 9 U.S. studies meeting inclusion criteria for the mortality estimate for the species analysis. The 2 excluded studies did not provide data at the species level (Oxley et al. 1974, Gerow et al. 2010).

### Data Extraction

From most studies meeting the above inclusion criteria, we extracted a single mortality rate. However, for studies that

<sup>a</sup> Whether we used the mortality rate to estimate bird-vehicle collision mortality on U.S. roads.

<sup>b</sup> Whether we used the source to calculate average proportional representation for individual species (excluded U.S. studies focused on particular bird group(s) without including all species; we excluded all international studies).

<sup>c</sup> We calculated mortality rates using raw data (i.e., we did not directly extract reported rates from studies because calculation approaches varied among studies and were not always calculated transparently). We first divided the total number of fatalities reported for a road segment by the length of road corridor covered by that segment. For rates representing >1 year of sampling, we then divided by the number of years sampled; we applied a partial-year sampling correction in the mortality estimation model (see Methods section in main text for details).

<sup>d</sup> Study meets inclusion criteria but was removed from calculation of mortality rate probability distribution because mortality rate is a statistical outlier among studies meeting criteria.

<sup>e</sup> Study meets inclusion criteria but was removed from calculation of mortality rate probability distribution because mortality rate is adjusted for biases associated with carcass surveys (detection probability and scavenger removal); these biases were separately accounted for in our mortality estimation model.

sampled along more than 1 road type (e.g., paved and unpaved roads and/or roads with different numbers of lanes) or used different sampling methods (e.g., different sampling intervals or survey types) for different portions of the study area, we extracted separate mortality rates. This resulted in extraction of 25 mortality rates (17 U.S. and 8 European rates; Table 1) from the 16 included studies. We calculated all rates as the number of dead birds found per kilometer of road corridor sampled. This approach is different than that of

some studies that calculate mortality rates using the total length of lanes sampled (e.g., for a 2-lane road, lane-length is twice the length of the road corridor). Some studies did not provide enough information to clarify how they calculated mortality rates. Therefore, rather than directly extracting the reported rates, we recalculated rates based on the number of fatalities reported for a road segment divided by the length of road corridor covered by that segment. Because we recalculated rates using this raw data, the mortality rate we

calculated was sometimes different than that presented in the original study.

We then used one of several approaches to convert multi-year mortality rates to annual rates. For multi-year studies that sampled across the entire calendar year in every year of the study, we divided mortality rates by the number of years to generate the annual rate (Table 1). We also took this approach for multi-year studies that only sampled a portion of each year; we accounted for partial-year sampling coverage separately (see following subsection). For 4 studies that sampled at least 1 entire calendar year as well as an additional partial year (Seibert and Conover 1991, Baudvin 1997, Hell et al. 2005, Glista et al. 2008), we treated the partial year as a full year when calculating the annual rate. This approach led to conservative rate estimates because mortality was spread across a longer time period than it actually occurred in.

We excluded 3 mortality rates from the above data set for being statistical outliers and 2 for being adjusted for various sampling biases that we accounted for separately in the mortality estimation model (see Supplementary Methods, available online at [www.onlinelibrary.wiley.com](http://www.onlinelibrary.wiley.com)). The final data set used for estimation of mortality therefore included 20 mortality rates (12 U.S. and 8 international rates) extracted from 13 studies (6 U.S. and 7 European studies; Table 1).

### Quantification of Annual Bird Mortality

To increase the comparability of mortality estimates from different studies, mortality rates should ideally be standardized to account for varying proportions of the year being covered by sampling (Loss et al. 2012). Potential standardization approaches include 1) using mortality rates from year-round studies to proportionally correct partial-year studies (Longcore et al. 2012, Loss et al. 2013a), 2) including a correction factor in the mortality estimation model that accounts for partial-year sampling (Loss et al. 2014), or 3) using only full-year mortality rates to generate mortality estimates. We were unable to implement the first approach because year-round vehicle collision studies either do not present data separately for different portions of the year or only provide seasonal data for single bird species or taxa other than birds. Because the second and third approaches were both possible, we repeated mortality estimation using each approach. We expected the estimate generated using approach 2 would represent a maximum value because this approach assumed that mortality rates observed during the sampled portion of the year—typically the peak periods of vehicle collision mortality in spring, summer, and/or autumn—also applied to the un-sampled portion of the year (see Supplementary Methods).

Our approach for estimating mortality was to combine a mortality rate probability distribution with a probability distribution for the length of U.S. roads susceptible to that range of mortality rates. We defined the maximum susceptible road length to be the entire U.S. road network and the minimum susceptible length to be only the length of roads in rural areas (see Supplementary Methods). This approach assumes that mortality rates in urban areas are

likely lower than in rural areas, but does not entirely discount mortality in urban areas. We also incorporated correction factors to account for sampling coverage of less than the entire calendar year (for estimates that included partial-year mortality rates) and for biases associated with carcass surveys (all estimates), including removal of carcasses by scavengers and imperfect detection of carcasses by surveyors (Loss et al. 2013a, 2014). Because a preliminary analysis found little support for differences in mortality rates between 2-lane, 4-lane, and gravel roads, and because the sample of mortality rates was too small to generate separate probability distributions for different road types, we applied the same range of mortality rates across all U.S. road types. This simplified approach contributes uncertainty to our mortality estimate; however, we did not have enough available data to allow separate mortality estimates for different road types. In addition to repeating mortality estimation with and without inclusion of partial-year studies, we also estimated mortality with and without inclusion of European mortality rates. Thus, we generated 4 separate estimates of annual mortality using different subsets of data: U.S. year-round mortality rates, U.S. year-round and partial-year rates, U.S. and Europe year-round rates, and U.S. and Europe year-round and partial-year rates.

For the estimates based only on year-round mortality rates, we used the model:

$$\text{Mortality}_{\text{year-round studies}} = R \times K_{\text{year-round studies}} \times B \quad (1)$$

where  $R$  is the length of U.S. roads susceptible to the range of mortality rates in the mortality rate probability distribution ( $K$ ),  $K$  is the range of collision mortality rates per km of road corridor, and  $B$  is a bias correction factor to account for removal of carcasses by scavengers prior to surveys and imperfect detection of carcasses remaining at the time of surveys.

For the estimates based on year-round and partial-year rates, we used the model:

$$\begin{aligned} \text{Mortality}_{\text{year-round and partial-year}} \\ = R \times K_{\text{year-round and partial-year}} \times Y \times B \end{aligned} \quad (2)$$

where  $Y$  is a correction factor that accounts for the average proportion of the calendar year not covered by sampling in the studies used to develop the mortality rate distribution (Loss et al. 2014). The partial-year sampling correction factor was a fixed value; however, we defined all other parameters as uniform probability distributions (specific distributions shown in Table 2; rationale for distributions in Supplementary Methods). For all estimates, we used the `runif` function in Program R (R Version 3.0.1., <<http://www.r-project.org/>>. Accessed 14 Apr 2014) to draw random values from each probability distribution, and we calculated mortality using the above formulas. We repeated this calculation 10,000 times for each of the 4 estimation approaches to generate ranges of uncertainty for mortality estimates.

### Sensitivity Analyses

We used sensitivity analyses to quantitatively investigate the factors contributing to uncertainty in our mortality estimates.

**Table 2.** Probability distributions used for estimation of annual bird-vehicle collision mortality on U.S. roads.

Parameter	Distribution type	Distribution parameters	Source
Total length of road corridors in the United States <sup>a</sup>	Uniform	Min. = 3.76 M; max. = 4.33 M	U.S. Department of Transportation (2012)
Mortality rates (per km)			
U.S. studies (yr-round) <sup>b</sup>	Uniform	Min. = 3.48; max. = 6.78	95% CI across 5 rates meeting inclusion criteria
U.S. studies (all) <sup>c</sup>	Uniform	Min. = 2.78; max. = 6.73	95% CI across 12 rates meeting inclusion criteria
U.S. + Europe studies (yr-round) <sup>b</sup>	Uniform	Min. = 2.85; max. = 9.70	95% CI across 9 rates meeting inclusion criteria
U.S. + Europe studies (all) <sup>c</sup>	Uniform	Min. = 4.24, max. = 8.58	95% CI across 20 rates meeting inclusion criteria
Partial-yr sampling correction			
U.S. studies (all) <sup>c</sup>	NA <sup>d</sup>	Estimate = 1.49	1/average proportion of yr covered by mortality rates
U.S. + Europe studies (all) <sup>c</sup>	NA <sup>d</sup>	Estimate = 1.37	1/average proportion of yr covered by mortality rates
Bias correction factor	Uniform	Min. = 3.26; max. = 11.46	Bruun-Schmidt (1994), Gerow et al. (2010), Santos et al. (2011), Boves and Belthoff (2012), Texeira et al. (2013)

<sup>a</sup> Includes length in millions (M) of kilometers of all public roads in all states excluding Alaska and Hawaii.

<sup>b</sup> Estimate is based only on mortality rates from studies with year-round sampling coverage.

<sup>c</sup> Estimate is based on mortality rates from all studies meeting inclusion criteria.

<sup>d</sup> Parameter is a point estimate, not a probability distribution.

We defined univariate regression models with the 10,000 replicated mortality estimates as the dependent variable and randomly drawn values of model parameters as the independent variable. We repeated this analysis 4 times, once for each of the 4 mortality estimate models. We used the adjusted  $R^2$  values for each independent variable (averaged across the 4 sensitivity analysis iterations) to interpret the percentage of estimate uncertainty attributable to each model parameter (Blancher 2013, Loss et al. 2013a).

### Vehicle Collision Mortality by Species

In addition to estimating total annual mortality for all U.S. birds, we also calculated the average proportional representation of each bird species (Longcore et al. 2013, Loss et al. 2013a). We used this calculation rather than estimating species-specific mortality because the data from studies meeting inclusion criteria only represented 100 bird species. This value is likely much lower than the actual number of species killed along U.S. roadways each year. Estimates of species-specific mortality would therefore be biased high for observed species and biased low for species killed but not reported in the literature. Therefore, we would be unable to draw unbiased conclusions about species-specific collision risk. Nonetheless, to provide a rough summary of the findings to date, we estimated average proportional representation of species by 1) calculating the proportion of each study's total count represented by each species (i.e., multiple proportions calculated for each species, 1 from each study), and 2) averaging each species' individual-study proportions across all studies. For averaging, we only included zero-values of proportions (i.e., species was not found in study) when a species could have been found, as determined by overlap of breeding, migration, and/or wintering ranges with study sites (Sibley 2000).

## RESULTS

We found considerable variation (41.8%) among median mortality estimates produced using the 4 models (Table 3). The model using only year-round mortality rates from the United States produced the lowest annual estimate (median = 145.7 million; 95% CI = 61.9–274.6 million), and the model including both year-round and partial-year mortality rates and rates from both the United States and Europe produced the highest estimate and the estimate with the greatest range of uncertainty (median = 250.5 million; 95% CI = 103.8–476.8 million). Averaging across all 4 models (i.e., averaging the 4 estimates produced in each model iteration and then averaging these values across 10,000 iterations) resulted in a median annual mortality estimate of 199.6 million birds (95% CI = 88.7–339.8 million). Regardless of the model used, sensitivity analyses indicated that the bias correction factor for scavenger removal and searcher detection contributed the greatest uncertainty to estimates (average variance explained = 63.2%), followed by the mortality rate (32.5%) and the road corridor length over which the mortality rate applies (1.3%).

Among the species documented in studies meeting inclusion criteria, the barn owl had the highest average proportional representation across studies, averaging 32.4% of total counts (all species proportions in Table S2). Four other species, including 3 in the Corvidae family, had average proportional representation of at least 5%: common raven (*Corvus corax*; 6.3%), gray jay (*Perisoreus canadensis*; 6.0%), black-billed magpie (*Pica hudsonia*; 5.0%), and European starling (*Sturnus vulgaris*; 5.0%). Several species were found in 3 or fewer studies, and these species' proportions were more likely to be biased by abnormally high or low counts documented in single studies. Given the small sample of

**Table 3.** Estimates of annual bird-vehicle collision mortality on U.S. roads.

Mortality data used	Total mortality (millions)		Mortality per km

studies included in the species summaries (7 studies including 3,246 total fatality records), caution should be used when interpreting these results.

## DISCUSSION

### Annual Bird-Vehicle Collision Mortality on U.S. Roads

All of our estimates of annual bird-vehicle collision mortality exceed the previous estimates of between 60 and 80 million birds, which were produced by extrapolating the results of 1 British study (Hodson and Snow 1965) across the entire U.S. road network (Banks 1979, Erickson et al. 2005). We improved upon these earlier estimates by systematically incorporating 20 mortality rates from 13 studies that used a prospective sampling design and reported results for all potentially killed bird species. Even when considering the lowest estimate range (between 62 and 275 million birds), our results suggest that bird-vehicle collisions outrank many other sources of direct anthropogenic mortality. Among threats with estimates that are data-driven and systematically derived, only predation by free-ranging domestic cats (Loss et al. 2013<sup>a</sup>) and collisions with buildings and their windows (Loss et al. 2014) are estimated to cause greater annual bird mortality in the United States. Estimates of total numbers of birds killed by anthropogenic threats are useful for prioritizing conservation and management efforts. However, increased attention should also be given to documenting which species and regions are most vulnerable to vehicle collisions and other mortality sources (Longcore et al. 2013; Loss et al. 2013<sup>b</sup>, 2014).

As expected, estimates that incorporated both year-round and partial-year mortality rates were higher than those that used only year-round rates. This likely occurred because the partial-year correction factor was calculated under the assumption that mortality rates were constant across all seasons. Among the studies we used, sampling periods typically covered spring, summer, and/or autumn, seasons characterized by relatively high mortality rates for most species (Loos and Kerlinger 1993, Smith and Dodd 2003, Orłowski 2005, Gryz and Krauze 2008). Extrapolating mortality rates from these peak seasons to un-sampled seasons that are generally characterized by lower mortality rates may have inflated our estimates. Estimates from models including partial-year rates should therefore be viewed as maximum values. Additional year-round studies that present results separately by month and/or season are needed to

clarify intra-annual variation in vehicle collision mortality rates.

Estimates that included European mortality rates were higher than those that used only U.S. rates. This may have occurred due to the inclusion of 2 European rates that were not statistical outliers but were higher than all U.S. rates meeting inclusion criteria (11.6 and 17.0 birds/km/yr; Hell et al. 2005, Gryz and Krauze 2008). Although exceptionally high annual mortality rates of up to 91 birds/km (Ashley and Robinson 1996) have been documented locally in the United States, such rates likely do not apply across most roads. Roadkill fatalities are often clustered in hotspots (e.g., Gunson et al. 2010), and these areas are often the focus of mortality studies. This tendency to focus on areas already known to experience bird mortality may have contributed positive bias to individual estimates of mortality rates and to our national mortality estimates. Nonetheless, we sought to minimize this source of bias by removing mortality rates that were identified as statistical outliers.

We were unable to assess regional variation in bird-vehicle collision mortality rates and to produce regional mortality estimates. Only 6 U.S. studies met our inclusion criteria; this sample was insufficient to allow for quantification of regional variation. Filling this data gap will require rigorous and prospective studies across a broad cross-section of the United States within numerous ecosystems, states, and regions. Individual studies that randomly sample roadkill mortality across a large spatial scale (e.g., entire states or regions) will also provide increased understanding of regional variation.

### Research Needs and Estimate Limitations

The relatively small sample of data meeting inclusion criteria resulted in substantial uncertainty in our mortality estimates. When assessing specific uncertainty contributions of individual model components, sensitivity analyses indicate that the model parameter contributing the greatest uncertainty to our estimates is the bias correction factor, which accounts for both scavenger removal and imperfect detection of carcasses. Further research on these biases may decrease the uncertainty associated with this correction factor and allow for increased precision of future mortality estimates. However, the magnitude of these biases depends on a suite of factors, including the local scavenger community, habitat type, traffic volume, and weather conditions (Santos et al. 2011, Boves and Belthoff 2012, Guinard et al. 2012, Texeira et al. 2013). Development of a

narrow distribution of bias correction factors that apply across a national scale may therefore not be possible. An alternative approach is for future studies to estimate scavenger removal and searcher detection rates to calculate adjusted mortality rate estimates. A large sample of locally adjusted mortality rates would obviate the need for post hoc correction factors (Loss et al. 2013*b*). Recent studies outline considerations for scavenger removal and detection trials (Santos et al. 2011, Teixeira et al. 2013). Of particular promise are approaches that allow for estimation of both biases using a single experimental trial incorporated into standard fatality monitoring (Smallwood 2013) or using only the dead birds found during fatality monitoring, thus removing the need for separate experimental trials (Etterson 2013).

Mortality rate probability distributions also contributed substantial uncertainty to our estimates. The relatively small sample of studies meeting inclusion criteria along with the inherently variable nature of collision rates likely contributed to this uncertainty. To increase the number of mortality rates that can be used to estimate national mortality, future studies should seek to meet the level of rigor captured by our inclusion criteria. In particular, more studies are needed that sample and present data for all bird species. When summarizing average proportional representation of collision mortality, we found that a few species (particularly barn owls and several corvids) comprise a relatively large percentage of all fatalities that have been identified to species. However, sample sizes of usable studies and available data were small, and results of the species summary were likely biased by high detection probabilities for large species and by geographical biases in sampling. Taking a more species-inclusive approach to studying bird-vehicle collisions will improve understanding of species- and taxa-specific vulnerabilities to vehicle collisions. Because of the above limitations, species proportions should not be used to draw conclusions about national-scale vulnerabilities of bird species to vehicle collisions. Nonetheless, they provide a descriptive summary of the bird species that have been documented as roadkill victims along U.S. roads.

In addition to estimate bias caused by scavenger removal and imperfect detection of carcasses, an unknown number of birds that collide with vehicles fly out of detection range (i.e., crippling bias; Slater 2002, Teixeira et al. 2013) or are destroyed or carried away by vehicles (Stewart 1973, Mumme et al. 2000). Because these biases have never been formally quantified in the context of vehicle collisions, substantial uncertainty remains about to what degree they contribute to under-estimation of roadkill mortality rates. Future research of these bias sources is necessary for fully understanding the magnitude of bird mortality caused by vehicle collisions.

Numerous biotic and abiotic factors influence bird collision mortality rates along roads. These correlates collectively result in bird fatalities being clustered along particular road segments (Clevenger et al. 2003, Smith and Dodd 2003, Glista et al. 2008, Gunson et al. 2010). Further research is needed to clarify the combination of factors that lead to carcass clustering (e.g., habitat, characteristics of the road

and its cleared corridor, and community composition and population abundance of birds) and to assess how these correlates vary seasonally and regionally. When possible, studies should employ sampling designs that allow for separation of often-confounded mortality correlates (e.g., road width, traffic volume, and traffic speed).

The negative bias contributed to mortality rate estimates by scavenger removal is amplified with increasing time intervals between surveys. This occurs because—with all other factors held constant—more collisions occur between surveys, and a greater proportion of carcasses are removed by scavengers. Because carcass removal adjustment factors are less accurate across long search intervals (Smallwood 2013) and because carcass removal rates appear to be especially high along roadways (Bruun-Schmidt 1994, Antworth et al. 2005, Santos et al. 2011, Teixeira et al. 2013), optimal search intervals for documenting roadkill mortality are very short (e.g., sampling on alternate days for large birds and daily for small birds; Santos et al. 2011). Because the search intervals in the studies we used were between 2 and 15 days, mortality rates in individual studies could have been substantially under-estimated. This under-estimation could have contributed negative bias to our mortality estimates.

In addition to using long search intervals for carcass surveys, the studies we used conducted surveys using various transportation methods, including foot, bicycle, and automobile. Because of the relatively high speed at which sampling is conducted, automobile surveys usually detect only a small fraction of carcasses (Slater 2002, Gerow et al. 2010, Guinard et al. 2012, Teixeira et al. 2013). In the sample of mortality rates extracted from studies meeting our inclusion criteria, the majority of rates (15 of 20) were based on automobile surveys, and estimated mortality rates for automobile surveys averaged 2.3 times lower than for other survey types. Therefore, the use of automobile surveys may have contributed additional under-estimation bias to our mortality estimates. The use of automobile surveys may have also influenced our species summary, with surveys likely over-representing large-bodied species (e.g., raptors and corvids) that are relatively easy to detect from a fast-moving automobile.

## MANAGEMENT IMPLICATIONS

The large magnitude of mortality caused by vehicle collisions combined with the potential for impacts at the population level highlights the need for conservation and management attention to mitigate this threat. Mitigation efforts may be most relevant at areas known to experience exceptionally high rates of collision mortality (e.g., clear examples include the studies that were identified as statistical outliers for our mortality estimate). Following identification of mortality hotspots, potential options to reduce bird collision mortality along roads include (see also Boves and Belthoff 2012, Bishop and Brogan 2013) placing flight deflectors along roadsides to force birds to fly above vehicle height (Bard et al. 2001, Ramsden 2003, Gomes et al. 2009), locally reducing speed limits and erecting signage to alert drivers, reducing or removing the amount of favorable bird habitat

along roadsides, and using visual or auditory deterrents. All of these approaches have rarely been implemented and remain largely untested. Research is therefore needed to determine which combinations of the above approaches are most effective at reducing mortality and to clarify how responses vary by bird species, region, habitat, season, and road type. Identification and implementation of effective conservation measures is especially crucial given the increasing length of U.S. roadways, increasing traffic volume, and an increasing number of direct and indirect anthropogenic threats to bird populations.

## ACKNOWLEDGMENTS

We thank J. Rutter and R. Schneider for assisting with data compilation, management, and analysis. S.R.L. was supported by a postdoctoral fellowship funded by the U.S. Fish and Wildlife Service through the Smithsonian Institution's Postdoctoral Fellowship program. The findings and opinions expressed in this paper are those of the authors and do not necessarily reflect the opinions of the U.S. Fish and Wildlife Service, the Smithsonian Institution, or Oklahoma State University.

**Abstract:** Concerned that San Joaquin kit foxes from urban areas may be exposed to commensal anticoagulants, the California Department of Fish and Game, Pesticide Investigations Unit, in conjunction with the Endangered Species Recovery Program's Urban Kit Fox Project, began monitoring San Joaquin kit foxes from the Bakersfield, CA population. Necropsies were performed and liver tissue samples collected from kit fox carcasses. Livers from archived kit foxes dating back to 1977 were also analyzed. A non-urban population of San Joaquin kit foxes from Lokern was used as a control. Other predators in the area, including coyotes and red foxes, were also analyzed for comparison. Between 1999 and 2007, tissue samples from 45 animals have been analyzed for residues of anticoagulant rodenticides. Anticoagulant compounds identified included brodifacoum, bromadiolone, pival, and chlorophacinone. Twenty-six of the 30 San Joaquin kit foxes from Bakersfield contained at least one anticoagulant, and the most commonly detected anticoagulant was brodifacoum. None of the 12 Lokern San Joaquin kit foxes contained anticoagulants. Other predators followed the same pattern: both red foxes from Bakersfield contained anticoagulant residues, but the coyote taken from Lokern did not.

**Key Words:** anticoagulants, brodifacoum, bromadiolone, chlorophacinone, diphacinone, kit fox, pival, rodenticide, *Vulpes macrotis*

## INTRODUCTION

Monitoring by the California Department of Fish and Game (DFG) Pesticide Investigations Unit has shown that a number of predatory avian and mammalian species that inhabit the urban landscape have been exposed to anticoagulant rodenticides, presumably as a result of secondary exposure (Hosea 2000). Species that had residues of anticoagulants were coyote *Canis latrans*, gray fox *Urocyon cinereoargenteus*, San Joaquin kit fox *Vulpes macrotis mutica*, raccoon *Procyon lotor*, fox squirrel *Sciurus niger*, bobcat *Lynx rufus*, red fox *Vulpes vulpes*, mountain lion *Felis concolor*, Heermann's kangaroo rat *Dipodomys heermanni*, golden eagle *Aquila chrysaetos*, great horned owl *Bubo virginianus*, barn owl *Tyto alba*, red-shouldered hawk *Buteo lineatus*, red-tailed hawk *Buteo jamaicensis*, Cooper's hawk *Accipiter cooperii*, turkey vulture *Cathartes aura*, and wild turkey *Meleagris gallopavo*. The most frequently detected anticoagulant was brodifacoum. Anticoagulant rodenticides vary in terms of persistence in tissues, and brodifacoum, difethialone, and bromadiolone (second-generation anticoagulants) are the most persistent. In addition, as the second-generation anticoagulants may require several days to cause mortality, there is opportunity for rodents to ingest several doses and be available for predation while carrying high concentrations of anticoagulants.

A population of San Joaquin kit foxes *V. m. mutica* inhabits part of the City of Bakersfield in Kern County, California. This subspecies is currently federally listed as endangered and by the State of California as threatened. The proximity of this predator population to the urban environment puts kit foxes at elevated risk for secondary

exposure to rodenticides used by homeowners and businesses. This urban population contributes to conservation and recovery efforts by contributing to the genetic diversity of the subspecies and serving as a source population for reintroduction efforts.

## METHODS

San Joaquin kit fox carcasses were recovered by the Endangered Species Recovery Program (ESRP; California State University–Stanislaus) in an ongoing monitoring effort dating back to 1977. Approximately 10-20 carcasses were recovered per year from both urban (Bakersfield) and non-urban (Lokern) areas. The Lokern Natural Area is 40,000 acres of high-quality habitat located approximately 30 miles west of Bakersfield. The land is managed by a number of owners, including the California Department of Fish and Game and the Bureau of Land Management. The management objective is to maintain a functioning desert ecosystem for a number of sensitive species, including Kern mallow *Eremalche kernensis*, giant kangaroo rat *Dipodomys ingens*, Tipton kangaroo rat *Dipodomys nitratooides nitratooides*, San Joaquin antelope squirrel *Ammospermophilus nelsoni*, blunt-nosed leopard lizard *Gambelia sila*, and San Joaquin kit fox. Thirty San Joaquin kit fox liver samples from Bakersfield and 12 Lokern liver samples were analyzed. Two liver samples from red foxes recovered from Bakersfield, and one from a coyote recovered from Lokern, were also analyzed.

Liver tissue was homogenized by the DFG Pesticide Investigations Unit in Rancho Cordova, CA, and analyzed by DFG Water Pollution Control Laboratory in Rancho Cordova, CA, using high performance liquid chromatog-

raphy with mass spectrometry analysis. Anticoagulants analyzed were brodifacoum, bromadiolone, chlorophacinone, diphacinone, pival, and warfarin. Detection limits varied among anticoagulants with generally lower detection levels in the later analyses as laboratory methods were refined (Table 1).

## RESULTS

San Joaquin kit fox livers taken from Lokern contained no residues of anticoagulants (Table 1). Of the 30 livers tested from Bakersfield, 26 (87%) contained residues of brodifacoum, 13 (43%) contained residues of bromadiolone, one contained a residue of chlorophacinone, and one contained a residue of pival (Table 2). Anticoagulant residues, expressed as fresh weight, were as high as 11,000 ng/g for brodifacoum (mean of 1,960 ng/g for all samples with detections), 3,123 for bromadiolone (mean of 661 ng/g for all samples with detections), 246 ng/g for chlorophacinone, and 6.93 ng/g for pival. Livers of two red foxes *V. vulpes* from Bakersfield were also analyzed and both contained both brodifacoum and bromadiolone (Table 3). A coyote liver from Lokern contained no anticoagulant residues (Table 3).

## DISCUSSION

Results from this study confirmed that San Joaquin kit foxes are exposed to anticoagulants in urban environments. Eighty-seven percent of San Joaquin kit foxes in Bakersfield had been exposed to anticoagulant rodenticides, compared to none taken at the control site. The most commonly detected rodenticides, brodifacoum and bromadiolone, are registered for use only against commensal rodents. This suggests that commensal rodents are likely the source of secondary exposure for San Joaquin kit foxes. Further study on the predation habits of San Joaquin kit foxes would be helpful to determine route of exposure.

There was a single detection of pival, a first-generation anticoagulant rodenticide. The detection was in a fox that died in 2002, when all registrations for pival had been inactive for a decade or more. This product is less persistent in animal tissues than the second-generation anticoagulants, making secondary poisoning less likely. It is possible that this exposure was due to a improper disposal of an old product.

It has been noted that the lower detection limits for second-generation anticoagulant rodenticides than for the first-generation products could partially explain the greater number of detections of the newer products. However, the data in this study do not support this, as the majority of detections of the second-generation products were well above the higher detection limits used for the older products. A total of 22 out of 26 detections for brodifacoum and 12 out of 13 detections for bromadiolone were above

2 ng/g (the detection limit for first-generation anticoagulants).

The U.S. Environmental Protection Agency issued a risk mitigation decision for 9 rodenticides in May 2008. This decision will prohibit the sale of second-generation anticoagulants to homeowners, beginning in 2011. There will be a need to continue sampling to determine the effectiveness of the regulation change in reducing exposure of San Joaquin kit foxes and other predators. This is particularly true, as it is not known whether misuse or proper use of these products has resulted in secondary exposure. It will also be important to monitor first-generation anticoagulant rodenticides, as the regulations will likely result in a more frequent use of the older products by homeowners.

The consequences of anticoagulant exposure to predators are not fully known. It is likely that impairment of normal clotting factors makes animals more susceptible to excessive bleeding from minor injuries. Several studies also indicate that sub-lethal concentrations of second-generation anticoagulants may cause mortality to embryos (Laas et al. 1985, Godfrey and Lyman 1980, Munday and Thompson 2003). Population impacts that jeopardize recovery efforts of San Joaquin kit foxes may occur as a result of widespread anticoagulant exposure.

## ACKNOWLEDGEMENT

This project was funded by a grant from the U.S. Fish and Wildlife Service.

**Abstract.** Connectivity among populations and habitats is important for a wide range of ecological processes. Understanding, preserving, and restoring connectivity in complex landscapes requires connectivity models and metrics that are reliable, efficient, and process based. We introduce a new class of ecological connectivity models based in electrical circuit theory. Although they have been applied in other disciplines, circuit-theoretic connectivity models are new to ecology. They offer distinct advantages over common analytic connectivity models, including a theoretical basis in random walk theory and an ability to evaluate contributions of multiple dispersal pathways. Resistance, current, and voltage calculated across graphs or raster grids can be related to ecological processes (such as individual movement and gene flow) that occur across large population networks or landscapes. Efficient algorithms can quickly solve networks with millions of nodes, or landscapes with millions of raster cells. Here we review basic circuit theory, discuss relationships between circuit and random walk theories, and describe applications in ecology, evolution, and conservation. We provide examples of how circuit models can be used to predict movement patterns and fates of random walkers in complex landscapes and to identify important habitat patches and movement corridors for conservation planning.

**Key words:** circuit theory; dispersal; effective distance; gene flow; graph theory; habitat fragmentation; isolation; landscape connectivity; metapopulation theory; reserve design.

CONCEPTS & SYNTHESIS

### INTRODUCTION

Connectivity among habitats and populations is considered a critical factor determining a wide range of ecological phenomena, including gene flow, metapopulation dynamics, demographic rescue, seed dispersal, infectious disease spread, range expansion, exotic invasion, population persistence, and maintenance of biodiversity (Kareiva and Wennergren 1995, Ricketts 2001, Moilanen and Nieminen 2002, Calabrese and Fagan 2004, Moilanen et al. 2005, Crooks and Sanjayan 2006, Damschen et al. 2006, Fagan and Calabrese 2006). Preserving and restoring connectivity has become a major conservation priority, and conservation organi-

zations are investing considerable resources to achieve these goals (Beier et al. 2006, Kareiva 2006).

Understanding broad-scale ecological processes that depend on connectivity, and making effective conservation planning decisions to conserve them, requires quantifying how connectivity is affected by landscape features. Thus, there is a need for efficient and reliable tools that relate landscape composition and pattern to connectivity for ecological processes. Many ways of predicting connectivity using landscape data have been developed (reviewed by Tischendorf and Fahrig 2000*a, b*, Moilanen and Nieminen 2002, Calabrese and Fagan 2004, Fagan and Calabrese 2006). Common approaches include the derivation of landscape pattern indices (e.g., Schumaker 1996), individual-based movement simulations (e.g., Schumaker 1998, Hargrove et al. 2005), and analytic measures of network connectivity, such as graph theory and least-cost path models (Keitt et al. 1997, Urban and Keitt 2001, Adriaensen et al. 2003, Minor and Urban 2007). The latter have gained increasing attention in recent years and are widely

applied in connectivity modeling and in conservation planning.

We propose that connectivity models from electrical circuit theory can make a useful addition to the approaches available to ecologists and conservation planners. Circuit theory has been applied to connectivity analyses in chemical, neural, economic, and social networks, and has recently been used to model gene flow in heterogeneous landscapes (McRae 2006, McRae and Beier 2007). The same properties that make circuit theory useful in these fields hold promise for ecology and conservation as well. Because connectivity increases with multiple pathways in circuit networks, distance metrics based on electrical connectivity are applicable to processes that respond positively to increasing connections and redundancy. Additionally, previous work has shown that current, voltage, and resistance in electrical circuits all have precise relationships with random walks (Doyle and Snell 1984, Chandra et al. 1997). These relationships mean that circuit theory can be related to movement ecology via random-walk theory, providing concrete ecological interpretations of circuit-theoretic parameters and predictions. Finally, because algorithms to implement circuit models are well developed, they can be applied to large networks and raster grids.

Here we present several ways in which circuit theory can be used to model connectivity in ecology and conservation. We describe ecological applications of previously developed theory relating resistance, current, and voltage in electronic circuits to random walks on analogous graphs (Doyle and Snell 1984, Klein and Randic 1993, Chandra et al. 1997). This theory can be applied to predict movement patterns and probabilities of successful dispersal or mortality of random walkers moving across complex landscapes, to generate measures of connectivity or isolation of habitat patches, populations, or protected areas, and to identify important connective elements (e.g., corridors) for conservation planning. Our approach does not require new ways of representing landscape data; rather, it takes advantage of graph-theoretic data structures, which are already familiar to many ecologists, and can be applied in traditional graph-theoretic or raster GIS frameworks. Coupled with applications of circuit theory to predict equilibrium patterns of gene flow (McRae 2006, McRae and Beier 2007), these new applications comprise a modeling framework that integrates spatial aspects of ecology, evolution, and conservation.

BASIC CONCEPTS

Graph data structures and terminology

Connectivity models from circuit theory are applied to *graphs* (Harary 1969), so we will use the terminology of graph theory here (see Urban and Keitt 2001 for a review). Briefly, graphs are networks comprised of sets of *nodes* (connection points which represent, e.g., habitat patches, populations, or cells in a raster landscape) connected by *edges* (Fig. 1). Edges reflect functional

FIG. 1. Three graphs at left (A, B, C), with edge weights of 1. Traditional shortest path or geodesic distance,  $d$ , between nodes a and b is identical ( $d = 2$ ) all three cases. At right (D, E, F), edges have been replaced with unit resistors to create analogous circuits. Effective resistance,  $\hat{R}$ , measured between nodes a and b decreases from top to bottom ( $\hat{R} = 2, 1,$  and  $2/3$ , respectively), reflecting additional contributions from multiple pathways (figure modified from Klein and Randic [1993]).

connections, such as dispersal, between nodes. The *weight* of each edge typically corresponds to the strength of the connection (e.g., the ease of movement or number of dispersers exchanged) between the nodes it connects.

Circuit theory

In this paper, circuits are defined as networks of nodes connected by *resistors* (electrical components that conduct current) and are used to represent and analyze graphs (Fig. 1). The basic concepts of resistance, conductance, current, and voltage all apply, and their definitions and ecological interpretations are summarized in Table 1. Recall Ohm's law, which states that when a voltage  $V$  is applied across a resistor, the amount of current  $I$  that flows through the resistor depends on (1) the voltage applied and (2) the resistance  $R$ , such that  $I = V/R$ . The lower the resistance (or the higher the conductance,  $G$ , which is simply the reciprocal of resistance), the greater the current flow per unit voltage. Similarly, when a voltage is applied across two nodes in a resistive circuit (e.g., between nodes a and b in the circuits shown in Fig. 1), the total amount of current that flows across the circuit is determined by (1) the voltage applied and (2) the configuration and the resistances of the resistors the circuit contains. The *effective resistance* ( $\hat{R}$ ) between the nodes is the resistance of a single resistor that would conduct the same amount of current per unit voltage applied between the nodes as would the circuit itself, i.e.,  $\hat{R} = V/I$ .

In simple circuits, such as those shown in Fig. 1, effective resistance can be calculated using some basic rules. First, two resistors connected in series may be replaced by a single resistor with a resistance is that the sum of the two resistances. Thus, the effective resistance in the top circuit in Fig. 1D would be  $\hat{R} = R_1 + R_2 = 2$  ohms. Conversely, connecting resistors in parallel decreases their effective resistance, such that they may be replaced by a single resistor whose conductance is

TABLE 1. Electrical terms and their ecological interpretations.

Electrical term (symbol, unit)	Ecological interpretation
Resistance ( $R$ , ohm), the opposition that a resistor offers to the flow of electrical current.	Opposition of a habitat type to movement of organisms, similar to ecological concepts of landscape resistance or friction. Graph edges or grid cells allowing less movement are assigned higher resistance.
Conductance ( $G$ , siemens), inverse of resistance and a measure of a resistor's ability to carry electrical current.	Analogous to habitat permeability. In random-walk applications, it is directly related to the likelihood of a walker choosing to move through a cell or along a graph edge relative to others available to it. In population genetic applications (see McRae 2006), it is a measure of migrants exchanged between neighboring populations.
Effective resistance ( $\hat{R}$ , ohm), the resistance to current flow between two nodes separated by a network of resistors.	Also known as the <i>resistance distance</i> , a measure of isolation between pairs of nodes on a graph or cells on a raster grid. Similar to ecological concept of effective distance, but it incorporates multiple pathways (Fig. 1D–F). It scales linearly with equilibrium genetic differentiation in population genetic applications.
Effective conductance ( $\hat{G}$ , siemens), inverse of effective resistance, a measure of a network's ability to carry current between two nodes.	A measure of connectivity between pairs of nodes on a graph or cells on a raster grid. It increases with additional available pathways and scales linearly with effective migration in population genetic applications.
Current ( $I$ , ampere), flow of charge through a node or resistor in a circuit.	Current through nodes or resistors can be used to predict expected net movement probabilities for random walkers moving through corresponding graph nodes or edges (Fig. 2).
Voltage ( $V$ , volt), the potential difference in electrical charge between two nodes in an electrical circuit. Related to current and resistance by $V = IR$ .	Voltages can be used to predict the probability that random walkers leaving any point on a graph will reach a given destination (representing, e.g., successful dispersal) before another (representing, e.g., mortality; Fig. 3).

given by the sum of the conductances of the two resistors, that is,  $\hat{G} = G_1 + G_2$ . (In terms of resistance, these quantities are given by:  $\hat{R} = R_1 R_2 / [R_1 + R_2]$ .) Applying these equations to the circuits shown in Fig. 1, the effective resistance declines from the top to the bottom circuit.

Applying circuit theory to graphs involves preserving the same graph structure with interconnected nodes, but replacing graph edges with resistors, as in Fig. 1. The conductance of each resistor is typically a function of the corresponding edge weight or probability of movement between the pair of nodes it connects. The resistance of a resistor is the reciprocal of its conductance and can be thought of as representing isolation or movement cost between nodes.

#### INTERPRETATION OF RESISTANCE, CURRENT, AND VOLTAGE

##### *Resistance and conductance*

The simplest connectivity measure from circuit theory is the *resistance distance* (Klein and Randić 1993), a distance metric defined as the effective resistance between a pair of nodes when all graph edges are replaced by analogous resistors (as in Fig. 1D–F). A convenient property of the resistance distance is that it incorporates multiple pathways connecting nodes, with resistance distances measured between node pairs decreasing as more connections are added. Hence, the resistance distance does not reflect the distance traveled or movement cost accrued by a single individual. Rather, it incorporates both the minimum movement distance or cost and the availability of alternative pathways. As additional links are added, individuals do not necessarily travel shorter paths, but have more pathways available to them. For example, in the three

graphs in Fig. 1A–C, the minimum distance required to travel from node a to b (called geodesic distance in graph theory) is the same. However, the resistance distance decreases as more connections are added, reflecting increased flow capacities and levels of redundancy. In short, the resistance distance is small when two nodes are connected by many paths with low resistance (high conductance) edges and large when there are few paths with high resistance. Resistance distances can be calculated across irregular networks or with continuous landscape data, which are typically represented as discretized lattices or grids. On continuous surfaces, the resistance distance increases linearly with Euclidean distance in homogeneous one-dimensional habitats and with its log transformation in two-dimensional habitats, a property important for modeling gene flow (McRae 2006).

Resistance distances can also be related to random-walk times between nodes. For the theory and examples that follow, we assume that conductances are chosen so that the probability of moving from a node along any given edge is equal to the conductance assigned to the edge divided by the sum of the conductances of all edges connected to the node. For an organism moving through a habitat network (the main focus of this paper), this would correspond to a scenario where the individual chooses to move along an edge in proportion to the edge's conductance, a surrogate for habitat quality or (inverse) perceived risk, relative to the quality of all other choices of direction; this choice is then repeated at each subsequent step. For genes moving across a network of populations over many generations, this would correspond to a scenario where edge conductances correspond to per-generation migration rates (McRae 2006).

Chandra et al. (1997) showed that, when resistors are parameterized in this way, the resistance distance between a pair of nodes is precisely related to the *commute time* between the nodes, i.e., the expected time for a random walker to move from one node to the other and back again. The commute time between any pair of nodes  $u$  and  $v$  can be calculated using the following formula:

$$\text{Commute time} = \hat{R}_{uv} \sum_{x=1}^n \sum_{y=1}^n (1/R_{xy}) \quad (1)$$

where  $R_{xy}$  is the resistance of the resistor connecting nodes  $x$  and  $y$  and  $n$  is the number of nodes in the network. Note that Eq. 1 accommodates resistors connecting a node to itself, which would reflect a nonzero probability of staying at the node for any time step. Chandra et al. (1997) also provided formulas to calculate a commute *cost*, if there is a cost imposed for each step that is independent of the resistance (and thus independent of the behavior of a random walker). An interesting result of Eq. 1 is that if the goal is to minimize commute times between a pair of nodes, there is a penalty for adding connections which is offset by the degree to which the new connections help to lower effective resistance between the two nodes. Within a fixed network, commute times between different pairs of nodes will be directly proportional to the effective resistances measured between them. Another potentially useful way to apply resistance calculations across graphs is to compute upper and lower bounds for the *cover time*, or the expected number of steps of a random walk visiting all nodes in the graph (Chandra et al. 1997).

*“Functional” or “effective” distance.*—Used as an ecological distance metric, the resistance distance provides a conceptual complement to commonly used least-cost distances in two important ways. First, it integrates all possible pathways into distance calculations, whereas least-cost distances are measured along a single optimal pathway. Second, it offers a measure of isolation assuming a random walk, whereas least-cost distances presumably reflect the route of choice if a disperser has complete knowledge of the landscape it is traversing.

The resistance distance also provides a quantitative complement to least-cost distances. If only a single pathway between two nodes is available (e.g., in Fig. 1A or in any graph that is a tree), the resistance distance will equal the least-cost distance. On the other hand, when two identical and independent pathways connect a pair of nodes in parallel, the resistance distance will be half the least-cost distance. This suggests an interpretation of the resistance distance as an indicator of redundancy in connections relative to the least-cost distance:

$$\text{Redundancy} = (\text{least-cost distance})/(\hat{R}).$$

Thus, the two measures can be compared directly, their

ratio providing a rough measure of parallel pathways available to dispersers.

The relationship between resistance distances and commute times is one way to link circuit and ecological theories and is the basis of using resistance distances to predict patterns of gene flow and genetic structuring in heterogeneous landscapes (McRae 2006). Calculating commute times directly may provide valuable additional information because commute times take into account how efficiently a given landscape configuration will channel dispersal between source and destination nodes. Additional pathways that primarily result in increased wandering behavior rather than directed movement may reduce resistance distances but will increase commute times. Low commute times and low resistance distances between pairs of nodes indicate that dispersers will be efficiently directed between them.

### Current

Currents in circuits can also be interpreted in terms of random walks on corresponding graphs. Consider again a graph in which the probability that a random walker will move from a node along any graph edge is proportional to its conductance. Doyle and Snell (1984) showed that when 1 A (ampere) of current is injected into one node (node a in Fig. 2A) and a second node (node e) is tied to ground, the current  $i_{xy}$  flowing through the resistor connecting any pair of nodes  $x$  and  $y$  is equivalent to the expected net number of times that a random walker, starting at a and walking until it reaches e, will move along that branch. Because we are tallying net passages through the branch, movements from  $x$  to  $y$  are counted as positive, whereas movements from  $y$  back to  $x$  are counted as negative.

*Corridor identification and dispersal predictions.*—By predicting net movement probabilities along branches or through nodes, current density can be used to identify landscape corridors or “pinch points,” i.e., features through which dispersers have a high likelihood (or necessity) of passing. High current through a node or branch indicates that removing or converting it will have a high impact on connectivity. In Fig. 2, all the current passes through node b; removing that node (or the link between nodes a and b) would completely disconnect nodes a and e, whereas removing node c, through which only half the current passes, would reduce redundancy but would still leave nodes a and e connected via the lower branch. In graph terminology, node b is a *cutnode*, and the resistor connected nodes a and b is a *cutlink*.

### Voltage

Doyle and Snell (1984) also showed that voltage can be related to random walk probabilities. Consider a graph in which a voltage source set to 1 V is connected to one node (or to a set of nodes), and another node (or set of nodes) is connected to ground (Fig. 3). The voltage measured at any remaining node on the graph will equal the probability that a random walker, starting at that

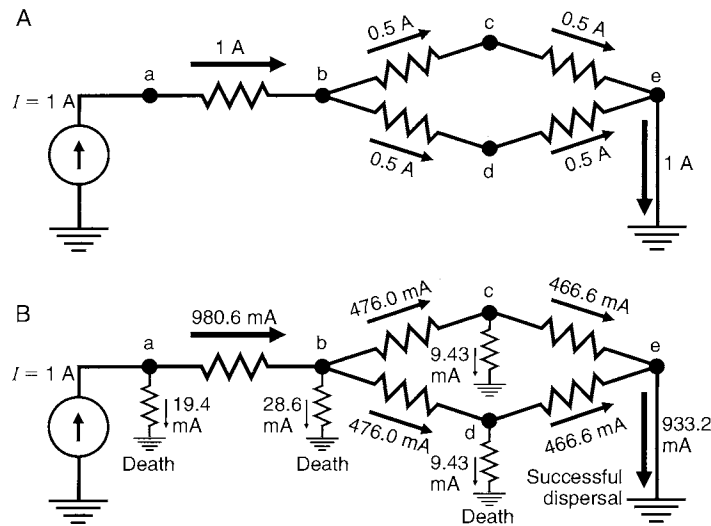

FIG. 2. (A) A simple circuit, with a 1-A (ampere) current source ( $I$ ) placed at node a, and with node e tied to ground. Branch currents that would be observed with unit resistors are shown and reflect the net number of times that a random walker, starting at node a, is expected to pass along each branch before reaching node e. All random walkers must pass across the first branch, but half would be expected to take the upper pathway, and half the lower. Resistances connecting nodes were set to 1 ohm for this simple example; the methods we describe here can accommodate heterogeneous resistances with values from 0 to infinity. (B) The same circuit as in (A), but with ground resistors added to reflect a 1% probability of mortality as the random walker passes through each node. To achieve this, resistances to ground for nodes a–d were set to 99, 33, 49.5, and 49.5 ohms, respectively. Currents show the expected number of net movements along each branch, as well as the expected number of deaths at each node. For example, the proportion of dispersers leaving node a expected to successfully reach node e is 0.9332 (933.2 mA equivalent). Deaths at each node exceed 1% because nodes are visited multiple times by random walkers, with the highest numbers of deaths observed in nodes with the highest numbers of visits. Only one possible dispersal destination was included here, but the method can accommodate as many dispersal destinations as desired. Although we tied the destination node directly to ground, resistors could be added between destination nodes and ground, with their conductances set to reflect a finite probability that a walker would settle rather than continue walking once reaching a node.

node, will reach any of the nodes set to 1 V before reaching any node connected to ground. The most obvious application of this property is to predict the probability of successful dispersal via a random walk from any node on a graph. Suitable destination patches for dispersal can be set to 1 V, whereas mortality can be represented by resistors connected to ground, with their conductances reflecting probabilities of mortality (Fig. 3).

#### APPLYING CIRCUIT ANALYSES TO RASTER GRIDS

Predicting connectivity using circuit theory requires translating spatial data sets into a graph structure, but that doesn't mean that primary landscape data must be in a patch-based or network-style format. In fact, we envision most landscape applications operating on raster data, with a graph extracted from these data as is done for least-cost path analyses (Adriaensen et al. 2003). Since well-developed computer algorithms allow millions of cells to be processed, large raster landscapes can be accommodated.

Analyzing a raster grid involves first assigning resistances to different habitat types in the grid. Fig. 4 shows a simple example with three different habitat types: assigned unit, infinite, and zero resistance. The last is useful when practitioners wish to measure connectivity or identify important connective elements between areas (representing, for example, habitat

patches or reserves), rather than points on a landscape. To represent a grid as a circuit, cells with finite resistances are converted to nodes (gray), whereas cells with infinite resistance (i.e., those representing complete barriers, black) are dropped. Adjacent nodes are connected by resistors, with resistances reflecting a function (typically the mean) of the resistances of the cells they connect. Adjacent cells with zero resistance (open) are consolidated into a single node that is then connected by resistors to all nodes adjacent to the zero-resistance patch. Following this procedure, the 16-cell

FIG. 3. The same circuit shown in Fig. 2B, but with a voltage source ( $V$ ) of one volt at node e instead of a current source at node a. Node voltages reflect the probability that a random walker, starting at each node, will successfully reach node e. Consistent with the result from Fig. 2B, the probability of successful dispersal from node a to node e is 0.9332.

FIG. 4. A simple landscape represented as both a grid and a circuit. The landscape contains two contiguous patches of 0-resistance cells (open), dispersal habitat of finite resistance (gray), and one “barrier” cell with infinite resistance (black). Cells with finite resistance are replaced with nodes (small dots), and adjacent nodes are connected by resistors. Patches of cells with 0 resistance are each consolidated into a single node (large dots). Connections between diagonal neighbors and nonadjacent cells can also be incorporated, the latter representing “hops” over intervening cells. Current sources, voltage sources, and ground connections can be added as in Figs. 2 and 3.

grid in Fig. 4 is now represented as a circuit with 13 nodes and 18 resistors.

#### COMPUTATION

Although simple circuits can be solved by hand, *nodal analysis* is typically used to analyze larger circuits, such as those derived from raster grids (McRae 2006). Given a circuit with current or voltage sources, nodal analysis uses Kirchoff’s and Ohm’s laws in matrix form to solve for a vector, specifying voltages at each node; once these are known, Ohm’s law can be used to calculate currents passing through individual resistors or nodes. Effective resistance between a pair of nodes is given by the voltage between them when one is connected to a 1-A current source and the other is connected to ground (e.g., Fig. 2A). The method is described in standard circuit theory textbooks (e.g., Dorf and Svoboda 2003); an example of its use to calculate effective resistances is provided by McRae (2006).

Computer languages used for scientific computing such as Java, C, MATLAB, and Python include linear solver routines that can solve for effective resistances on graphs. Fast graph operations can be used to define connected components in a landscape and discard from a graph any components that are completely isolated. Very large graphs can be processed relatively easily and efficiently; we have solved for effective resistances, voltages, and current on landscapes containing over 1 million cells using Java (Sun Microsystems, Mountain View, California, USA), and up to 48 million cells using a parallel version of MATLAB (MathWorks, Natick, Massachusetts, USA) implemented using Star-P (Interactive Supercomputing, Waltham, Massachusetts, USA). Solving 1 million cells on a notebook computer

with a 2-GHz processor and 2 GB of RAM took us 16 minutes using Java and only 20 seconds using MATLAB. This calculation must be repeated for each configuration of current sources and grounds, but typical connectivity applications will require a small number of calculations (e.g., for each pair of populations or reserves between which connectivity is to be modeled). Calculations between multiple pairs can be sped up considerably using matrix preconditioning and/or parallel processing. Software implementing many of the algorithms in this manuscript is available (B. H. McRae, *unpublished data*).

#### EXAMPLE APPLICATIONS TO HETEROGENEOUS LANDSCAPES

Here we provide examples of the applications described above to predict connectivity and movement of random walkers across large raster grids. For the example analyses described next, we solved for effective resistances and node currents using code written in MATLAB R2007b. The example landscapes (i.e., resistance surfaces) were all created using ArcView GIS 3.2 (ESRI, Redlands, California, USA) and exported as ASCII raster grids, with cell values corresponding to resistances ranging from 0 to infinity (Fig. 5). For circuit analyses, cells with finite resistances were converted to nodes, whereas those with infinite resistances were dropped. Cells were connected to their eight neighbors such that the resistance between a pair of first-order neighbors was set to the mean of the two cells’ resistances, and the resistance between a pair of second-order (diagonal) neighbors was set to the mean resistance multiplied by the square root of 2 to reflect the

FIG. 5. Nine simple raster landscapes (A–I), consisting of  $1000 \times 1000$  cells. Habitat patches (shown in white and assigned 0 resistance, or infinite conductance) are connected by different configurations of dispersal habitat (light gray, 10 ohms/cell; dark gray [lower corridor in panel C], 20 ohms/cell; black = infinite resistance or 0 conductance).

FIG. 6. Least-cost distances and resistance distances between habitat patches for the nine simple landscapes shown in Fig. 5. Least-cost distances decrease from (A) to (B) but are equivalent for all remaining maps. Effective resistances decrease not only from (A) to (B), but also from (B) to (I), reflecting the availability of more and wider pathways. Redundancy, defined here as the ratio of least-cost distance to effective resistance, would be roughly equal for cases (A) and (B) but would increase from (B) to (I). Cost-weighted distance (measured in cost units) were calculated using PATHMATRIX software. Resistance distances (measured in ohms) were calculated using Circuitscape software.

greater distance between cell centers. We converted individual cells to single nodes, except for cells in areas of zero resistance, i.e., open source/target patches; as in the simple landscape in Fig. 4, these cells were considered collectively and consolidated into a single node for the analyses. For all examples, we used the same resistance surfaces to calculate least-cost distances and map least-cost corridors using PATHMATRIX software (Ray 2005).

We started with nine simple landscapes (Fig. 5) meant to illustrate different properties of circuit models. The landscapes consisted of  $1000 \times 1000$  cells each and contained two primary habitat patches, which were always the same distance from one another and always occupied the same total area. Least-cost and resistance distances calculated between habitat patches in the nine simple landscapes illustrate some advantages of the resistance distance (Fig. 6). Although least-cost distances correctly identify decreased isolation between habitat patches in landscape B relative to A, they were identical in landscapes B through I. Resistance distances show a similar decrease from landscape A to B, but they also decrease from B to I, reflecting the availability of additional, or wider, pathways. Note that between landscapes H and I, only the shape of the primary habitat patches has changed, and not their area or the distance separating them. Yet the resistance distance differs because the greater surface area of each habitat patch in landscape I acts as a “drift fence” to better intercept or release dispersers.

Commute times ranged from 1.2 million steps (landscapes B, C, and G) to 6.2 million steps (landscape A). They were intermediate for landscapes D, E, F, H, and I, which had commute times of 2.6, 3.0, 1.6, 2.7, and 2.0 million steps, respectively. Lower commute times reflect configurations in which dispersers are efficiently channeled between habitat patch pairs, minimizing wandering time.

These same simple landscapes also demonstrate how current maps (Fig. 7) can highlight connective elements in raster maps (Fig. 7) can highlight connective elements in raster maps. As the availability of multiple pathways increases, current density—indicating cells through which dispersers are likely to pass moving from one patch to the other—decreases. Pinch points are highlighted in landscapes D–F, and the “drift fence” effect resulting from the more linear shape of the habitat patches in landscape I is evident as well. Fig. 7J shows a least-cost path map for the “braided stream” corridor configuration. The technique identifies the route with the lowest cumulative cost, but gives no information about the contribution of alternative pathways. By contrast, the current map (Fig. 7D) clearly indicates the importance of different corridor segments, with current densities at their highest in the two critical linkages and at their lowest in segments that are most redundant.

We can now illustrate how these models can be used to analyze connectivity in more realistic landscapes. Fig. 8A shows a complex landscape, with patches of high-quality habitat, lower quality “matrix” habitat, corridors, and complete barriers. Fig. 8B shows cumulative travel cost mapped between two high-quality patches using standard least-cost path techniques. The map highlights the most efficient pathway between the two patches, as well as low-cost detours that do not actually contribute to connectivity, e.g., into habitat cul-de-sacs or along “corridors to nowhere.” By contrast, the current map between the same two habitat patches (Fig. 8C) highlights critical pinch points between the two patches. Habitat cul-de-sacs and corridors that do not contribute to connectivity have minimal current flow. The current map also indicates two broad routes linking the habitat patches, whereas only one is highlighted in the least-cost map. The current map thus gives important insight into the redundancy that would be lost if the second route were to be blocked.

Often it will be useful to summarize connectivity between many habitat patches or protected areas in a single map. Fig. 9A shows the result of adding 10 pairwise current maps calculated among all pairs of five habitat patches. These maps show which landscape elements are most important for overall connectivity among the five habitat patches, indicating the net number of times random walkers are expected to move through raster cells if one random walker moves from each patch to each other patch.

We could also extend the analyses of our raster maps in much the same way as the analyses in Fig. 2A were extended in Figs. 2B and 3. Ground resistors could be added to incorporate mortality or finite probabilities of

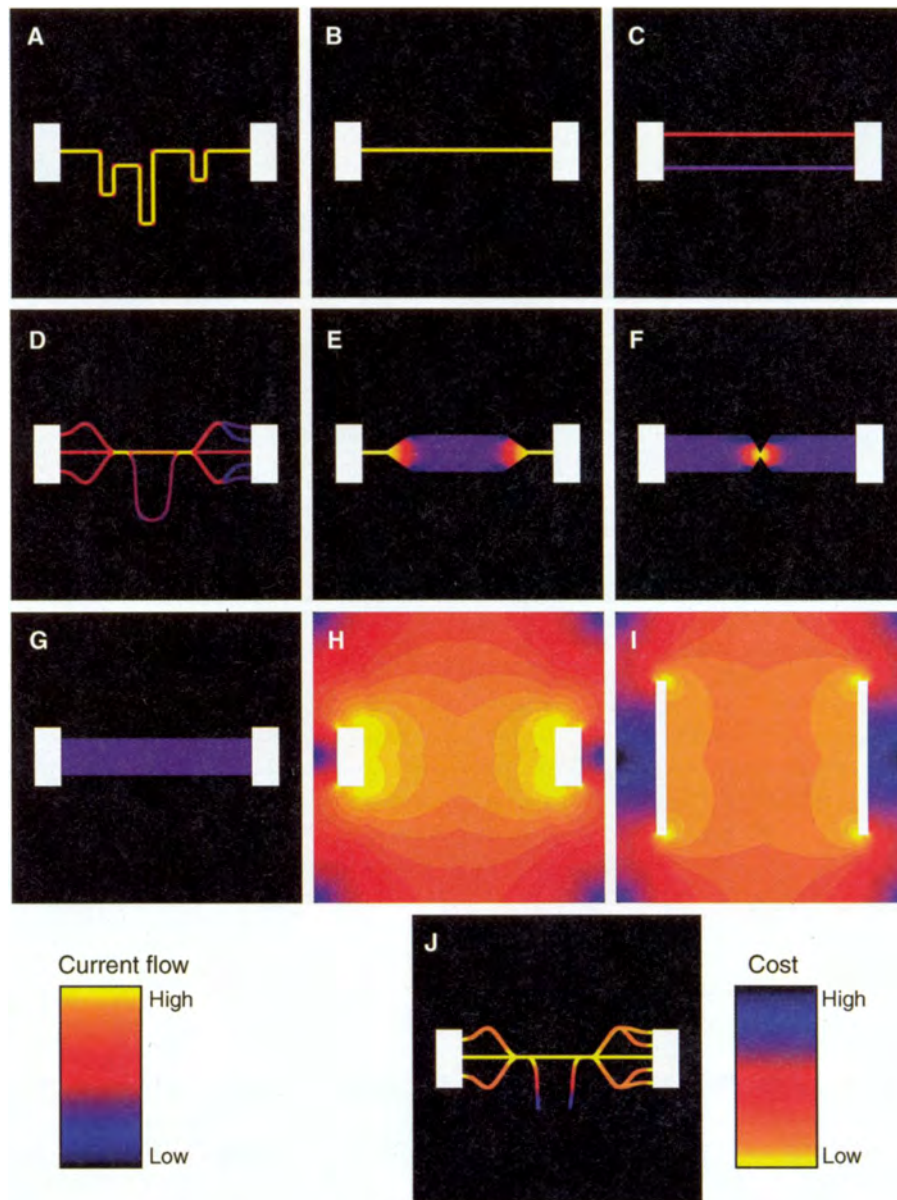

FIG. 7. Current flow through landscapes shown in Fig. 5 when 1 A (ampere) of current is injected into one habitat patch and the other is connected to ground. Current maps were log-transformed to facilitate display. Among the nine panels, three different quantitative scales are applied to the color schemes in order to most clearly illustrate differences in current densities. The three schemes are applied in panels (A)–(D), (E)–(G), and (H)–(I). Highest maximum current densities (indicating the greatest impact of habitat cell removal or conversion) are observed in (A), (B), and (D)–(E), where connectivity depends on single, narrow corridor segments. The lowest maximum current densities are observed in landscape (I), which provides the most redundancy and lowest effective resistance. This landscape also exhibits a drift-fence effect, in which the linear shapes of the habitat patches act to intercept dispersing individuals. (J) The least-cost path solution of the “braided stream” landscape shown in Fig. 5D. Whereas this technique highlights the most efficient travel path, it gives no indication of pinch points or effects of multiple parallel corridors.

settling once a disperser reaches a habitat patch or protected area. With multiple destination patches, a matrix of asymmetrical dispersal rates between all patch pairs could be generated. Or, target patches could be set to 1 V and probabilities of successful dispersal (or dispersal to one patch vs. others) from any point on the landscape could be mapped. Finally, additive maps (such as the one shown in Fig. 9A) could be adjusted to

give greater weight to important source or destination patches, with more current released or absorbed by larger or higher quality habitat patches.

#### *Model sensitivity to landscape scale*

Representing a landscape as a raster grid always involves choosing an appropriate scale of analysis (cell size and map extent). Because different species respond

FIG. 8. Connective elements identified using least-cost path and circuit models in a complex landscape. (A) Map of the landscape, with resistances and costs for circuit and least-cost path analyses ranging from 1 (light gray) to 100 (dark gray) to infinite (black). (B) Results from least-cost modeling between habitat patches in lower left and upper right corners of the map. The value assigned to each cell indicates the cost accumulated moving along the most efficient possible route that passes through the cell from one habitat patch to the other; brighter areas indicate cells along the route of lowest cumulative cost. Some habitat cul-de-sacs are highlighted because the most efficient path connecting one patch to the other via the cul-de-sac has a low cost relative to most other features in the landscape. For the same reason, some “corridors to nowhere” are highlighted, such as the one leading off of the top of the map. (C) Current map between the same two habitat patches. Higher current densities indicate cells with higher net passage probabilities for random walkers moving from one patch to the other. The map highlights “pinch points,” or critical habitat connections, between the two patches. Habitat cul-de-sacs have minimal current flow because they do not contribute new, independent pathways between habitat patches.

to landscape structure at different scales (Wiens 1985, Wiens and Milne 1989; Beier et al., *in press*), there will be no single correct approach to this. The extent of an analysis will obviously have important consequences, since map edges will constrain potential movement routes. Cell size is also important, but our analyses indicate that as long as it remains fine enough to capture relevant landscape elements, such as narrow corridors and barriers, there is considerable robustness in the technique to changes in cell size. Fig. 9B shows the same

landscape as in Fig. 9A, but analyzed using cell sizes that are an order of magnitude larger. Notably, current densities and resistance distances calculated among habitat patches are highly correlated between the two scales, a consistent result in our analyses in a wide range of natural and artificial landscapes. However, these analyses also show that it is particularly important to capture absolute barriers to movement that may not easily be detected at coarser cell sizes. Such barriers (such as the narrow roads in Fig. 9A) were automatically

FIG. 9. Summed current from all pairwise current maps between five habitat patches, each shown in white. Calculations were performed (A) at the original  $1000 \times 1000$  cell resolution and (B) at a reduced  $100 \times 100$  cell resolution. To produce the coarser resolution habitat map, blocks of  $10 \times 10$  cells were converted to single cells, with the resistance of each new cell set equal to the mean resistance of the 100 cells it contained. The current maps at the two resolutions identify the same pinch points and important corridors, and pairwise effective resistances measured between all habitat patch pairs at the two scales are highly correlated ( $R^2 = 0.963$ ), illustrating the method's robustness to scale.

incorporated into our analyses in Fig. 9B because we averaged resistances among consolidated cells, with infinite resistances “trumping” all others.

#### DISCUSSION

Although a wide variety of methods exists for predicting connectivity across landscapes, circuit-theoretic models provide some distinct advantages. First, the precise relationships between circuit theory and random walks lend theoretical justification to these models and mean that the metrics they generate can genuinely be considered to be process based. Second, these relationships also mean that circuit models will often be more straightforward to parameterize than other connectivity models because conductances and resistances assigned to edges or raster cells have clear interpretations in terms of movement probabilities. Third, unlike commonly applied least-cost path approaches, circuit methods incorporate multiple pathways, not only in generating metrics of connectivity and isolation, but also in identifying corridors and other important landscape elements connecting habitat patches or protected areas. An advantage of this property is that when dispersal pathways are lost, the predicted importance of remaining pathways increases. Finally, circuit models have an intuitive appeal in that the idea of using resistance and current to model connectivity across landscapes is readily understood by both practitioners and nonscientists. In effect, we find that the method objectively identifies important connective elements similar to those

identified by the human eye, replicating expert opinion but removing potential sources of bias once relative resistance values and scales of analysis have been defined.

#### *Niches for circuit models*

We envision several roles for circuit theory in evolution, ecology, and conservation. Circuit theory has already been shown to be useful for predicting patterns of gene flow in heterogeneous landscapes, particularly when data on absolute population sizes and migration rates are lacking, but relative population densities or permeabilities to movement are hypothesized for different landscape features (McRae 2006, McRae and Beier 2007). As discussed in the section below, the theory underlying gene flow modeling is similar to that described here, but relates resistance distances to random walks of genes over multiple generations rather than to random walks of individuals within single lifetimes.

In ecology, circuit models can be used as simple movement models, e.g., when data or time required for simulations are lacking or when the comparison of simple and complex model predictions is desirable. An example application would be to predict dispersal rates between populations based on simple landscape data in order to parameterize metapopulation models. Additionally, just as it can be used to predict gene flow, circuit theory may be useful in modeling other emergent

processes that depend on dispersal. Some ecological phenomena, e.g., community similarity and diversity, may respond to dispersal not of one species, but of several species with only somewhat similar dispersal abilities or habitat requirements. Here, simulations may be prohibitive or inappropriate because of the large number of species involved. However, analytic approaches like ours may be able to adequately capture these processes without imposing prohibitive data or computational requirements.

Measurements of resistance distances, commute times, and current densities have clear applications in conservation planning, such as corridor design or predicting the effects of different land use practices on connectivity. Circuit theory should provide an especially powerful tool for designing robust reserve networks, i.e., those that still provide for connectivity in the face of uncertainty in species distribution data and/or future habitat loss (Moilanen et al. 2006a, O'Hanley et al. 2007; Pinto and Keitt, *in press*). Importantly, circuit methods can be applied to the same resistance surfaces that are commonly employed in least-cost path analyses, and with little added computational expense.

In this paper, we limited our examples of circuit-based analyses to accessible interpretations of resistance, voltage, and current. However, there should be a large number of tools that could be derived from these basic properties. For example, metrics that combine predictions of efficient travel paths, pinch points, and mortality risks could allow practitioners to map landscape features that most effectively contribute to connectivity while minimizing mortality rates. Or, metrics derived from shortest path or least-cost distances, such as the Harary index (Ricotta et al. 2000, Jordán et al. 2003) or the integral index of connectivity (Pascual-Hortal and Saura 2006) could be modified by substituting resistance distances for least-cost distances in their calculation. Additionally, algorithms like edge and node thinning, used to evaluate impacts to connectivity of habitat loss in graph theory (Urban and Keitt 2001), can also be applied using circuit-based measures.

#### *A note about ecological vs. evolutionary applications*

It is important to be aware of subtle differences in assumptions behind applications of circuit theory to different processes. So far we have identified two distinct frameworks, one which models gene flow across population networks and the other focused on individual movement across habitat networks. The former assumes nodes (or cells) represent subpopulations (or occupied habitat for continuously distributed populations), with resistors representing numbers of migrants exchanged between adjacent nodes per generation (McRae 2006). By contrast, applications focused on individual movement will typically be implemented at finer temporal and spatial scales, with nodes (cells) mapped at the scale at which individual movement

decisions are made. Thus, the two will often be applied at different scales and with (at least somewhat) different habitat models. Similarly, predictions from the two frameworks must also be interpreted differently. For example, in applications where nodes or cells represent occupied habitat exchanging migrants, a decrease in the resistance distance between two nodes corresponds to a proportional increase in gene flow predicted between them; however, when nodes represent dispersal habitat rather than subpopulations, a decrease in the resistance distance corresponds only to an increase in available dispersal pathways, and not necessarily a commensurate increase in individual movement rates or gene flow. It does, however, indicate that there will be more pathways available to dispersers, and presumably greater robustness of the network to future habitat loss. Conservation applications may be implemented using either framework, but it is important to specify the process being modeled.

#### *Model parameterization*

A critical and challenging step in applying circuit models to landscape data will be assigning relative movement, mortality, and/or settlement probabilities to different land cover classes. Many of the same strategies for parameterizing least-cost path models using expert opinion, literature review or data on species occurrences, animal movement paths, or interpatch movement rates (reviewed by Beier et al., *in press*) will be useful in circuit modeling, particularly when viewed in light of the concrete interpretations of resistances in terms of random walk probabilities outlined here. Practitioners should also consider approaches taken to parameterize other models that consider habitat heterogeneity, such as diffusion and simulation models (e.g., Dunning et al. 1995, Schumaker 1996, Ovaskainen 2004; Arellano et al., *in press*; Ovaskainen et al., *in press*).

Connections between resistance distances and gene flow (McRae 2006, McRae and Beier 2007) should facilitate the use of genetic data to estimate relative resistances of different habitats. Still, because assumptions differ between evolutionary and ecological applications of circuit theory (as discussed here), using data from one to parameterize the other must be done with care.

Regardless of the method used to assign them, there will always be uncertainty in resistance values. We encourage uncertainty analyses to address how decisions at each modeling step affect results; Beier et al. (*in press*) reviewed strategies for conducting uncertainty analysis in least-cost path modeling, and these should be equally applicable to circuit theory. Additionally, for corridor and reserve designs, uncertainty in landscape resistances could be incorporated in much the same way as proposed by Moilanen et al. (2006b), with penalties that reflect modeled error incorporated into landscape resistance input maps.

### Limitations and alternatives

As with other methods for describing connectivity in complex landscapes, there are limitations to our approach that should be considered when deciding if it is appropriate for a given problem. First, because resistors are isotropic, i.e., their resistance to current flow is the same in both directions, the methods described here cannot accommodate movement that is biased in one direction (as in directed graphs). This will limit applications in some systems, e.g., marine environments, where directional currents play a large role in determining dispersal rates. Second, circuit models are restricted to Markovian random walks, i.e., random walks in which each step is independent of previous moves. Random walkers thus have no “memory,” and our framework cannot incorporate correlated random walks, changes in movement behavior with time, or mortality rates that increase with an organism’s age. Even when the assumption of constant mortality with time is reasonable, incorporating mortality into circuit models must be done with care. Because they have no memory or long distance perception, random walkers can retrace their steps over and over, inflating mortality rates because travel time and exposure to mortality risks are increased (Fig. 2B).

Several other connectivity modeling frameworks provide complements to ours. The conceptually and computationally simplest are based on Euclidean distances, and can be quickly calculated on grids with millions of cells (e.g., Moilanen et al. 2005, Moilanen and Wintle 2007). Least-cost path models have been applied for over a decade in connectivity analyses and have proven useful in conservation planning efforts (e.g., Beier et al. 2006, Rouget et al. 2006). Although they do not have the theoretical foundation in random walk theory that circuit models do, their intuitive appeal and ability to identify efficient movement pathways make them useful counterparts to the applications we have described here. Recently, variants on these approaches have been developed that identify and rank the importance of multiple pathways across landscapes (Theobald 2006; Pinto and Keitt, *in press*).

More sophisticated analytical and simulation models can be used to derive results similar to those produced by circuit theory, with some advantages. Markov chain models use the same data structures as those described here, but can accommodate directionality in movement along edges, providing more flexibility for modeling, e.g., effects of directed dispersal, prevailing winds, or ocean currents. Still, although Markov chain models have been available for decades, ecologists and conservationists have been slow to adopt them, whereas simpler, more intuitive least-cost path models have been widely employed. Spatially structured diffusion models (Ovaskainen 2004) are promising because they also integrate over all movement paths and can approximate correlated random walks in their long-term behavior, but their mathematical formulation can be quite

challenging. Of course, individual-based movement simulations (e.g., Schumaker 1998, Hargrove et al. 2005) offer much more flexibility than analytic models, can incorporate subtle effects of dispersal behavior and other aspects of life history, and can simulate transient effects of landscape characteristics that evolve over time. However, the data and computational requirements of such models will likely continue to limit their use in many applications (Minor and Urban 2007). Our hope is that circuit models will fill a niche between simpler Euclidean or least-cost path analyses and more powerful analytic and simulation approaches.

### Future prospects

Our focus has been on measuring connectivity in heterogeneous landscapes using models from circuit theory. Even in this context, there remain many exciting applications to explore. Nonequilibrium circuit analyses may be applicable to ecological problems (McRae and Beier 2007), and nonlinear circuit elements show promise as well (for example, diodes would allow incorporation of movement probabilities with directional bias). Additionally, analytical techniques developed to minimize effective resistances across networks (Ghosh et al. 2006) may be useful in designing optimal networks for connectivity conservation. More broadly, circuit theory will likely benefit other areas of ecology that deal with networks, such as the analysis of community interactions, food web structure, exotic invasion, or disease transmission. In the meantime, circuit models are being actively applied to conservation planning for species of concern in rapidly developing landscapes, including pumas (*Puma concolor*; see Plate 1) in southern California.

## Abstract

Landscape connectivity is crucial for many ecological processes, including dispersal, gene flow, demographic rescue, and movement in response to climate change. As a result, governmental and non-governmental organizations are focusing efforts to map and conserve areas that facilitate movement to maintain population connectivity and promote climate adaptation. In contrast, little focus has been placed on identifying barriers—landscape features which impede movement between ecologically important areas—where restoration could most improve connectivity. Yet knowing where barriers most strongly reduce connectivity can complement traditional analyses aimed at mapping best movement routes. We introduce a novel method to detect important barriers and provide example applications. Our method uses GIS neighborhood analyses in conjunction with effective distance analyses to detect barriers that, if removed, would significantly improve connectivity. Applicable in least-cost, circuit-theoretic, and simulation modeling frameworks, the method detects both complete (impermeable) barriers and those that impede but do not completely block movement. Barrier mapping complements corridor mapping by broadening the range of connectivity conservation alternatives available to practitioners. The method can help practitioners move beyond maintaining currently important areas to restoring and enhancing connectivity through active barrier removal. It can inform decisions on trade-offs between restoration and protection; for example, purchasing an intact corridor may be substantially more costly than restoring a barrier that blocks an alternative corridor. And it extends the concept of centrality to barriers, highlighting areas that most diminish connectivity across broad networks. Identifying which modeled barriers have the greatest impact can also help prioritize error checking of land cover data and collection of field data to improve connectivity maps. Barrier detection provides a different way to view the landscape, broadening thinking about connectivity and fragmentation while increasing conservation options.

## Introduction

Landscape connectivity, or “the degree to which the landscape facilitates or impedes movement among resource patches” [1], is crucial for many ecological and evolutionary processes, including dispersal, gene flow, demographic rescue, and movement in response to climate change [2–7]. Many research and conservation planning efforts have focused on mapping areas important for connectivity using GIS models (e.g., [8–12]). The results of these analyses are guiding investments by governmental and non-governmental organizations to promote ecological connectivity across large areas. In the USA and Canada, for example, numerous broad-scale conservation efforts such as the U.S. Department of Interior Landscape Conservation Cooperatives, the Western Governors’ Association’s Initiative on Wildlife Corridors and Crucial Habitat, and the Yellowstone to Yukon Conservation Initiative are working to integrate and coordinate connectivity conservation actions spanning millions of acres and crossing many political and ecoregional boundaries.

Conservation practitioners employ two primary strategies to promote connectivity. The first focuses on conserving areas that *facilitate* movement; the second focuses on restoring connectivity across areas that *impede* movement (e.g., by removing a fence or building a wildlife-friendly highway underpass). Most connectivity analyses have focused on the former strategy by modeling and mapping areas important for movement under present landscape conditions. A wide array of tools have been developed for this purpose: least-cost corridor modeling [8,13,14], circuit theory [15], individual-based movement models (e.g., [16–18]), graph theory [19,20], and centrality analyses (e.g., [21,22]) have all been used to identify areas important for movement of plants and animals. Outputs from such models are now being used as inputs to reserve selection algorithms (e.g., [23]) to optimize actions to conserve connectivity.

In contrast, there has been little effort by conservation scientists towards identifying candidate areas for the second strategy: that is detecting restoration opportunities by mapping barriers that strongly reduce movement potential. We define a barrier as a

landscape feature that impedes movement between ecologically important areas, the removal of which would increase the potential for movements between those areas. Here we are concerned with movements important for access to resources, demographic rescue, gene flow, range shifts, and other ecological and evolutionary processes. In this context, barriers are distinguished from features that are impermeable but not situated such that they block biologically relevant movement routes. Barriers are thus the inverse of corridors, which delineate pathways facilitating movement. Barriers can either be complete (impermeable) or partial (e.g., land cover types that hinder movement relative to ideal conditions, but may still provide some connectivity value). Barriers may be human-made (e.g., roads, fences, or urban areas) or natural (rivers or canyons); they may be linear (e.g., highways) or span large areas (agricultural fields). As with traditional connectivity concepts [1,24], what constitutes a barrier, the impact it has, and whether it reduces connectivity through behavioral inhibition, increased mortality, or other means will differ among species.

Detecting barriers to movement would complement traditional connectivity analyses in several important ways. First, some barriers may be restorable. Knowing where barriers have the greatest impact would help practitioners decide where and how to invest scarce conservation resources to conserve and enhance connectivity. For example, it may be cheaper to restore a barrier that blocks a movement corridor through public land than to establish permanent protection of a functioning corridor that runs through private land [25]. Quantifying such trade-offs would be necessary to integrate connectivity restoration into systematic conservation planning analyses aimed at optimizing conservation investments [26–28], but tools to incorporate connectivity conservation and/or restoration into such efforts remain rare [29–31]. Second, consider that corridor modeling often produces corridors that may not be good enough to realistically support movement [32]. Barrier detection analysis could reveal such cases, allowing practitioners to ‘triage’ a landscape, focusing efforts on more viable movement routes. Finally, surprising results in a barrier analysis could alert analysts to situations in which poor land cover data or incorrect model parameterization may be causing spurious results.

In this paper, we introduce a new method to identify barriers and rank them by their impact on connectivity. Our method complements existing connectivity modeling approaches, is applicable in least-cost and other connectivity modeling frameworks, and can be extended to centrality analyses. The method can be readily applied across large landscapes, efficiently analyzing barriers among many locations and at different scales corresponding to different sizes of barriers and types of restoration activities. It also quantifies the extent to which restoration can be expected to improve connectivity. We provide example applications of the method, showing that the potential for connectivity conservation is not constrained to narrow corridors, but includes options spanning much more of the landscape when restoration options are considered. We also discuss how our approach can facilitate sensitivity analyses, data quality screening, and prioritization of areas for error checking of GIS base data.

### Method for Detecting Barriers and Restoration Opportunities

Our method identifies areas that most reduce connectivity between two locations on a landscape. Making these areas permeable to movement would therefore most increase connectivity between the locations. Thus, these are areas that practition-

ers should consider when implementing restoration to promote connectivity.

To illustrate the method, we use a least-cost corridor modeling framework [13,14,32], which is commonly used to map and prioritize areas important for connectivity conservation (e.g., [8–12]). However, our approach could also be used with other modeling frameworks capable of producing measures of effective distance, such as circuit theory and individual-based movement models (see Discussion).

As with least-cost corridor models, input data include locations to be connected (hereafter, “patches”) and a raster resistance surface (Figure 1A). The former may consist of points or polygons, and typically represent natural landscape blocks, protected areas, or core habitat for a particular species or species guild [33]. The resistance surface represents the difficulty, energetic cost, or mortality risk associated with movement through each pixel (see [34] for a review of resistance surface development).

Least-cost methods calculate the cost-weighted distance (*CWD*) of all pixels to a source location, creating a raster of *CWD* values (Figures 1B and 1C). Adding together *CWD* rasters from two locations produces a corridor (Figure 1D), showing the pathways with the lowest cumulative movement cost between the locations [14]. The minimum value of the corridor raster is the least-cost distance (*LCD*); this represents the cumulative resistance encountered moving along the optimal path from one location to the other, and is a common measure of isolation in spatial ecology (e.g., [35,36]), landscape genetics (e.g., [37,38]), and related fields.

Our method is based on this simple assumption: if a certain area (the size is defined by the user) is restored such that the resistance across it is reduced, then the *LCD* of the best route connecting the patches through the restoration area will also be reduced. Systematically quantifying the potential reduction across a landscape will allow us to detect those areas where restoration would lead to the greatest reduction in least-cost distance.

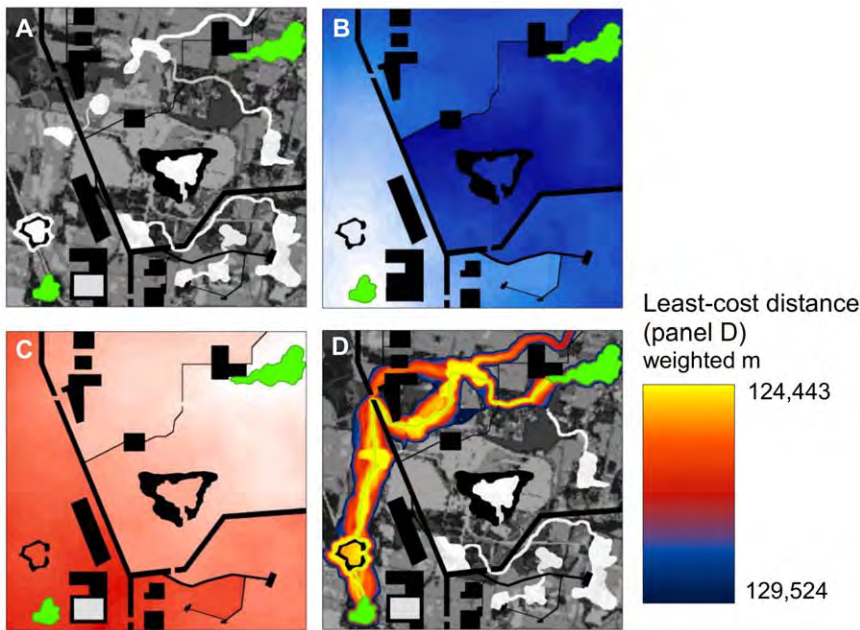

The method begins with *CWD* calculations from two patches (Figures 1B and 1C). However, rather than adding the two *CWD* surfaces together to produce a corridor, we instead calculate the minimum value of each *CWD* surface within a localized area around each pixel location (e.g., within a 500 m radius). We then add the minimum values from both *CWD* surfaces to calculate the cumulative resistance that would be incurred moving between the patches and through the focal pixel assuming the area within the search window is restored:

$$LCD' = CWD1_{MIN} + CWD2_{MIN} + (L * R'), \tag{1}$$

where *LCD'* is the least-cost distance of the best path between the patches passing through the focal pixel after barrier removal, *CWD<sub>X</sub><sub>MIN</sub>* is the minimum *CWD* value from patch *X* within the search window, *L* is the length of the longest axis of the search window, and *R'* is the resistance value of the feature replacing (or cutting through) the barrier. We use a circular moving window to illustrate the method (Figure 2), but consider alternative search window shapes in the Discussion. Note that the longest axis of a circle is its diameter.

For each pixel, this formula yields the cost of the best corridor that would pass through that pixel if the resistance of a strip of land crossing the search window were changed to *R'*. Including *R'* and the search window length accounts for the cost of moving across the search window, assuming restoration or removal of the intervening barrier.

If *LCD'* is less than *LCD*, then restoration across the moving window (e.g., the circle in Figure 2) would reduce effective distance and increase connectivity between the two patches. When this is

**Figure 1. Cost-weighted distance modeling.** (A) Example 3 km × 3 km landscape with a pixel size of 3 m (from [15]). Two habitat patches (green) are embedded in a matrix of land cover types with differing resistance to movement. Resistances range from 1 (white) to 100 (dark grey); complete barriers with infinite resistance (e.g., linear features representing roads and highways) are shown in black. (B) Cost-weighted distance (CWD) from leftmost patch, with darker shades representing higher cumulative resistance from the patch. (C) CWD from rightmost patch, with darker shades representing higher cumulative resistance from the patch. (D) Modeled least-cost corridor produced by adding CWD surfaces shown in panels B and C (best 20% of study area shown). The least-costly path (traced in green) has a cumulative least-cost distance (LCD) of 124,443 weighted meters. doi:10.1371/journal.pone.0052604.g001

**Figure 2. Detail of resistance and CWD surfaces with circular moving window.** For a window with a diameter of 60 m (20 pixels) centered on the barrier, the arrows show the pixels in the window that have the lowest CWD to each patch (values shown are in weighted meters). Because the lowest CWD values from each patch will always be found on the edge of a moving window, only pixels on the perimeter need to be examined, increasing processing efficiency. doi:10.1371/journal.pone.0052604.g002

the case, a simple metric of connectivity improvement that would result from restoration across the moving window is:

$$\Delta LCD = LCD - LCD' \quad (2)$$

Dividing  $\Delta LCD$  by the search diameter gives the connectivity benefit per unit distance restored; dividing  $\Delta LCD$  by  $LCD$  gives the proportional improvement relative to unrestored effective distance.

To illustrate the method, we first apply it to the relatively simple landscape described in Figure 1 using a search window with a diameter of 60 m (20 pixels at 3 m resolution; Figure 2). The search window size is chosen to match the size of the barrier that one is interested in detecting: a diameter of 20 pixels will fully incorporate effects of barriers up to 20 pixels across. We assign a resistance of 1 to optimal movement habitat, so that the cumulative cost of movement is identical to the Euclidean distance traversed when no barriers are encountered. For the circular window centered on the highway in Figure 2, the lowest  $CWD$  values from the left and right patches are 36,719 and 41,724 weighted meters, respectively. Summing these values and adding 60 (the cost of crossing the circle if it were restored to optimal movement habitat with a resistance of 1), gives the least-cost distance of the path crossing through the restored area (36,719+41,724+60 = 78,503 weighted meters). Since this is considerably lower than the least-cost distance between the patches without restoration (124,443 weighted meters), this location is a potent barrier, and the center pixel is assigned an improvement value of 45,940 weighted meters. This is repeated for every pixel on the landscape using standard GIS neighborhood analyses, resulting in a raster surface of improvement scores (Figure 3A).

The removal of the barrier where the improvement score is maximal – for example, by constructing a wildlife crossing structure – would re-route the best movement path (Figure 3B) and lower the effective distance between the two patches by 37% (45,940/124,443). Once that improvement is carried out, a second barrier analysis with the altered landscape conditions suggests that additional restorations along the highway will not further reduce the  $LCD$  at this point (Figure 3C). The next priority would be a road crossing in the upper right of the panel (dark orange in Figure 3C), connecting the rightmost patch to high-quality movement habitat above the road. The method is computationally efficient enough that different restoration scenarios can be tested iteratively: a barrier analysis with a 20-pixel search diameter across a landscape with 1 million pixels takes less than 2 seconds using a 2.7 GHz notebook computer.

### Identifying barriers across scales and across large landscapes with multiple patches

The method described above can be extended across scales and across networks of patches, and we explore a few approaches to accomplish this here. By modifying the search diameter, the method can detect barriers of different sizes (Figure 4). Windows the width of a highway will best highlight where highways act as barriers, as in Figures 2 and 3. Larger windows will best detect barriers like agricultural fields, or cases in which narrow barriers run parallel to one another. Summary maps showing barrier effects across search window sizes may be created by first dividing improvement scores by the window size to produce maps of barrier strength per unit width, and then taking the maximum pixel score across scales (Figure 4B). This puts results from different analysis scales in the same units, allowing them to be

summarized in a single map. Alternative summary metrics are possible, and we address some of them in the Discussion.

To summarize across multiple sets of patch pairs, we have implemented a similar approach in which the maximum or sum of improvement scores across all patch pairs is assigned to a pixel. Taking the maximum of improvement scores shows the features that have the greatest effect for any patch pair (Figure 4C). Summing improvement scores highlights those barriers that isolate multiple pairs of patches from one another, extending the method to quantify barrier centrality (Figure 4D).

The methods described in this paper have been implemented in Barrier Mapper software [39], freely available as a new addition to the Linkage Mapper Toolkit for ArcGIS [40].

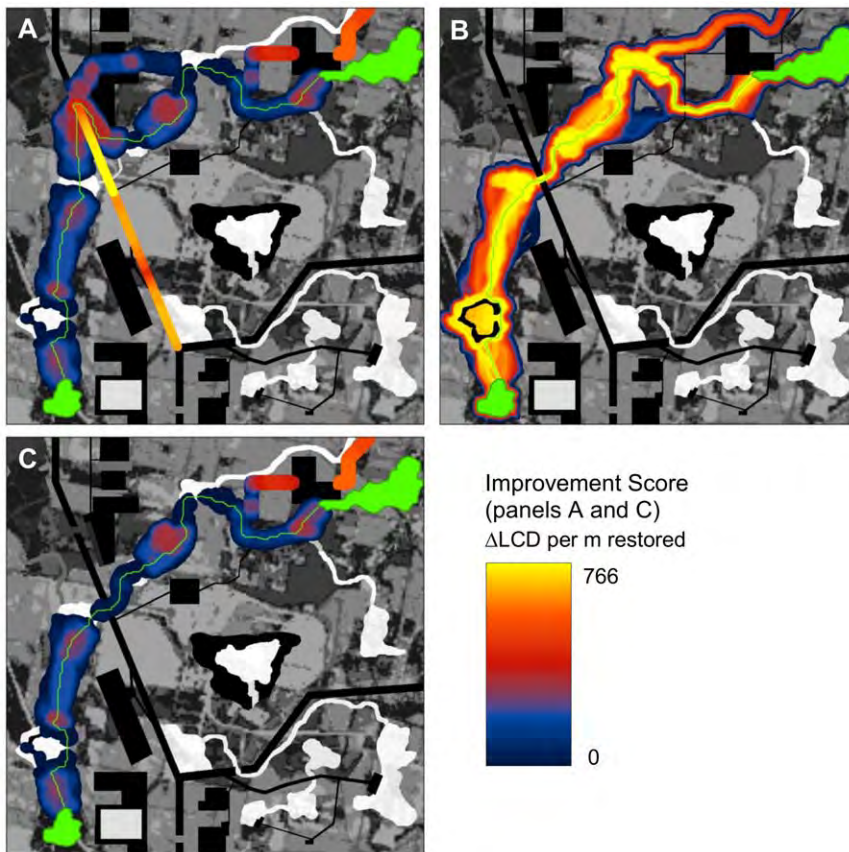

### Example application in a landscape undergoing active conservation planning

The Washington Wildlife Habitat Connectivity Working Group, a collaboration of land and resource management agencies, non-governmental organizations (NGOs), universities, and Washington treaty tribes, recently completed a connectivity analysis across the Columbia Plateau Ecoregion in Washington, Oregon, and Idaho, USA [41]. The Working Group focused on the Columbia Plateau because the ecoregion is home to a large portion of Washington's sensitive plant and animal species but is also highly fragmented by agriculture and other anthropogenic activities. The Group modeled corridors to connect habitat for 11 focal species and also to connect natural landscape blocks scoring highly on an index of landscape integrity (i.e., large areas with relatively low levels human modification). Products from the analysis are being used to inform conservation planning efforts by several state and federal agencies and NGOs. Many of the corridors identified by the analysis pass through human-dominated landscapes, where roads, agricultural fields, and other human uses likely still act as barriers to movement.

We reanalyzed results for a corridor connecting two natural landscape blocks identified by the Working Group in Douglas County, Washington (Figure 5). We chose these blocks because they have been identified as important for many species of concern; for example, the blocks contain important habitat or corridors for 8 of 11 focal species analyzed by the Working Group. Moreover, both are occupied by greater sage-grouse (*Centrocercus urophasianus*, categorized as a Species of Greatest Conservation Need in Washington and a candidate for listing under the US Endangered Species Act), and both fall within a recovery area designated for the species by Washington State [42]. In addition, this landscape contains a complex mix of native systems and agricultural lands – the latter including both annual cropland and perennial vegetation cover – and includes roads, transmission lines, and other human-made features affecting animal movement [41].

To represent species with differing degrees of sensitivity to human modification, the Working Group used different resistance surfaces for landscape integrity analyses [41]. These surfaces all contained resistance values that increased with the degrees of human modification, differing only in the range of resistances assigned. Resistance scores of 1–100, 1–1000, and 1–10,000 were used for minimum, medium, and maximum sensitivity surfaces respectively (see [41] for details). We present results from a barrier analysis using the medium sensitivity resistance surface.

The modeled least-cost corridor connecting the patches dips south from the western patch, runs east to Banks Lake, and then north along a narrow strip of native vegetation and cliffs sitting between the lake and cropland (Figure 6A). A secondary and much longer corridor follows broad swaths of native vegetation through

**Figure 3. Barrier analysis of landscape.** (A) Improvement scores ( $\Delta LCD$ ) for a 60 m search diameter using an enhanced version of Linkage Mapper software ([40]). Only positive values (indicating barriers whose removal would reduce isolation) are shown. To facilitate visualization of the barriers, scores were mapped so that they filled the search window (i.e. the maximum  $\Delta LCD$  value within the search radius of each pixel is displayed). The greatest improvement potential was detected crossing the highway. Note that a natural corridor is bisected by the highway at the point with the highest improvement potential (see detail in Figure 2). (B) Creating a new gap in the barrier where restoration potential is highest re-routes the modeled least-cost corridor and greatly reduces resistance between the patches ( $LCD = 78,503$  weighted meters compared with an  $LCD$  of 124,443 pre-restoration). Best 20% of study area shown. (C) Barrier detection at 60 m search diameter after restoration. doi:10.1371/journal.pone.0052604.g003

Moses Coulee and Beezley Hills to the south. A barrier analysis indicates numerous opportunities for improving the least-cost corridor, particularly within its east-west segment (Figure 6B). There are also opportunities outside of the main corridor, occurring along the longer route to the south and to the north as well (Figure 6B). Restoring any of these latter areas would re-route the modeled least-cost corridor, causing it to occur in a different location than it did in the unrestored landscape.

Restoration of any of several barriers identified to the south would improve connectivity as measured by  $LCD$  (Figure 6B); however, this would result in a much longer least-cost corridor. Restoration to the north has the potential to both improve  $LCD$  and shorten the distance traversed by the corridor. We simulated a restoration by changing a  $1 \text{ km}^2$  ( $500 \text{ m} \times 2 \text{ km}$ ) swath of agricultural land (indicated by the arrow in Figure 6B) to a resistance of 1. We chose 2 km because the greatest improvement was detected at the 2 km scale, and we assumed 500 m was wide enough to accommodate movement. A second corridor analysis following the simulated restoration shows the new corridor to the north (Figure 6C). The corridor has 9.4% less cumulative resistance than the original (1348 weighted km vs. 1489 weighted km), and its least-cost path is 44% shorter in un-weighted length. A post-restoration barrier analysis indicates that the highest improvement scores now fall along the new corridor (Figure 6D);

restoring a second  $1 \text{ km}^2$  swath in this new corridor at the point indicated by the arrow would further reduce  $LCD$  by 50%.

### Discussion

Connectivity models have provided valuable guidance to conservation planning efforts, as well as predictions of movement, gene flow, and isolation important to landscape genetics and other fields concerned with movement ecology. Yet they have almost exclusively emphasized identifying features that facilitate, rather than impede, movement; this emphasis gives an incomplete picture of how landscape features affect connectivity, what connectivity management strategies might be appropriate, and the uncertainty underlying model predictions. We see considerable potential for barrier detection analyses to help practitioners overcome these limitations. In particular, the ability to identify restoration opportunities can provide valuable alternatives to traditional conservation efforts focused on existing movement corridors.

Our reanalysis of the Columbia Plateau data (Figure 6) illustrates these points, showing how detecting barriers can increase conservation options available to practitioners, improve understanding of analysis products, and result in more robust conservation plans. Without a barrier analysis, conservation

**Figure 4. Barrier analyses integrating across multiple scales and patch pairs.** (A) Results of barrier analysis with original patch pair at 12 m search diameter, which detects restoration opportunities equal to or less than 12 m across (e.g., local roads). (B) Maximum per-meter improvement value across 10 search window sizes (from 6 m to 60 m, with 6 m steps between search diameters). The map highlights where actions at different scales would have highest impact per meter restored. (C) Maximum per-meter improvement value across same window sizes and 5 patches, showing where greatest improvement could be achieved for any single pair of patches. (D) Sum of improvement scores among 5 patches (green). As in Panels A–C, the maximum per-meter improvement score was calculated for each patch pair at each scale. These were then summed across patch pairs to incorporate cumulative benefit for multiple patch pairs across multiple scales. The area scoring highest (bright yellow) had high improvement scores for multiple patch pairs; we interpret this area as having high ‘barrier centrality,’ i.e. being an important restoration opportunity for keeping the overall network connected. Note that the area occurs at a road intersection; if practical, placing a wildlife crossing structure here would re-route four corridors connecting the two leftmost patches to both the central and upper-right patch. doi:10.1371/journal.pone.0052604.g004

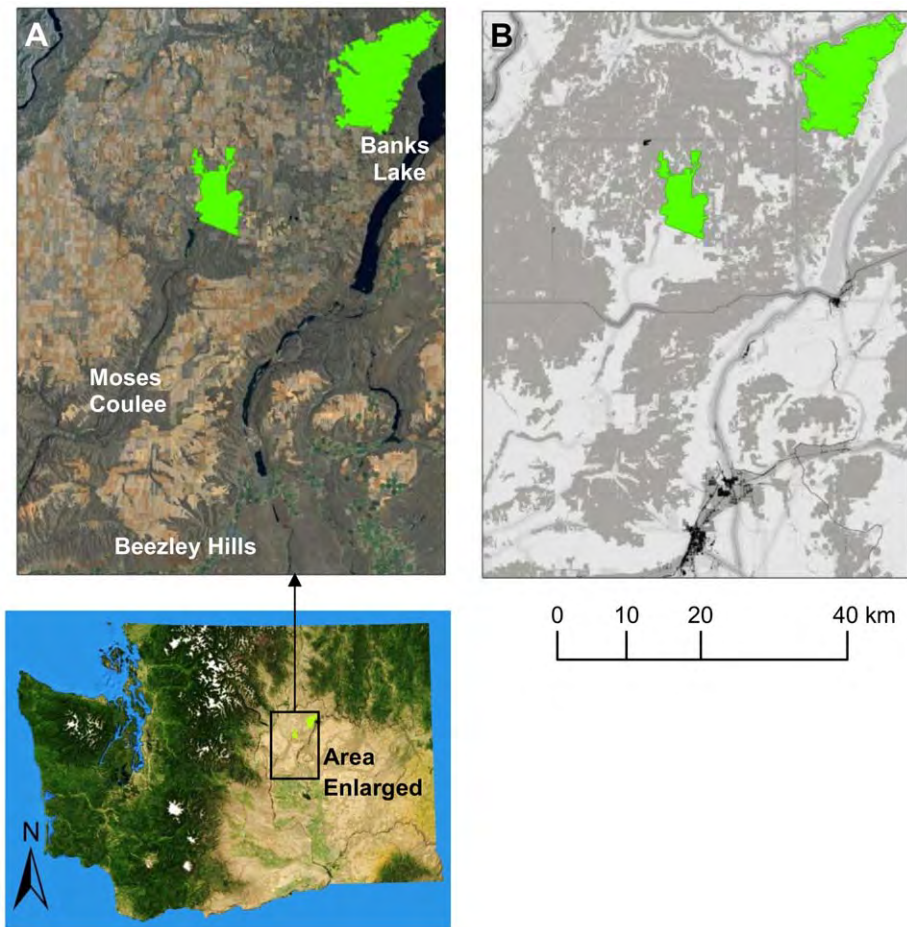

planners would likely have focused on conserving land in or adjacent to the original least-cost corridor. Our analysis revealed numerous opportunities to improve this corridor, but also that restoration of a 1 km<sup>2</sup> swath of cropland would create a new corridor with several desirable characteristics. Specifically, the new corridor has a lower least-cost distance, is shorter in length, and appears to have fewer pinch-points (narrow sections) than the original corridor—all desirable characteristics for corridor design [15,32]. Moreover, if the two original corridors remain in place, the new, northern corridor adds redundancy to connections between the natural landscape blocks. This is important because organisms seldom follow a single optimal path [43], and because redundant connections help to ensure continued connectivity in the face of unpredictable environmental changes [15].

The analysis showed that connectivity conservation options need not be limited to a small portion of the landscape, opening up much more area for actions that could conserve or enhance connectivity and illustrating tradeoffs between different conservation strategies and target locations. Beyond the corridor quality differences cited above, we note that the original corridor runs along a narrow stretch of land bordering Banks Lake, sometimes

traversing cliffs. The cliffs were assigned low resistance because the landscape integrity model used by the Working Group only quantified the degree to which pixels have been converted to human land uses. Practitioners, however, may consider cliffs to be impermeable for some species of conservation concern. The barrier analysis allows the user to quickly focus a more critical examination of corridor characteristics on areas influencing the results, and to identify options for alternative corridors that may better fit specific planning needs.

Similarly, the analysis underscored the potential sensitivity of corridor mapping to errors in GIS base data: our results show how the misclassification of a single agricultural field could have entirely altered the location of the original least-cost corridor shown in Figure 6A. The sensitivity of connectivity analysis results to landscape features at key locations has consequences for disciplines that depend on corridor maps (like conservation planning) and for disciplines that depend on connectivity measures (like landscape genetics). We discuss applicability of barrier detection methods to sensitivity analysis and error checking below.

Following the first barrier analysis and simulated restoration, a subsequent barrier analysis indicated that the restoration would

**Figure 5. Corridor analysis in a landscape undergoing active conservation planning.** (A) 60 km by 80 km study area in eastern Washington, USA, containing two natural landscape blocks to be connected (green). (B) Resistance map used to model corridors in a recent multi-partner connectivity analysis across the Columbia Plateau Ecoregion [41]; values range from 1 (white) to 1000 (black). Low resistance areas include native grassland and shrub-steppe, whereas high resistance areas include roads, developed areas, and agriculture.  
doi:10.1371/journal.pone.0052604.g005

open up further restoration opportunities of considerable value, one of which would cut *LCD* values by half. Thus, simulating restorations and re-running corridor and barrier analyses will likely improve final conservation and restoration plans.

Although we are aware of no other efforts to automate identification of terrestrial connectivity restoration opportunities, least-cost corridor analyses have been used to guide placement of crossing structures across roads to restore connectivity for wildlife. For example, Beier et al. [44] assigned a single, finite resistance value to all segments of a highway between two protected areas, regardless of whether a segment contained wildlife crossing structures. The least-cost corridor between the areas crossed the highway at the location where a crossing structure would result in the lowest ecological cost of travel. If highway crossing structures were not located in this corridor, Beier et al. [44] recommended specific structures at particular locations. This approach is useful, but does not quantify the improvement compared to existing conditions, does not identify restoration opportunities outside of least-cost corridors, and cannot be readily applied to barriers more complex than roads.

In addition to overcoming these limitations, our method is also amenable to highlighting barriers that affect multiple corridors, introducing the concept of barrier centrality. As shown in Figure 4, barriers can be mapped across all patch pairs, and the results

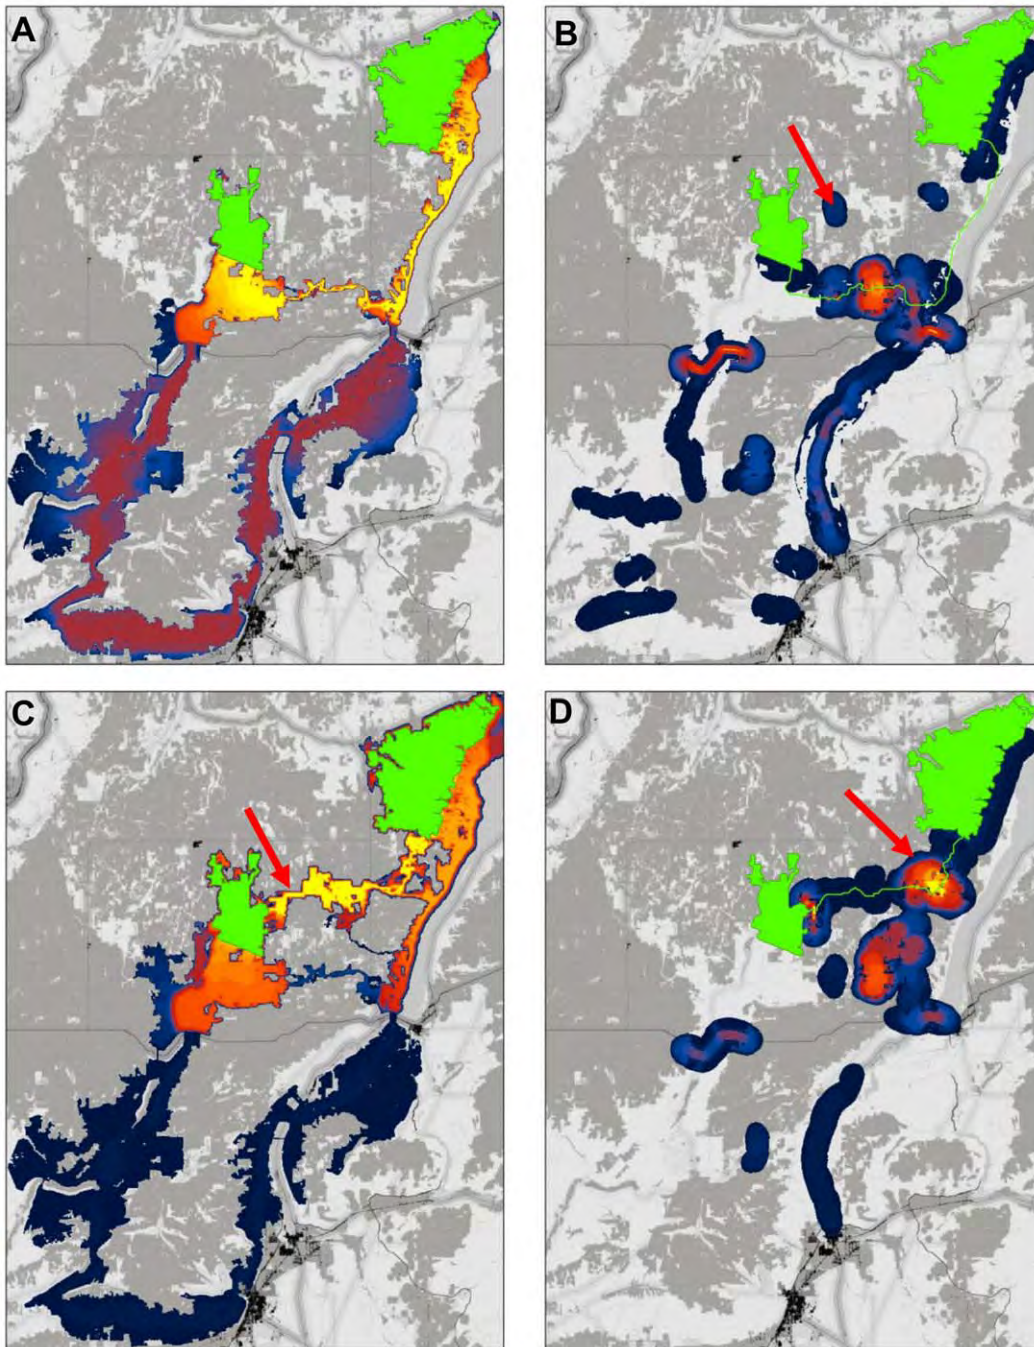

summed. This identifies barriers with high network centrality, similar to analyses that identify corridors or pathways with high centrality [21,22,45,46].

#### Applications for error checking and sensitivity analyses

GIS land cover data used to develop resistance layers for connectivity analyses are typically based on satellite or aerial imagery and often suffer from high levels of classification error [34,47]. Although our method relies on these same base data, it can help to prioritize error checking of the data by highlighting mapped features that strongly influence corridor locations. If a permeable feature is misclassified as impermeable and identified as a barrier, the misclassification could entirely alter a corridor's location. We recommend examining detected barriers, either by manually checking aerial imagery or conducting field surveys. Similarly, impermeable features misclassified as permeable that occur along least-cost paths can change corridor locations as well. Examining features along least-cost paths in tandem with barriers could thus further reduce the effects of classification error in connectivity analysis products.

Barrier detection can also be applied to parameter sensitivity analyses, important because resistances are often assigned based on expert opinion, which can be unreliable [34,47,48]. For example, if a given land cover type fell along a corridor's least-cost

**Figure 6. Reanalysis of connectivity modeling results using barrier detection algorithm.** (A) Corridor connecting natural landscape blocks, showing least-cost movement routes. Best 20% of study area shown. (B) Barriers detected at diameters from 200 m to 2 km, with original least-cost path shown in green for reference. Mitigating barriers along the least-cost path (i.e., intersecting the green line) would improve the existing corridor without changing its location; mitigating barriers away from the path would re-route the best modeled corridor. (C) Restoring a 1 km<sup>2</sup> (500 m × 2 km) swath spanning the barrier indicated by the arrow establishes a new least-cost corridor to the North. (D) A barrier analysis incorporating the simulated restoration indicates opportunities to substantially improve the new corridor with additional restorations.  
doi:10.1371/journal.pone.0052604.g006

path or encompassed an influential barrier outside of the corridor, the resistance assigned to that land cover type would be known to influence the corridor's location. The sensitivity of the corridor's location to the resistance value assigned the land cover type could then be analyzed using alternative parameterization methods as described by Beier et al. [47]. As with connectivity models, our method will depend on the grain size of the resistance raster; to

adequately resolve features that potentially impede movement, we recommend pixels no larger than  $\frac{1}{2}$  the width of barriers one is interested in detecting.

#### Potential enhancements

**Directionality of barrier effects.** Our methods could be improved to more precisely pinpoint barriers. For example,

elongated moving windows (search polygons) could perform better than circles to identify the best path for an improved corridor design. Measuring  $ALCD$  along elongate polygons placed at different angles, although more computationally complex than measuring across circles, would allow the attribution of directionality to barrier effects as well as adjustment of improvement scores at large search distances to reflect improvement achievable at smaller (nested) distances. New procedures to select the best orientation and width of such polygons could obviate the need to subjectively orient restoration polygons, like the 500 m $\times$ 2 km polygon in our simulated restoration (Figure 6).

**Restoration cost.** We measured barrier strength by conservation improvement per meter restored because it was the simplest way to illustrate our approach. An alternative metric would be conservation improvement per restoration dollar; this would reflect, for example, that the cost per meter of a 10 m road crossing structure exceeds the cost per meter of a 50 m crossing structure, which in turn exceeds the cost per meter of restoring agricultural land. This enhancement would facilitate incorporation of connectivity restoration into return-on-investment analyses [49,50], helping managers to balance improvement potential, corridor importance, costs, and risk of conversion or degradation when deciding which parts of a landscape should be conserved or restored. The disadvantage, or course, is that this metric would require more data to calculate.

**Restoration efficacy.** Different  $R'$  resistance values could be applied to different land cover types to reflect the fact that some barriers would be more permeable to movement following restoration than others. For example, a highway underpass installed to allow animal movement may still have considerable resistance, whereas a restored forest stand may have resistance similar to undisturbed forest.

**Other enhancements.** Just as areas that cannot be conserved can be removed from reserve selection algorithms [51], unremovable barriers, such as urban areas, could be excluded from barrier analyses. The metrics described in equation (2) could be modified to incorporate restoration costs that vary by feature type, or land prices mapped using parcel data. Metrics of corridor importance (e.g., link centrality) could be integrated by multiplying improvement scores by such metrics, which would highlight opportunities to restore the most potent barriers in the most important corridors. Or, rather than focusing on pairs of patches, the method could be altered to focus on the connectedness of each patch by summing barriers detected between each patch and all others. Lastly, improvement scores may be expressed in terms of absolute improvement or percent improvement relative to unrestored corridor resistance. An advantage of the latter approach is that it would favor restoration in corridors in which  $LCD$  values are already low, presumably meaning they are more viable.

Which of these enhancements are most valuable will depend on the objectives of individual users and projects.

### Application in other connectivity modeling frameworks

Although least-cost corridor models are by far the most commonly applied connectivity planning tool, they rely on simple assumptions about animal movement and other processes [43,48,52,53]. However, our approach can be applied in any connectivity modeling framework that produces measures of effective distance. For example, circuit-based connectivity analyses can model the relative proximity of each pixel to two patches by setting the voltage of one patch to 1 and the other to ground (see [15] for details on applying circuit modeling to landscapes). The resulting voltage surface gives the probability that a random

walker will reach one patch before reaching the other [15,54]. Strong gradients in voltage indicate barriers that separate areas relatively accessible to one patch from areas relatively accessible to the other. If removed, such barriers would reduce effective resistance between the patches, an analog to  $LCD$  that takes into account the availability of multiple, parallel connections. A similar approach is widely used in microchip design: simulated voltage levels reveal areas with strong voltage gradients (known as IR drops) where electrical connectivity must be enhanced [55]. Thus barrier analysis using circuit theory can identify opportunities to provide valuable redundant connections even when  $LCD$  would not be reduced. In contrast, barrier analysis using least-cost methods will not identify these opportunities.

Individual-based movement models provide a more complex but also more powerful framework for modeling connectivity, capable of incorporating more biological realism and behavioral information than least-cost or circuit analyses [56]. As long as an individual-based model can produce maps of effective distance (e.g., based on the probability of, or energetic expenditure associated with, reaching different locations from a source patch), the approach described here could be applied to the model. Models such as PATH [16] and HexSim [17] can be used to derive such measures.

### Potential for integration with systematic conservation planning

Our method is not a substitute for algorithms like Marxan [57] or Zonation [51], which are designed to optimize selection of reserves or sets of conservation actions. Although our method identifies and ranks candidate areas for restoration actions, it does not select optimal *sets* or portfolios of conservation actions to achieve given conservation goals while minimizing cost. The same can be said for algorithms designed to map areas that most facilitate movement and connectivity (e.g., [22,40,46,58–60]); rather than incorporating optimization routines, such algorithms instead produce maps that must be interpreted by practitioners, who then make conservation decisions in light of costs, benefits, and other management objectives.

Although it has long been recognized as important to reserve network design [61], incorporating connectivity directly into optimization algorithms has proven difficult. Most such efforts can be characterized as minimizing local fragmentation by either considering the geographic proximity of candidate areas to other areas (e.g., [62–64]) or maximizing the compactness and contiguity of reserves by favoring selection of adjacent cells or using boundary quality or length penalties (e.g., [29,57,65,66]). Because these algorithms favor conserving or restoring contiguous natural areas, they may neglect areas that, although fragmented, contribute to connectivity between natural areas. Thus, relying solely on maximizing the proximity or contiguity of protected areas could lead to elimination of movement routes that cross human-dominated landscapes.

Progress toward synthesizing connectivity and optimization algorithms has likely been hampered by the ‘network’ nature of connectivity planning: conservation in one area can affect the function and value of distant areas, contingent upon the conservation status and characteristics of the intervening landscape. Incorporating this complexity into optimization algorithms becomes computationally prohibitive with large numbers of planning units [67]. Still, practitioners are beginning to use outputs of multi-species connectivity models as inputs to optimization algorithms like Zonation [23,68]. Such examples are promising, and should be equally applicable with restoration-oriented algorithms such as ours.

An alternative to our approach that would seek to develop a near-optimal set of conservation actions would be to employ a routine similar to that used by Zonation software, which begins with an intact landscape and iteratively removes grid cells with low conservation value [51,69]. Starting with a landscape in which all restorable barriers have been removed, different sets of barriers could be added back in and connectivity metrics recalculated at each iteration. As with traditional connectivity models, however, this would be computationally prohibitive with large numbers of patches or restoration sites because of the computational time required for recalculating connectivity metrics. A promising hybrid approach could be to use the method described in this paper to identify sets of pre-screened restoration opportunities, which could then be removed from a resistance surface and added back in using an algorithm like Zonation's.

### Practical considerations for improving conservation and restoration decisions

Managing for connectivity to facilitate gene flow, climate adaptation, and other processes is challenging without reliable maps to guide practitioners [33]. Connectivity analyses have provided valuable implementation guidance in the past; barrier mapping can increase the rigor of such analyses and the range of conservation options they reveal. It can help practitioners a) decide if connectivity conservation is a worthy investment in a landscape; b) identify opportunities to restore vs. conserve different areas; c) reduce uncertainty due to errors in GIS base data; and d) balance potential improvement against costs so that investments can be prioritized.

The goals of managers and planners can be used to guide applications of barrier detection methods. For example, if a transportation agency is interested in determining which highway segments are likely to have the greatest impact on wildlife movement, the search window should correspond to the width of highways, with outputs clipped to highways and the  $R'$  value determined based on the estimated resistance of the kind of crossing structure (or alternative structures) being considered. If a land management agency is prioritizing restoration of degraded native vegetation, the search window should relate to the size of appropriate restoration projects, and outputs should be clipped to the eligible land base (e.g., limited to the type of vegetation the restoration would target). If an NGO is identifying landowners interested in obtaining voluntary incentive payments for wildlife-friendly management, the window should reflect the scale of such management. Summarizing barrier analyses across multiple scales will be desirable for collaborations among organizations with differing goals and mandates. As noted above, iterative application of the model with simulated restorations will likely provide the most informative results and most robust conservation plans.

Similarly, the method may have potential to help adapt results from coarse-filter connectivity assessments, such as landscape integrity/human modification-based connectivity maps, to more

fine-filter objectives (see [70] for a review of coarse- and fine-filter conservation planning). Alternative corridors revealed by the method could be assessed for their suitability under different planning constraints (e.g., corridors for species that must avoid cliffs, as in the Columbia Plateau example). While not a replacement for species-specific connectivity analyses, such an approach could help land managers evaluate alternatives if a mapped corridor is deemed unsuitable for their particular needs.

Connectivity maps do not always identify functioning routes that need to be maintained and protected; rather, they frequently map routes that may not be currently viable, but appear to provide the best opportunities for future work toward enhancing connectivity. In this sense connectivity maps often represent visions and goals for desired future conditions [71]. Barrier detection can add insight into the practicality of these goals, and identify specific options for achieving them. It can also help practitioners to 'triage' a connectivity plan, identifying corridors that traverse numerous barriers – and therefore would require significant investment to fully restore – so that efforts may be focused on more viable movement routes.

Perhaps most importantly, the ability to detect options to re-route corridors also opens up a broader suite of potential actions to improve connectivity. It can help managers identify new corridors that add additional movement pathways in areas important to the overall connectivity of a landscape (i.e. linkages with high centrality). Combined with spatially explicit land cost data, the method could help to improve conservation efficacy while reducing costs.

We hope barrier analyses will expand conservation options available to managers, and broaden conversations about restoration of connectivity more generally. By identifying new ways to improve connectivity in a particular area, the method can allow managers to consider different suites of strategies, or engage with new sets of stakeholders with interests in different areas. Both from the perspective of entities mandated to carry out conservation actions, and from the perspective of stakeholders with interests in the lands that are the focus of such actions, broadening the suite of alternatives and tools can only increase the opportunities for finding common ground in pursuit of multiple objectives.

### Acknowledgments

We are grateful to the Washington Wildlife Habitat Connectivity Working Group for making data used in this manuscript publicly available. We also thank Theresa Nogeire, Adina Merenlender, and two anonymous reviewers for comments on early drafts.

### Author Contributions

Conceived and designed the experiments: BHM. Performed the experiments: BHM. Analyzed the data: BHM. Contributed reagents/materials/analysis tools: BHM. Wrote the paper: BHM SAH PB DMT. Suggested refinements to methods and analyses: SAH, PB, DMT.

## IMPROVING THE SUCCESS OF WETLAND CREATION AND RESTORATION WITH KNOW-HOW, TIME, AND SELF-DESIGN<sup>1,2</sup>

WILLIAM J. MITSCH AND RENÉE F. WILSON

*School of Natural Resources and Environmental Science Program, The Ohio State University, 2021 Coffey Road, Columbus, Ohio 43210 USA*

**Abstract.** The creation and restoration of new wetlands for mitigation of lost wetland habitat is a newly developing science/technology that is still seeking to define and achieve success of these wetlands. Fundamental requirements for achieving success of wetland creation and restoration projects are: understanding wetland function; giving the system time; and allowing for the self-designing capacity of nature. Mitigation projects involving freshwater marshes should require enough time, closer to 15–20 yr than 5 yr, to judge the success or lack thereof. Restoration and creation of forested wetlands, coastal wetlands, or peatlands may require even more time. Ecosystem-level research and ecosystem modelling development may provide guidance on when created and restored wetlands can be expected to comply with criteria that measure their success. Full-scale experimentation is now beginning to increase our understanding of wetland function at the larger spatial scales and longer time scales than those of most ecological experiments. Predictive ecological modelling may enable ecologists to estimate how long it will take the mitigation wetland to achieve steady state.

**Key words:** *achieving successful wetland mitigation; creating wetlands; ecological engineering; ecological modelling; freshwater marshes; functional analysis of wetlands; mitigation of wetland loss; Olentangy River Wetland Research Park, Ohio; wetland succession.*

### INTRODUCTION

The way in which we measure “success” of created or restored wetlands and our ability to achieve success are two issues that have come under increased discussion in recent years by wetland scientists and managers. Success in the general sense here means the establishment of a biologically viable and sustainable wetland ecosystem. Some call a wetland a success when it replaces the functions lost in a wetland that is being replaced; others would gauge success of a created or restored wetland against natural reference wetlands in the region. Unfortunately, there has been little formal published follow-up of the poorly named (see Renner 1994) “mitigation wetlands” that are constructed to replace wetlands that are unavoidably lost and there are few satisfactory methods for assessing replacement of the functions lost with the original wetland (Mitsch and Gosselink 1993). Regulators and consultants have chosen to use simple indicators of “success” to expedite the process and to keep monitoring costs low. Normally 3–5 yr of simple once- or twice-per-year monitoring is required, with easily measured parameters such as plant lists, animals witnessed, and percentage vegetation cover as the overall indicators. Assessing success is then based on comparing these easily measured parameters with a relatively simple set of criteria that were stipulated in the original permit for

the project; these criteria may or may not accurately reflect wetland function.

After reviewing pertinent literature, we discuss three fundamental requirements for achieving success of wetland creation and restoration projects: understanding wetland function, giving the system time, and appreciating the idea of self-design. Our hypothesis is that most attempts to measure and achieve success of created and restored wetlands—caused by a lack of application of good wetland science to the problem and compounded by the existing construction-schedule-driven process—are flawed because of misunderstanding or misapplication of these factors. We then argue that ecosystem-level research and ecosystem modelling may provide better guidance on when created and restored wetlands can be expected to comply with criteria that measure their success.

### STUDIES ON WETLAND MITIGATION SUCCESS

Most studies suggest that there is much room for improvement in the building of wetlands. Maguire (1985) used area, vegetative cover, and implementation of permit conditions to estimate mitigation success in Virginia and found that only 50% of 23 mitigation wetlands were “successful.” In most unsuccessful cases, the mitigation project had not been implemented. An additional study by Reimold and Cobler (1985) conducted for the U.S. Environmental Protection Agency (EPA) gave similar results. Glubiak et al. (1986) and Quammen (1986) both suggested the need for better management of mitigation wetlands. Additionally Glubiak et al. (1986) predicted that while the protection

<sup>1</sup> Manuscript received 10 June 1994; revised 3 April 1995; accepted 12 April 1995.

<sup>2</sup> For reprints of this group of papers on wetland mitigation, see footnote 2, page 33.

of wetlands through a permit process—Section 404 of the Clean Water Act enacted by the U.S. Congress in 1972—was somewhat effective, it would not prevent wetland area losses as effectively as it should.

In the mid-1980s some scientists involved in wetland restoration and mitigation believed that mitigation was working (Harvey and Josselyn 1986), while others suggested that more research needed to be done and that, if not properly conducted, a wetlands mitigation project could easily fail (Race 1986). Kusler and Groman (1986) raised concerns about the granting of Section 404 permits to contractors when alternative sites are available. Many questions and issues were raised by Kusler and Groman (1986) and Golet (1986) regarding permitting processes and the actual success of wetland mitigation projects. Their major issues were: When should destruction/damage and subsequent creation/restoration be permitted? How is the damage to the original system measured and how is the creation/restoration deemed sufficient? Golet (1986) suggested that under no circumstances should damage to a wetland be allowed unless there is absolutely no alternative.

While there are many factors that could be used to monitor progress of mitigation wetlands, observing vegetation has often been the easiest and probably the most common method (see, e.g., Wentworth et al. 1988, Jarman et al. 1991, Atkinson et al. 1993). This concept has already been codified in several parts of the country. For example, in Massachusetts, vegetation cover of  $\geq 75\%$  is the major success criterion, even if vegetation composition is very different from that of the original wetland (Jarman et al. 1991). Reinartz and Warne (1993) argue that while vegetation cover may be an easy measure of success, it is a poor indicator of function.

Recent investigations of wetland mitigation projects, as a greater number of mitigation sites have become available for scrutiny, generally reinforce the early concerns. For example, Erwin (1991) found that, of 40 mitigation projects in south Florida involving wetland creation and restoration, only about half of the required 430 ha of wetlands had been constructed and that 24 of the 40 projects (60%) were judged to be incomplete or failures. The most significant problems identified with created wetlands were improper water levels and hydroperiod. Sifneos et al. (1992) collected information from permits on Louisiana, Alabama, and Mississippi wetland mitigation projects and found that in Louisiana (their primary area of interest) only 8% of areas impacted by dredge-and-fill activity was compensated for, and  $>50\%$  of the areas receiving permits covered  $<0.4$  ha. Additionally, only 10% of the mitigation wetlands were monitored by at least one site visit. The lack of standardized record-keeping from state to state made the study difficult. The study suggests that follow-up monitoring and information on wetland functions be required in future permit decisions. Kentula et al. (1992) investigated several mitigation wetlands in Or-

egon and Washington and found a net loss in wetland area of 43% for Oregon and 26% for Washington. Data were either incomplete or of poor quality and up-to-date standardized databases were recommended. In a similar study, but without field checks, Holland and Kentula (1992) examined  $>300$  Section 404 permits issued in California from 1971 to 1987 and found that while 1260 ha of compensatory mitigation (wetland creation, restoration, or preservation) had been required for impacts to 1180 ha of wetlands over that period, there was little follow-up of the permits and fewer than one-third (31.5%) required any field monitoring. Confer and Niering (1992) found that when comparing five created freshwater marshes with five nearby natural ones, the created marshes generally had greater water depth and thus more open water. They state that most of their created wetlands were highly dependent on highway runoff as a water source. Roberts (1993), quoting several ecologists, summarizes the skepticism by calling wetland trading “a loser’s game.”

#### IMPROVING THE ODDS OF WETLAND SUCCESS

We propose three general concepts that will need attention of those involved in wetland mitigation if we are truly going to address the issue of creating and restoring viable wetland ecosystems: (1) Understand wetland function; (2) Give the system time; and (3) Allow for the self-designing capacity of nature. These points are discussed in detail below.

##### *Understand wetland function*

Mitsch and Cronk (1992) proposed that the “know-how” of building and restoring wetlands is based on an empiricism with little scientific backing, and is learned and relearned every time a new wetland is built. Wetland restoration and creation are relatively new fields and few engineers are trained in ecology and few ecologists have any experience in engineering methods. Engineers, consultants, scientists, and landscape architects can, and frequently do, claim to be experts with little experience or little knowledge of wetland ecology; without any certification standards for individuals involved in wetland creation and restoration, projects are often carried out by organizations and individuals not well versed in wetland ecology. A relatively high number of “failures” of mitigation wetlands can be attributed to a general lack of understanding of first principles of wetland science.

For example, an understanding of wetland hydrology as the fundamental forcing function of wetlands is well understood conceptually (Mitsch and Gosselink 1993) yet not always put into practice by many of those involved in wetland mitigation. The importance of hydrology is discussed in detail in a companion paper by Bedford (1996). Erwin (1991) pointed out that a number of Florida wetlands were considered failures in his Florida study because they lacked suitable hydrology. In so-called “on-site mitigation,” wetlands are devel-

FIG. 1. Comparison of a hypothetical stream hydrograph in a natural watershed vs. one from a highly disturbed urban or suburban watershed. Placing the wetland in either of these two watersheds would probably lead to significantly different wetland structure and function.

oped in watersheds near the wetlands being drained or lost; their success is often problematic because of the usual proximity of the mitigation project to a human-altered landscape and the accompanying changes in hydrologic conditions. In these settings, created and restored wetlands can be subjected to "flashy" streams and human-regulated hydrologic conditions. In urban and suburban settings, floods are often greater and occur more quickly after precipitation; low-flow conditions are drier than in a "natural" hydrology (Dunne and Leopold 1978). Both of these conditions lead to generally greater water level fluctuations compared to those in more natural settings (Fig. 1). Unpredictable and rapidly fluctuating hydrology can lead to washouts, scouring, planting failure, and animal and macroinvertebrate emigration, leading to decreased biodiversity and even loss of water quality function.

#### *Give the system time*

A flaw in the measurement of mitigation wetland success is the limited amount of time that regulators and the land development process allow for newly created wetlands to develop before passing judgment. The legal and economic necessities seem to dictate the ecological patterns of nature, encouraging "quick-fix" wetlands while not allowing for the stochasticity of nature. Engineers have long recognized the probabilistic nature of hydrologic events (e.g., precipitation and streamflow) yet relatively deterministic indicators such as wetland plant viability, open water area, endangered species, and waterfowl are expected to develop in a relatively short time span, usually 5 yr. The very best that we can have after 5 yr of monitoring a mitigation wetland is a general idea of the wetland's ecological trajectory and even less understanding of its function.

In one of the longest-running documentations of a constructed wetland in this country, an 8-ha freshwater tidal marsh (Windmill Point), was constructed in 1974–1975 within dikes in the James River in eastern Virginia, USA. Early indications, from 1978 to 1982, considered the wetland a success as it supported a diversity of herbaceous vegetation typical of tidal freshwater

marshes (Newling and Landin 1985). At that time the monitoring was referred to as "long-term." But the dikes were breached in 1986 due to flooding on the James River, eliminating the vegetation and submersing the wetland in the river (Landin 1994, *personal communication*). Sixteen years after construction the project could be termed by some as a hydrologic and ecological failure if long-term survival of the wetland was one of its goals.

Because of the stochastic nature of hydrologic events and the slow development of ecosystems, sometimes in spurts, sometimes in the slow process of recruitment and growth, the 5-yr time horizon can be viewed as arbitrary and probably much too short. As ecological models show (see e.g., Jørgensen 1994), the further initial conditions are from steady-state, the longer it will take for that system to reach or approach steady state (Fig. 2). Short monitoring times favor measuring success with transplanted vegetation and pioneer organisms; long-term success is less dependent on these initial conditions.

#### *Allow self-design*

There are two general approaches for introducing vegetation (and other organisms) in wetland creation and restoration projects. One is the "designer" approach of introducing species and expecting their survival in Gleasonian zones, akin to gardening or landscape architecture. The other emphasizes the "self-design" or "self organization" capacity of Nature to both recruit species on its own and to make choices from those species introduced by humans (Odum 1989, Mitsch 1993). In self-design the emphasis is on the introduction of as many species as possible, knowing that natural forces will help in the ultimate design by choosing the most appropriate species. Self-design also recognizes the importance of natural colonization of species in wetlands.

In one of the few studies to make a preliminary comparison of these two general approaches, Reinartz and Warne (1993) compared 11 created wetlands in southeastern Wisconsin that were naturally colonized with 5 wetlands in the same region where 22 species were

FIG. 2. Hypothetical comparison of the pattern of one wetland criterion for "success," e.g., percentage vegetation cover, for two different initial conditions at the same hypothetical wetland site. In Case 1 the wetland would be considered a "success" after 5 yr, while in Case 2 the wetland would be considered a "failure." Each wetland case could end up eventually at the same level, but well after 5 yr. In reality, a multiplicity of criteria would be used in this comparison.

introduced by seeding. The diversity and richness of plants in the colonized wetlands increased with age, size, and proximity to the nearest wetland source even though *Typha* spp. comprised 15% of the vegetation for 1-yr-old wetlands, and 55% for 3-yr-old wetlands. Seeded wetlands had a high species diversity and richness after 2 yr and *Typha* cover in the seeded sites was lower than in the naturally colonized sites after a 2-yr period.

Many studies to date (e.g., Confer and Niering 1992, McKnight 1992), especially those on restoration of non-coastal wetlands, have probably over-predicted—because of short time horizons and small spatial scales—the survivability of transplanted species in "designer" wetlands. (An exception to this short time horizon is the long-term observation of Frenkel and Boss [1988], through aerial photography, of the spread of *Spartina patens* in areas along Oregon's coastal wetlands.) With enough time and space, introduced species may be less successful than we initially believed. A better idea is to give the wetland system many possibilities through multiple-seeding, multiple-transplanting, and establishment of hydrologically open systems; this allows nature to participate in the wetland design.

#### PROVIDING THE NEEDED RESEARCH TOOLS

In addition to the above suggestions for wetland managers and ecological engineers who are attempting to design and monitor wetlands, there are some important approaches that wetland scientists can use to reduce the uncertainty of wetland mitigation.

##### *Select the proper experimental scale*

The limited ability of science as we generally practice it to both understand and solve our dilemmas in natural resource conservation was argued by Ludwig et al. (1993) and debated in the pages of *Ecological Applications* (Levin 1993). Taking the cue from Holling (1993) and Costanza (1993) in that discussion, we question whether reductionistic experimental science, with its short time scales (often the time required for

a Ph.D. dissertation) and its small spatial scales (often in laboratories or small field plots) can correctly prescribe how to build large wetlands. A holistic systems approach, with the appropriate time and space scales, should at least have equal emphasis.

As one example, a number of studies of wetland function were carried out with four full-scale constructed wetlands at the Des Plaines River Wetland Demonstration Project in northeastern Illinois (Sanville and Mitsch 1994). Hydrologic conditions were varied for high- and low-flow conditions for entire wetlands (average size: 2.4 ha), not just experimental plots; the studies were carried out over 3 yr. Researchers had important findings in estimating detention and mixing (Kadlec 1994), water quality function (Hey et al. 1994, Phipps and Crumpton 1994), sedimentation (Brueske and Barrett 1994, Fennessy et al. 1994a), vegetation development (Fennessy et al. 1994b), aquatic metabolism (Cronk and Mitsch 1994a, b), and avian success (Hickman 1994) in created wetlands, most as a function of hydrology.

In a comparison of two natural tidal marshes with a 0.65-ha constructed marsh in coastal Virginia 5 yr after construction, Havens et al. (1995) found seasonal differences in fish and shellfish abundances between natural and constructed marshes, with lower numbers in the latter. They attribute the differences to relative lack of organic carbon and less morphometric heterogeneity (e.g., stream rivulets, microtopography) in the created marsh.

We recently initiated a full-scale comparison of "self-design" and "designer" approaches to wetlands at the Olentangy River Wetland Research Park at The Ohio State University (Fig. 3; Mitsch and Wu 1995, Mitsch 1995). In one newly constructed wetland basin (1 ha), we planted, in approximately the stratification that we would find in nature,  $\approx 2500$  individuals representing 14 species of wetland plants. In an identical constructed wetland basin nearby, we planted nothing. Hydrologic conditions are being maintained as similar as possible in the two basins and there is no predeter-

FIG. 3. The Olentangy River Wetland Research Park at The Ohio State University in Columbus, Ohio, USA, is a whole-ecosystem long-term experiment begun on 14 May 1994 with the planting of one of the deep-water marshes shown in foreground (right basin) with  $\approx 2500$  plants representing 15 wetland species. The second deep-water marsh (left basin) remains unplanted. Each basin is 1 ha in size and water is supplied by pumps in the lower right-hand corner of the site to create a similar hydrology for each basin. The Olentangy River, shown flowing from bottom right to the top of the picture (with the university  $\approx 0.5$  km downstream of the site on the horizon of the picture), is the source of the water, which is pumped in proportion to the river flow in the same patterns for each wetland basin. The photo was taken in November 1993 prior to the introduction of water to the wetlands (photo by Mark Myers, Apex, Columbus, Ohio).

mined completion date to our experiment. We believe that our "experiment" is closer to the scale necessary for documenting the forces, e.g., plant recruitment, geese and muskrat invasions, etc., that influence eco-

system development. Working at this full scale precludes extensive replication because of land and construction costs, yet our understanding of ecosystem development and other wetland functions will come only

from studying spatial scales and longer time scales to supplement traditional ecological experiments.

#### *Develop predictive modelling*

Little attention has been paid to ecological modelling—the one tool that can expand the time horizon—in predicting success of created and restored wetlands. While this approach must be used with caution and proper qualifications, it enables ecologists to project into the future and estimate how long it will take the mitigation wetland to achieve some type of steady state. A few publications (Costanza and Sklar 1985, Mitsch et al. 1988, Mitsch 1994) have reported on the state of the art of simulation modelling in wetland ecology, but this powerful “systems” tool has rarely been used to predict mitigation success. Stochastic inputs, adaptive model structure (Jørgensen 1994), higher-order modelling languages (e.g., STELLA) and spatially dynamic models are useful advances in ecological modelling, but simple-structure models that aggregate components into overall variables such as “vegetation” or “nutrients” can be just as effective (Mitsch et al. 1995). In an application of modelling for a mitigation project in central Ohio, Niswander and Mitsch (1995) used simulation models both to “fill in” information to make calculations about ecosystem function (phosphorus retention) of a created freshwater marsh and to “enhance the time horizon” by predicting one structural aspect of this project well into the future—the survival of planted wetland trees over the next 50 yr. Modelling, of course, will not provide an exact prediction of conditions well into the future but, when used with good wetland ecology and sufficient field monitoring, it can provide another tool for those interested in predicting the future of created and restored wetlands.

#### CONCLUSIONS

There is optimism that wetlands can be created and restored and that wetland function can be replaced, despite a recent spotty record in the United States with the mitigation of wetland loss. The spotty record is due, in our opinion, to little understanding of wetland function by those constructing the wetlands, insufficient time for the wetlands to develop, and a lack of recognition or underestimation of the self-design capacity of nature. Understanding wetlands enough to be able to create and restore them requires a substantial training in plants, soils, wildlife, hydrology, water quality, and engineering. We should give mitigation projects involving freshwater marshes enough time, closer to 15–20 yr rather than 5 yr, before judging their success. Restoration and creation of forested wetlands, coastal wetlands, or peatlands may require even more time. For example, the restoration of certain coastal salt marshes has been suggested to require at least 50 yr (Frenkel and Morlan 1991). Finally, we should recognize that Nature remains the chief agent of both self-

design and ecosystem development; humans are not the only participants in the design process.

Science will need to make significant contributions to the process of reducing our uncertainty about predicting wetland success. Wetland mitigation needs to become part of an applied ecological science, not a technique that is relearned each time without theoretical underpinnings. Scientists need to make the connections between structural measures (e.g., vegetation density, diversity, productivity) and functions such as wildlife use, organic sediment accretion, or nutrient retention in quantitative and carefully designed experiments. Simply having a list of plant species is inadequate for regulators or managers to estimate ecosystem function. Simulation models and experimentation at the proper spatial and temporal scales should be able to help us predict the behavior of these wetlands and estimate proper designs.

#### ACKNOWLEDGMENTS

The authors appreciate the very effective and useful reviews of two anonymous reviewers and the editorial comments and suggestions of the editor of this special issue, Joy Zedler. We also had good discussions with Robin Lewis on this subject that benefitted this paper. This paper is number 96-001 of the Olentangy River Wetland Research Park, the Ohio State University.

# Geometry of Forest Landscape Connectivity: Pathways for Persistence

Deanna H. Olson and Kelly M. Burnett

## Abstract

Streamside areas may be dispersal funnels or runways for a variety of species. For over-ridge dispersal, headwaters offer the shortest distance links among riparian zones in adjacent drainages. We summarize landscape designs for connectivity of habitats using headwater riparian linkage areas as the foundation for a web of landscape-scale links. We developed management considerations for placement of headwater linkage areas including: 1) providing connections between larger basins; 2) maintaining habitat connectivity in the face of climate change; 3) incorporating place-based disturbance regimes such as headwater debris-flow-prone areas; 4) targeting connectivity areas to address sensitive species conservation strongholds; and 5) accounting for geometry at the forest-stand scale of a single project or proposed timber sale, including managing habitats to connect lands on adjacent federal ownerships, by means of connecting corners of checkerboard landscape blocks along diagonals. Although our proposed linkage areas are designed to target headwater species, the resulting web of connections across the landscape is expected to benefit many forest-dependent species.

**Keywords:** watersheds, forest, headwaters, biodiversity, linkage areas, dispersal.

## Introduction

Biodiversity retention and restoration is an emerging priority for global ecosystems. Astounding losses within major taxonomic groups have been reported nationally and internationally (41 percent of amphibians, 25 percent of mammals, 15 percent of bony fishes, 13 percent of birds: Hoffmann et al. 2010; 50–60 percent of turtles: Kiester and Olson 2011). In particular, protection and restoration of forests and forest biodiversity has become a paramount concern worldwide (e.g., Convention on Biological Diversity: [www.cbd.int/forest/](http://www.cbd.int/forest/)). A toolbox of management approaches has been developed to conserve forest biodiversity, largely through

a mixture of fine- and coarse-grained habitat protections (e.g., United States Northwest Forest Plan: USDA and USDI 1993, 1994; Cissel et al. 1998; Lindenmayer and Franklin 2002; Raphael and Molina 2007; Lindenmayer et al. 2007) and site-specific designs to maintain or restore forest structural heterogeneity (McComb 2001; Lindenmayer and Franklin 2002; Brockerhoff et al. 2008).

Development of landscape designs to manage habitat connectivity for multiple species is an especially active research topic in forest biodiversity conservation, due to continuing trends of forest fragmentation and to an upswing

in world reforestation efforts. Managing forested landscapes for connectivity functions benefiting biodiversity requires incorporating several fundamental conservation concepts. These basic conservation tenets include identifying the critical habitats used throughout species' life histories (breeding, foraging, overwintering, and dispersal habitats), and commensurate habitat protections to ensure that these biotic functions are retained. If an organism uses different habitats through its life cycle, then maintaining connectivity among these habitats is essential to ensure its persistence. Of particular relevance is the characterization and retention or restoration of dispersal habitat. This includes the home ranges of individuals and the broader dispersal of offspring or individuals that tie sub-populations and populations together over larger areas. This broader-scale dispersal function maintains genetic variation within natural populations, which may foster resiliency needed to adapt to changing environmental conditions. The future of species may rely on our careful attention to managing for connectivity now.

Defining the adequacy of dispersal habitat in forests is a complex topic (Noss et al. 1997) and may address a variety of elements, including habitat condition, corridor sizes (length, width), and corridor redundancy (Pinto and Keitt 2008). Redundancy is especially relevant because multiple connectivity pathways can assist dispersal across landscapes by organisms in different locations and increase the probability of movement in the face of many interacting site-specific factors (microsite features, disturbances). Redundancy of habitat connectivity hedges against catastrophe, uncertainty, and stochastic processes that can affect individuals and sub-populations that vary in their movement propensities, possibly related to patch size, habitat quality, and population demography.

Low-mobility species may merit special attention devoted to the placement and redundancy of connectivity corridors, because barriers to dispersal may arise as a result of their

basic biology and ecology (Raphael and Molina 2007). These species may move slowly and require refugia along corridors because it may take them years to move between optimum habitat patches. Due to a potentially longer residency time within connectivity corridors, low-mobility species may be particularly vulnerable to sub-optimal corridor conditions and stochastic processes. Hence, redundancy of connections may be critically important to increase their likelihood of successful movement across landscapes for such low-mobility species. Patches of higher-quality habitat within dispersal corridors may be used as stepping stones for such species and may be an essential aspect of their long-term persistence (e.g., Grant et al. 2010). Such stepping stones may function as habitat refugia or "stopover reserves" (Dobson et al. 1999), which promote survival of individual organisms as they move through the environment. Stepping stones may have more suitable physical habitat conditions than the surrounding area, or may allow individuals to forage to replenish energy reserves or survive harsh seasons (summer, winter) in localized refugia, from which they may disperse again later.

Herein, we synthesize our ongoing studies of the utility of headwater riparian areas as proposed connectivity corridors, or linkage areas, for dispersal of riparian-associated and low-mobility species in Pacific Northwest forests. Once designed, such headwater linkage areas may benefit many taxa. Our studies also conceptually integrate aquatic network and upland-forest habitats, functions, and processes. The combination of protections for aquatic and upland systems is providing new insights into forest ecosystem management approaches. We summarize the key considerations for the geometric orientation of connectivity pathways to assist migration of species across watersheds and across webs of connections, to maintain linked aquatic-terrestrial populations at landscape scales. Our goal here is to provide

a summary of these conceptual designs, while research continues to address these issues and advance design effectiveness.

### **Utility of Watersheds as Redundant Landscape-scale Linkage Units**

Watersheds are widely accepted units for monitoring and evaluating the effects of land use on aquatic resources (Omernik and Bailey 1997). Where their boundaries can be clearly mapped, watersheds are increasingly common units for forest management planning and conservation designs. For example, in the U.S., the Aquatic Conservation Objectives of the federal Northwest Forest Plan (USDA and USDI 1994: p. B-11), address connectivity among watersheds:

*“Maintain and restore spatial and temporal connectivity within and between watersheds. Lateral, longitudinal, and drainage network connections include floodplains, wetlands, upslope areas, headwater tributaries, and intact refugia. These network connections must provide chemically and physically unobstructed routes to areas critical for fulfilling life history requirements of aquatic and riparian-dependent species.”*

Hydrologic units (HUs), delineated by the U.S. Geological Survey (Seaber et al. 1987), are also a convenient and widely used basis for forest assessment and planning (e.g., Maxwell et al. 1995; Suring et al. 2011). The HU coding describes a hierarchical system of units nested by drainage area; larger code numbers designate smaller drainage areas. Watersheds or segments of watersheds comprise HUs. Even though the majority of HUs at each level of the hierarchy are not true topographic watersheds, such a perspective can aid biodiversity conservation designs, especially as smaller headwater basins are delineated and used for replicating protected areas (e.g., 6<sup>th</sup>-code HUs: Suzuki et al. 2008) and creation of redundant connections across

landscapes (via 6<sup>th</sup>- and 7<sup>th</sup>-code HUs: Olson and Burnett 2009).

The value of using headwater basins as the premise for establishing connectivity corridors across forested landscapes is due to their habitat conditions, potential use by a variety of organisms, frequency of occurrence on the landscape, and minimization of dispersal distances (fig. 1). Olson et al. (2007) summarized some of the merits of headwater riparian habitats for species in the northwest, including providing cool, moist microclimates for interior-forest dependent organisms and aquatic-riparian associated species such as amphibians. Some taxa may use these areas due to their habitat suitability; others may respond to streams as movement barriers, and then move along banks parallel to such barriers. Streamside areas may be dispersal funnels or runways for a variety of species. For example, we have seen terrestrial salamanders (species that do not use stream or pond habitats for breeding or other life-history functions) moving predominantly through near-stream areas (D. Olson and M. Kluber, unpubl. data). Additional taxa that use riparian corridors in northwestern forests include a variety of lichens, bryophytes, fungi, vascular plants, mollusks, mammals (e.g., ground-dwelling mammals: Wilk et al. 2010), birds, and general forest-obligates that may occur in legacy forest attributes such as wolf trees along riparian buffer zones. As a minimum estimate across taxonomic groups, over 100 species were identified as likely to benefit by habitat protections of combined intermittent and perennial streams provided by riparian reserves in federal forest lands in the range of the Northern Spotted Owl (*Strix occidentalis caurina*) (table 1) (USDA and USDI 1997). Species with restricted dispersal abilities were identified for special consideration relative to utility of riparian reserves during watershed analyses under the Northwest Forest Plan (USDA and USDI 1997).

Furthermore, the high density of small streams in upland northwest forests has been widely recognized over the last 20 years, as our basic

**Table 1**—Species benefitting from interim riparian reserves developed for the federal Northwest Forest Plan (from table B1 in USDA and USDI 1997). Riparian reserve protection includes a one site-potential tree-height or 30.5 m (100 ft) buffer, whichever is greater, as an interim measure along all intermittent streams, and a two site-potential tree-height buffer as an interim measure along perennial streams (see USDA and USDI 1993, page III-9).

**Figure 1**—Example interim riparian reserve network from the US federal Northwest Forest Plan implemented in the Pacific Northwest, showing frequency of headwater streams on the landscape and the resulting one and two site-potential tree-height buffers along streams (upper left quadrant). Arrow indicates example over-ridge area where the distance between headwater riparian reserves in different watersheds is small and over-ridge connectivity may be more easily achieved. These headwater riparian areas can be used to facilitate landscape linkage area designs for organism dispersal and aquatic-terrestrial habitat connectivity functions.

knowledge of stream and forest ecology has expanded. In some areas, headwaters comprise 80 percent of a stream network (Gomi et al. 2002). This realization intersected with forest management practices when mapping of Northwest Forest Plan scenarios revealed that large percentages of watersheds were being incorporated into interim riparian reserves due to the high density of headwater stream networks (fig. 1). An additional value of using headwater drainages to plan landscape connectivity designs is that the distance from headwater streams to ridgelines is the shortest within a watershed, hence reducing travel distances for overland dispersal to neighboring stream-riparian areas or forest reserve blocks. Distance analysis tools, such as for “least-cost path” in landscape modeling (e.g., ArcGIS, Environmental Systems Research Institute, Inc., Redlands, CA), have been developed to assess distances between habitat patches. These tools would be useful for designing least-distance

headwater linkage areas. Least “cost” path is a relevant term applied to the economics of animal movements, to minimize the distance moved—especially for mobility-restricted organisms. This term may also apply to the economics of forest management if identification of a dispersal corridor results in a financial cost for on-the-ground implementation or affects revenue from resource extraction in a managed forest context.

Northwest Forest Plan riparian reserves were intended as major contributors to the maintenance and restoration of aquatic conservation objectives, including aquatic network connectivity (USDA and USDI 1994). The importance of linking headwater stream functions and processes to those of downstream stream networks has been a focus of much work in the last two decades. Welsh (2011) captured many elements of the developing history of stream network theory and the role of aquatic connectivity in summarizing the conceptual frameworks of geomorphic channel processes (transfer and depositional zones), nutrient cycling (upstream marine influence via salmonid migration, downstream nutrient spiraling via down wood movements), aquatic-riparian linkages via reciprocal subsidies, and the intersection of herpetofaunal distributions with the classic stream continuum concept of taxonomic patterns that vary with stream order. As we look up the aquatic network into headwater streams and beyond, we summarize how extending riparian buffers up drainages and connecting them over ridgelines can both maintain terrestrial connectivity and functionally link aquatic-terrestrial systems.

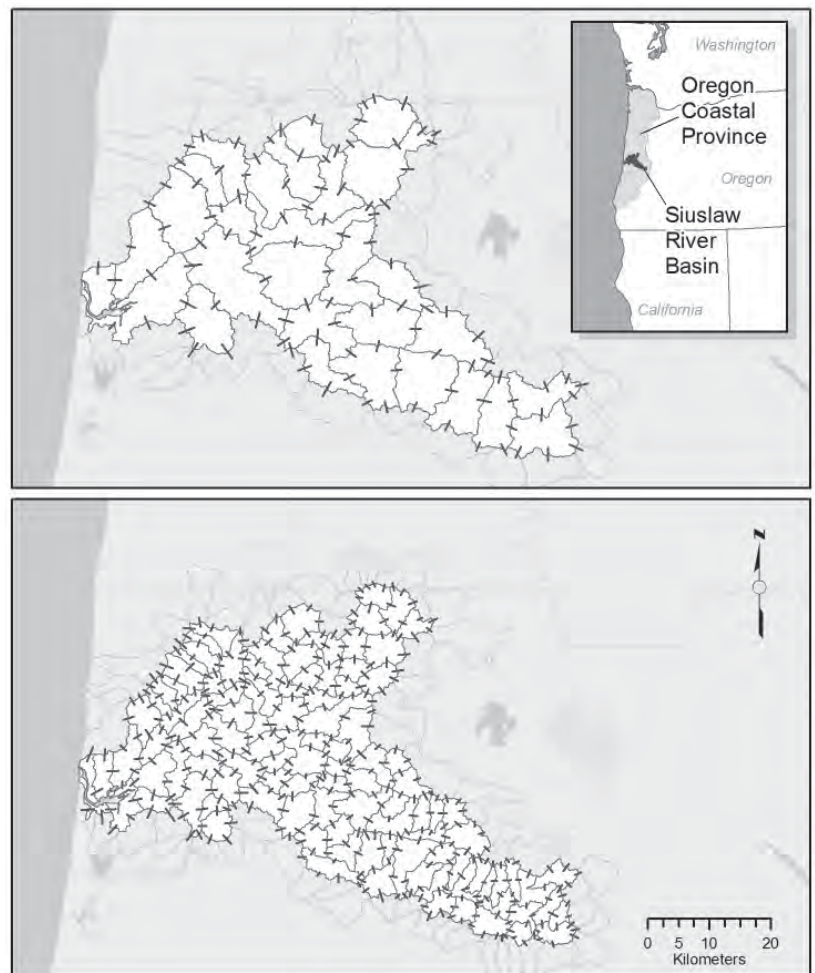

Several conceptual designs of riparian buffer widths and patch reserves have been proposed to assist over-ridge migration of organisms within forests (fig. 2; Olson et al. 2007). Over-ridge connectivity considerations were further developed by Olson and Burnett (2009), and modeled for the Oregon Coastal Province. This model of connectivity linked every 6<sup>th</sup>- and 7<sup>th</sup>-code HU to each neighboring HU. Focusing on the Siuslaw River basin, a 4<sup>th</sup>-code HU within

**Figure 2**—Headwater management considerations to retain aquatic-riparian biodiversity by stream buffers of different widths (A, B) and provide linkage areas between adjacent basins (C-G) using alternative forest management practices including uncut blocks (C, D, F), thinning (E), and leave islands (E, G) (from Olson et al. 2007).

that area, the linkage design illustrated where one over-ridge link could connect each adjacent HU (fig. 3). At the 7<sup>th</sup>-code HU scale, one link between each adjacent 7<sup>th</sup>-code watershed resulted in roughly 15 percent of headwater streams being extended and connected. For the Oregon Coastal Province, this resulted in over 5,000 links, with about one link per 4.6 km<sup>2</sup>. This is an example of redundant connectivity, essentially creating a web of connections across the landscape. Using the 6<sup>th</sup>-code HU scale, the amount of connectivity created is approximately halved, with one link per 9.3 km<sup>2</sup> for the Oregon Coastal Province.

There are no defined guidelines for how many links or how much habitat connectivity is necessary to maintain populations. The amount of dispersal habitat that might be needed to sustain even highly researched species, such as

**Figure 3**—Linkage areas between watersheds can provide connectivity of headwater habitats across landscapes. In the Oregon Coast Range Province, the Siuslaw River basin, a 4<sup>th</sup>-code Hydrologic Unit (HU), is used to illustrate: A) a single connection between adjacent 6<sup>th</sup>-code HUs; and B) a single connection between adjacent 7<sup>th</sup>-code HUs, which results in 376 connections across the basin and if expanded to the entire province, about 5000 links within 23 000 km<sup>2</sup> (from Olson and Burnett 2009).

the northern spotted owl, is unknown; a “more is better” attitude prevails in the face of this uncertainty. Nevertheless, research is accruing about how much dispersal may be needed to maintain genetic diversity within and among populations. The “one migrant per generation” rule has been offered as a minimum level to reduce genetic isolation, inbreeding, and bottlenecks (e.g., Mills and Allendorf 1996). However, such a rule has many underlying assumptions that may not be supported when the complexities of natural systems are considered (e.g., Wang 2004).

Furthermore, relating effective migration rates to habitat protections in managed systems is not a straightforward exercise: if we build corridors, will they be used? Ongoing mark-recapture, radio tracking, and genetic studies are helping us to answer this question. For example, genetic connectivity analyses of stream-associated Rocky Mountain Tailed Frogs (*Ascaphus montanus*) in Idaho supported this species’ affiliation with intact forested habitats: their path of connectivity followed riparian corridors in managed forests (Spear and Storfer 2010). This pattern supports the “riparian corridors as funnels” concept, but it contrasted with Coastal Tailed Frog (*A. truei*) genetic connectivity pathways in the Olympic Peninsula, Washington, which were primarily overland in areas that had timber harvest activities (Spear and Storfer 2008). Precipitation and population differences between these areas were hypothesized as accounting for these differences, as the more mesic conditions that prevail in northwestern Washington may facilitate the upland dispersal of moisture-reliant tailed frogs. Other studies (Wahbe et al. 2004; Johnston and Frid 2002; Dupuis and Steventon 1999; Nauman and Olson 2004) also found differences in riparian-corridor associations of various amphibian species in response to climate and forest conditions, generally supporting their ability to respond to microsite gradients with an apparent affiliation to cool, moist local conditions (e.g., riparian “funnels”) (Olson et al. 2007). Furthermore, Spear et al. (2012) reported

that Coastal Tailed Frogs track remnant tree patches in their migration pathways after the volcanic blast at Mount St. Helens, Washington. So, if we build it, will they come? The early answer is “yes, but...” —meaning that a variety of organisms appear to be occurring in or moving along pathways of retained habitats, but with geographic, taxonomic, and population-specific contexts being important considerations. A similar conclusion has recently been supported for hedgerows as corridors between woodland fragments (Davies and Pullin 2007). More research on the design of effective linkage areas will be needed. In the interim, conceptual priorities for landscape connectivity designs can be identified, and these relate directly to emerging research priorities.

### **Priority Areas for Habitat Connectivity**

Prioritizing linkage area placement may be important to address connectivity objectives under economic constraints, and to advance research into the effective design of linkage areas. Because linking all adjoining watersheds at small HU scales may be difficult for land managers to plan and implement in the face of myriad conflicting resource objectives, priorities may guide the first steps in connecting habitats. Olson and Burnett (2009) itemized linkage area considerations at two spatial scales, landscape and drainage area (table 2). Here, we further develop five of these priority considerations:

1. “Triads,” where three large basins, with limited or no aquatic connectivity, converge at their headwaters;
2. Climate change considerations including north-south, east-west, and altitudinal linkages;
3. Landslide-prone areas;
4. Species conservation strongholds; and
5. Diagonal considerations.

**Table 2**—Design considerations for placement of headwater linkage areas to assist migration of forest-dependent species in the Pacific Northwest (Olson and Burnett 2009). **Bold-face type** indicates new concepts discussed further in text.

<b>Linkage Area Design Considerations</b>	<b>Priorities</b>
<i>Landscape scale</i>	
1. Connections across large basins	<b>“Triads”</b> – headwater locations that link three adjoining basins having no aquatic connectivity.
2. Climate change migration corridors	North-south (latitudinal) dispersal routes. Altitudinal dispersal routes. Migration across ecoregion boundaries. <b>East-west dispersal routes.</b>
3. Linking landscape fragments	Connecting remnant late-successional and old-growth (LSOG) forest patches to other patches or restored habitats may aid dispersal of LSOG-associated species, especially those with dispersal limitations such as lichens, bryophytes, and mollusks; creation of connected archipelagos of patches.
4. Disturbance frequency	Correlating frequency of connections with rates of landscape-scale disturbances, natural or anthropogenic; i.e., more linkage areas in more-disturbed places.
5. <b>Redundancy</b>	Planning for multiple paths across landscapes will improve dispersal probabilities.
<i>Drainage-basin scale</i>	
6. Known sites for target species	Low-mobility species. LSOG-associated species. Species with status of concern. <b>Biodiversity hotspots</b> – communities. <b>Species “strongholds”</b> – priority species management areas such as key watersheds
7. Existing protections	Co-location of linkages on current set-asides (e.g., federal late-successional reserves, owl “cores”, Survey and Manage species sites, botanical set asides, landslide-prone areas included in riparian reserves)
8. Short connections	For economy of space, with economic and ecological benefits, shorter connectivity corridors are preferred; ecologically, shorter distances for dispersal may reduce energetic costs for individual movements and time needed for propagules to disperse.
9. Paths of least resistance	Easier dispersal routes may be lower-gradient or lower-elevation “saddles” across ridgelines. Wind-dispersers may have least resistance in paths that follow wind directions during seasons of dispersal.
10. Risk of disturbance	Use hazard models for disturbances such as landslides, debris flows, ice/wind damage, and fire in placement of linkage areas, or in decisions about the need for redundant linkages. For example, debris-flow-prone areas may be headwater set-asides during riparian reserve delineation, and such areas may be co-located with dispersal corridors; redundant links may be considered in fire-prone areas. Mapped overlays of roads, recreation areas, human development, and mining might be avoided during linkage area delineation, when alternative locations exist.
11. Land ownership patterns	Co-location of links on federal and state lands, where possible. <b>Diagonal linkage areas across checkerboard ownerships.</b>

Each of these five considerations results in a geometric view of how connectivity webs may be arranged across landscapes.

These five considerations are not mutually exclusive; how they may interact during prioritization exercises also is developed briefly here. Although they were derived for northwest forest landscapes, these concepts may have broader utility worldwide.

### 1. “Triads”

In the Oregon Coastal Province, Olson and Burnett (2009) highlighted the potential importance of linking larger river basins, which have no freshwater connectivity, through existing riparian buffer networks. Over-ridge forest habitat linkages may be absent unless reserves are placed in the area. Streams in such basins may flow directly to the Pacific Ocean or into a much larger river without a forested riparian area, and so have headwaters that are functionally disconnected. Here, we examined 4th-code HUs for the Oregon Coastal province, the scale of the Siuslaw River basin highlighted above. We then looked for locations where three of these 4th-code HUs joined at their headwaters: we call this a “triad” location. For example, headwaters of the Siuslaw River, Yaquina River, and Marys River converge at Marys Peak (between Corvallis, Newport, and Waldport, OR), which would be one such triad. Only 18 of these headwater triads exist for the Oregon Coastal Province (fig. 4). We suggest that such triads be considered priorities for habitat linkage areas because these would be spatially economical for land managers to implement and potentially ecologically efficient as connections across three watershed boundaries simultaneously.

A current research priority is to empirically assess the proposed linkage-area function of landscape locations such as headwater triads. Using a genetic approach, we have sampled northwestern amphibians from headwater streams of adjacent drainages that are potentially connected across ridgelines in the Oregon Coast Range, including

three adjoining headwaters in triads (such as Marys Peak). Preliminary genetic analyses of the Coastal Giant Salamander, *Dicamptodon tenebrosus*, generally support our contention of over-ridge connectivity among drainages (L. Knowles and M.R. Marchán-Rivadeneira, Univ. Michigan, unpubl. data). Previous studies have supported overland connectivity of stream-breeding amphibians (e.g., Spear and Storer 2008, 2010), and such animals have been found up to 400 m from streams (Olson et al. 2007), but no previous published study has designed

**Figure 4**—“Triads” are indicated (squares) where three 4th-code Hydrologic Units in the Oregon Coast Range Province meet at their headwaters. Triads are priority locations for linkage area or ‘species stronghold’ placement to effectively manage for species dispersal simultaneously across three distinct watershed boundaries.

sampling to specifically address headwater over-ridge connectivity among discrete drainages. This remains an information gap that could be addressed for all forest taxonomic groups, and would aid the adaptive management of the triad connectivity concept.

## 2. Climate Change

A second priority consideration for northwest forest connectivity is assisting migration in the face of climate change (Olson and Burnett 2009). Predicted climate change effects on northwest forest habitats include drought, insect, and fire effects on forest stands, with large conifers and high-elevation trees being vulnerable to losses (Spies et al. 2010). Aquatic habitat changes in forested landscapes are anticipated in cold-water mountain streams (Spies et al. 2010) and in headwaters (Olson and Burnett 2009). Increasing stream temperatures, with negative implications for cold-water fauna, are already apparent across the northwest (Isaak et al. 2011). Given uncertainty in the geographic specificity of climate change trajectories due to complex El Niño and Pacific Decadal Oscillation cycles, “dynamic and adaptive thinking” (Spies et al. 2010) is needed. A prudent course for linkage area placement may be to consider connected routes in north-south, east-west, and altitudinal directions within and among watersheds (fig. 5). Such consideration may allow multiple potential pathways of movement for species facing changing conditions. Pockets of suitable microhabitats for species persistence may be related to local conditions, and may occur as “stepping stones” along these linear trajectories, like beads along a string. Providing connectivity paths adjoining both riparian areas and north-facing slopes is one such example, with both near-stream areas and hill shading resulting from topographic relief providing cool, moist conditions for target species such as some late-successional and old-growth (LSOG)-associated salamanders (e.g., Suzuki et al. 2008). Landscape-scale monitoring of forest conditions and species distributions may inform

**Figure 5**—Designs for assisted migration of species in the face of climate change might include prioritizing headwater linkage area placement across north-south and east-west watershed boundaries. The Siuslaw River basin, a 4th-code Hydrologic Unit in the Oregon Coast Range Province, is shown highlighting perimeter sub-drainages (dark grey) where linkage areas could be made to discrete drainages to the north, south, and east.

adaptive management of likely climate change refugia for different taxa.

## 3. Managing Disturbances: Landslide-Prone Areas

A third priority consideration for the design of linkage areas is to integrate their placement with local disturbance regimes. Landslides and debris flows can be dominant disturbance processes affecting headwater streams in forested, mountainous regions (e.g., Benda 1990; Iverson et al. 1997). The Northwest Forest Plan directs that riparian reserves incorporate landslide-prone areas to reduce the probability that activities associated with timber harvest will alter wood and sediment inputs to streams by changing the rate, magnitude, composition, or timing of debris flows. Co-locating linkage areas with existing riparian reserves, where these include steep areas prone to landsliding, can provide

economic efficiency and conservation synergy for land and resource managers. Burnett and Miller (2007) modeled differences among hill slopes and headwater channels in probabilities of initiating and transporting debris flows that deliver to fish-bearing channels for the Oregon Coastal Province (fig. 6). Those headwaters with the highest likelihood of affecting downstream areas important for fish might be high priorities for extending riparian reserves over ridgelines. Because debris flows can be important sources of large wood (May and Gresswell 2003; Hassan et al. 2005), a fundamental component of stream habitat complexity (Bilby and Bisson 1998; Gregory et al. 2003), managing these expanded riparian reserve areas to accelerate tree growth could be an additional consideration. Redundancy of connections would be important when planning ground-disturbing activities for linkage areas with a high probability of landsliding. To aid identification and adaptive

management of landslide-prone areas, these areas have been mapped for many northwest forests by the NetMap interactive web-tool developed by Earth Systems Institute (<http://netmaptools.org/>).

#### 4. Species Strongholds

“Species strongholds” are areas where biodiversity conservation is a priority, and where thriving populations can occur to anchor species persistence in the region. Retaining connectivity among species strongholds enhances the likelihood of persistence under the uncertainty of stochastic events (catastrophic fire, disease outbreaks) or emerging patterns of disturbance (climate change) that may affect any particular stronghold. Managing stronghold-to-stronghold connectivity is a fourth priority to consider in developing linkage area designs across forest landscapes. Species strongholds may be created for communities of diverse taxa at larger spatial scales by land-use allocations such as

**Figure 6**—Placement of between-drainage links might consider other landscape-scale provisions such as management scenarios to retain the natural disturbance regime, including landslide-prone areas managed to deliver wood and sediment to streams. Top figures show models of 25 percent and 75 percent of the landslide-prone hillslopes in an example forest landscape, and bottom figures show their likely traversal paths to streams (Burnett and Miller 2007). Headwater riparian buffers of these areas provide long-term wood and sediment inputs for stream biota. From Olson and Burnett 2009.

Congressionally reserved lands (wilderness areas, national parks), or the Northwest Forest Plan late-successional reserves or key watersheds (USDA and USDI 1993, 1994). At smaller spatial scales, strongholds for a targeted species of concern may be critical habitat areas, such as caves, ponds, meadows, botanical set-asides, or areas managed for Survey and Manage species under the federal Northwest Forest Plan (USDA and USDI 1993, 1994). Riparian buffers themselves might be considered as strongholds, but here, we expand that perspective to other areas.

Developing new species strongholds is particularly important when considering connectivity issues. Three examples follow. First, areas with high “intrinsic potential,” the capacity to support high-quality habitats for salmon (Burnett et al. 2007), may serve as nuclei for designing linkage areas. Intrinsic potential models have been developed and broadly applied for salmonids in the Pacific Northwest and elsewhere (e.g., Mollot and Bilby 2008; Sheer et al. 2009; Busch et al. 2011; Barnett and Spence 2011). Streams with high intrinsic potential can be identified and then targeted, as appropriate, for salmon conservation across a landscape. Such areas of high intrinsic potential are essentially “species strongholds” from which aquatic-terrestrial linkage areas can originate. Areas of high intrinsic potential for some salmonid species may occur in larger streams, but tools exist to easily identify headwater streams that feed into these both laterally and from upstream (Clarke et al. 2008).

Second, criteria for Priority Amphibian and Reptile Conservation Areas (PARCAs) are under development for nationwide application (Riley et al. 2011). PARCAs are being discussed for integration into the landscape planning processes of other entities, such as the U.S. Department of Interior Landscape Conservation Cooperatives (<http://www.doi.gov/lcc/index.cfm>), which is a partnership network to sustain America’s land, water, wildlife, and cultural resources. Once established, PARCAs would function as species

strongholds. Similarly, the International Union for the Conservation of Nature (IUCN) is developing criteria to identify sites of global significance for biodiversity conservation, called Key Biodiversity Areas. Such areas are synonymous with the concept of species strongholds. The additional element that we suggest is to provide connectivity among such areas.

Third, triads, as we previously described, could be ideal locations for species strongholds, as these occur at the ridgeline junction of three large basins. However, we note that triads are not established biodiversity hotspots, and are proposed here as a conceptual design.

Development of landscape-scale linkage webs from either new or existing species strongholds is needed to reduce isolation of those areas, and as possible to allow them to function as potential “source” habitats with optimal conditions that can anchor species over time and also connect to adjoining areas, in a metapopulation context. Linking dispersal pathways from strongholds up and over ridgelines to adjacent watersheds and neighboring strongholds is a direct approach that may offer a least-cost path. Relevant to our proposed headwater linkage areas concept, connecting such species strongholds to headwaters which then extend and connect over ridgelines is another consideration. Additionally, strongholds may be linked to protected riparian areas along larger streams that are subsequently extended upstream into headwaters and connected over ridgelines. Multiple connectivity pathways may be conceived. As a web of connections is considered relative to species stronghold connectivity, the previous priorities discussed above and outlined in table 2 can be overlain, including large basins and triads, linear trajectories to address for climate change gradients, and occurrence of landslide-prone areas.

Adaptive management of strongholds may need to be addressed over the long term as future conditions unfold. As applied here, the concept of a stronghold evokes less of an immovable fortress than an anchor. A species stronghold intended

to anchor habitat may need to function as do real anchors on occasion, and be repositioned or “drag” across landscapes in response to changing conditions or management priorities (Olson et al. 2007). The temporal scale of strongholds can be addressed at the time of their development, and interact with the spatial scale of stronghold designs and the frequency of strongholds. For example, habitat anchors designed to drag across landscapes may be implemented more easily if they are smaller and more numerous. Olson et al. (2007) suggested considering 6th-code watersheds (HUs) as a spatial scale for amphibian habitat anchors. The anchor concept warrants testing, with a sufficient timeframe to weigh success at the landscape scale, in addition to replication. It may have greater success if it were to be implemented in areas with more resilient ecosystems.

## 5. Thinking Diagonally: Funnels and Chains

The geometry and land-management context of land-use and land-ownership parcels on the landscape is a final set of priority considerations for linkage-area placements that we will develop briefly here. The northwest forest landscape is a patchwork of land ownerships and land-use allocations, each with differing management priorities, which creates a complex challenge for biodiversity conservation (Suzuki and Olson 2007). During planning for large blocks of forest land, and during planning of individual projects at smaller spatial scales, managing for connectivity within and among ownership areas can be difficult due to differing priorities across boundaries. To diminish the dilemma of achieving effective biodiversity conservation in such a multi-ownership landscape, it may help to think of streams as dispersal “funnels” that serve to channel organisms along protected riparian areas, and connectivity corridors or linkage areas as “chains” functionally moving animals up and over ridgelines (Olson and Kluber, unpubl. data).

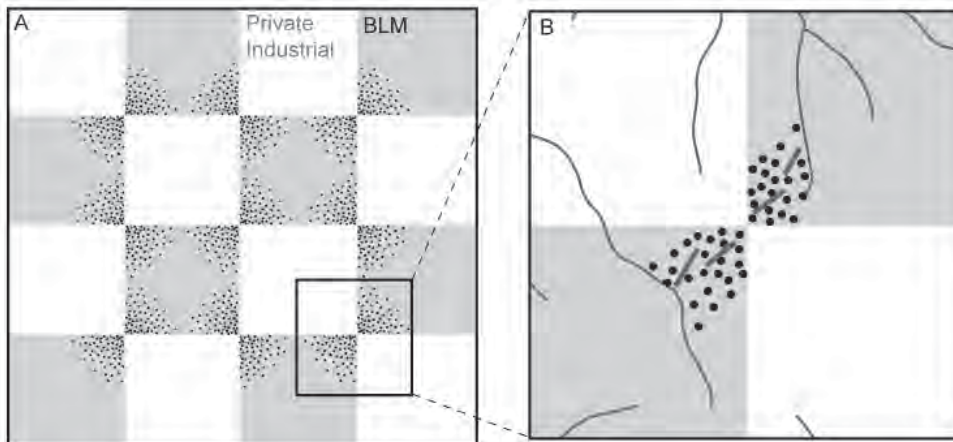

Overlaying many of the previously discussed priorities can provide an integrated perspective for addressing the challenges of land-ownership/ allocation geometries.

Diagonal linkage areas are of specific relevance in a landscape with a checkerboard ownership pattern (fig. 7), and in other landscape geometries that abut at corners or other edge types (Olson and Kluber, unpubl. data). Species dispersal along such diagonals might be promoted by forest management actions that retain habitat elements toward the corners of such lands. For example, weighted green-tree retention, leave islands, and directional felling of down wood (recruitment of large logs, in particular) from corners may assist migration of species along the diagonal by providing chains or stepping stones of suitable microhabitats for species refugia. Linking chains of habitat elements from corners to stream- and riparian-protected areas, especially headwaters (fig. 7B), may functionally extend and connect riparian buffers. Organisms that are funneled along riparian areas may venture through corners via these habitat chains. A chain of habitat need not extend from headwaters, but could extend from any part of a riparian buffer, or from a species stronghold, as discussed above.

It may be neither feasible nor desirable to address habitat connectivity at all corners of adjacent lands within an ownership. Similarly, when land parcels are in close proximity but do not adjoin, it may not be possible to consider linkage areas along their entire boundaries. Several additional design concepts arise and interface with ideas presented above.

First, linkage areas among land parcels might be “stream-lined” if streams align through corners (fig. 8), or connect nearby land blocks. When streams follow diagonals in a checkerboard landscape, riparian protection may more effectively promote multi-species diagonal dispersal: funnels without the added chains linking across diagonals. Streams that loosely follow diagonals, not intersecting exactly at corners, could be quite functional to assist species

**Figure 7**—In a checkerboard ownership pattern, such as that created by the Oregon and California Lands Act (1937) where US Bureau of Land Management (BLM) and private industrial forestlands are intermixed, management for connectivity along diagonals may improve likelihood of species dispersal within ownerships. A: Corners are shaded to show linkage area considerations. However, routes along selected diagonals to species strongholds, reserves, or triads might be used to prioritize which corners are chosen for connectivity emphasis. B: Forest management options to facilitate species dispersal from stream corridors (which may serve to funnel species movements) to corners might include chains of habitat structures provided by green tree retention, directional log placement from corners to streams, or both. Concepts could be applied to other ownership geometries with corners or edges in proximity.

**Figure 8**—Connectivity designs to aid species dispersal among ownership blocks may overlay on streamside riparian management zones. This US Bureau of Land Management study site for the Density Management and Riparian Buffer Study of western Oregon (Cissel et al. 2006) shows riparian buffers extending along the full diagonal (A) as well as laterally toward an opposing corner (B), with leave islands and dispersed tree retention aiding habitat connectivity, and to a neighboring private land block (C). “Stream-lined” connectivity (A) may aid within-watershed dispersal, but overland connectivity designs (B and C) may warrant consideration to link or “chain” habitats overland between watersheds. Photo provided by Oregon Bureau of Land Management.

migration, in this regard. Streams that link disconnected parcels may similarly function to funnel organisms’ movements. The context of the adjoining lands may need to be assessed, however. Managing such a stream-line to promote its potential connectivity function is a consideration,

but such stream-lined connectivity does not address overland dispersal. Chains from streams to ridgelines are needed to fully integrate aquatic and terrestrial landscape connectivity functions. Collaborative management of such stream-lines and overland chains among ownerships and

across land-use allocations within ownerships, remains a challenge.

Second, in multi-ownership landscapes, road densities may be higher than in single owner landscapes. An assessment of the effects of roads on species connectivity designs may be particularly important in these landscapes. In particular, paved roads or high-use unpaved roads may be barriers to low-mobility species. As roads intersect streams, aquatic organism passage may be affected, with consequences for overland connectivity. Site-specific designs can include these considerations.

Third, as hazard models of disturbances are developed for a landscape, it may be helpful to ask how hazards align with land-ownership boundaries, land-use allocations, and existing connectivity webs. For example, how are landslide-prone areas arranged relative to the geometry of lands by ownership and land-use allocation? As discussed above, can priority linkage areas be designed to overlay on landslide-prone areas that are already set-asides for riparian reserve management, and now also serve “to chain” habitats to adjoin land-ownership blocks?

Fourth, in a larger landscape context, it may be useful to know how larger basins, climate change projections, and species strongholds are arranged and whether these be used to prioritize connectivity area pathways. Can dispersal routes be conceived from streams and then through land-ownership diagonals or between ownership blocks to foster connections relative to these issues?

Multiple overlapping considerations are emerging, and a stepwise process may be needed to integrate them. Limitations may emerge due to topography, geometry of land configurations at local scales, or pre-existing conditions. For example, a dispersal barrier such as a road may need to be considered first. The existence of under-road culverts may create spatially explicit bottlenecks for connectivity planning. Routing linkage area pathways to those stream corridors and culverts may be needed to increase the odds

of dispersal across the road. Culverts that act as dispersal nodes in this way could be prioritized for enhancement to provide passage for non-aquatic species. Similarly, triads and species strongholds, as discussed above, are essentially dispersal nodes. Routing dispersal routes via headwater linkage area pathways to triads and strongholds could increase the overall effectiveness of these conservation measures.

## Conclusions

Forest biodiversity conservation is an ecosystem service that will continue to be addressed at local-to-landscape scales in the coming century. Retaining organisms across managed forest landscapes requires a toolbox of approaches including fine- and coarse-scale habitat protections and restoration practices, retaining or creating structural elements that are critical habitats for species, and development and management of connectivity pathways to allow gene flow. Renewed efforts to address communities of organisms as well as species of concern are called for as emerging stressors need evaluation, new knowledge is accrued, and adaptive management of existing forest plans are needed.

We review the numerous benefits of forest connectivity designs that rely on headwater linkage areas, and emphasize priorities for their placement at landscape scales. The benefits of headwater linkage areas include their likely functional role in integrating aquatic and terrestrial systems, their potential use by multiple taxonomic groups, their utility for creating webs of connections across forested lands to increase their effectiveness for biodiversity conservation, and their efficiency in minimizing both the distances that animals must move overland and the financial burdens of forest manager.

Placement of headwater linkage areas may include consideration of a variety of factors (table 2). Prioritizing linkage areas can provide a starting point for managing connectivity among

critical habitat areas, suggest directional routes for dispersal among areas, or identify dispersal nodes as anchors for connectivity webs. The five priority considerations that we developed include triads that effectively link three larger basins, north-south and east-west directional routes to address climate change scenarios, linkages overlaid on management of disturbances such as landslide-prone areas, links among species strongholds, and diagonal links that route dispersal across management boundaries. These five concepts can be integrated into an overall geometry of landscape connectivity designs. Our conceptualization of headwater linkage area utility and these priority considerations are posed as hypotheses warranting further study and development. We offer these ideas with the caveat that they will not benefit all taxa in forested landscapes. Extremely rare or patchily distributed organisms with low mobility may need a finer-grained, site-by-site conservation approach (Raphael and Molina 2007).

### Acknowledgments

Concepts developed here are outcomes of our large-scale projects with the Density Management and Riparian Buffer Study of western Oregon (DHO) and the Coastal Landscape Analysis and Management Study (KMB). We thank the US Forest Service and Bureau of Land Management for supporting those projects. We thank K. Christiansen and K. Ronnenberg for assistance with graphics, and P. Garvey-Darda and two anonymous reviewers for helpful comments.

**Abstract** The impact of the landscape matrix on patterns of animal movement and population dynamics has been widely recognized by ecologists. However, few tools are available to model the matrix's influence on the length, relative quality, and redundancy of dispersal routes connecting habitat patches. Many GIS software packages can use land use/land cover maps to identify the route of least resistance between two points—the least-cost path. The limitation of this type of analysis is that only a single path is identified, even though alternative paths with comparable costs might exist. In this paper, we implemented two graph theory methods that extend the least-cost path approach: the Conditional Minimum Transit Cost (CMTC) tool and the Multiple Shortest Paths (MSPs) tool. Both methods enable the visualization of multiple dispersal routes that, together, are assumed to form a corridor. We show that corridors containing alternative dispersal routes emerge when favorable habitat is randomly distributed in space. As clusters of favorable habitat start forming, corridors become less redundant and

dispersal bottlenecks become visible. Our approach is illustrated using data from a real landscape in the Brazilian Atlantic forest. We explored the effect of small, localized disturbance on dispersal routes linking conservation units. Simulated habitat destruction caused the appearance of alternative dispersal routes, or caused existing corridors to become narrower. These changes were observed even in the absence of significant differences in the length or cost of least-cost paths. Last, we discuss applications to animal movement studies and conservation initiatives.

## Introduction

Animal movement can occur at a range of temporal scales, influencing foraging, migration, and gene flow (Crooks and Sanjayan 2006). The dispersal routes associated with these processes can be strongly constrained by the landscape matrix. Thus models specifying the effect of matrix heterogeneity on movement rates can more successfully predict patch occupancy (Ricketts 2001; Verbeylen et al. 2003), metapopulation dynamics (Vandermeer and Carvajal

2001), genetic structure (Stevens et al. 2006), and persistence in fragmented landscapes (Laurance et al. 2002). The role of behavior and natural history in shaping species' responses to the matrix has recently motivated the concept of functional connectivity (Calabrese and Fagan 2004). While many connectivity studies have described the influence of different land cover types in channeling or repelling movement of particular species (e.g., Burel 1996; Lees and Peres 2008), few tools are available to integrate data on matrix heterogeneity and species' habitat preferences to model dispersal routes.

A challenge in modeling animal dispersal routes is that individuals rarely use a single optimum route (e.g., Driessen et al. 2007), and connectivity measures focusing on optimum routes fail to incorporate variation in individual behavior (Belisle 2005). In this paper, we model the location of multiple dispersal routes across a heterogeneous matrix. We employ a movement model that assumes successfully dispersing organisms are more likely to use the route of least resistance when moving between two points, or the least-cost path. Despite its simplifying assumptions, the least-cost path has been successfully used to predict patch occupancy (Chardon et al. 2003; Verbeylen et al. 2003) and inter-patch movement rates (Sutcliffe et al. 2003). The least-cost path is identified using a graph theory algorithm, Dijkstra's breadth-first search (Cormen et al. 2001). Many GIS software packages have functions to locate the least-cost path between two points. Although only one path is obtained, Dijkstra's algorithm can be easily modified to output multiple paths with similar costs. We describe this modification and its two outputs, the Conditional Minimum Transit Cost (CMTC) and the Multiple Shortest Paths (MSPs).

We propose that corridors are heterogeneous structures that may contain multiple dispersal routes. However, we do not advocate a method for designing corridors (including few or many dispersal routes), neither do we attempt to quantify corridors' role in conserving biodiversity. Rather, our goal is to integrate information on species' habitat preferences into regional-scale depictions of habitat connectivity. This paper has three parts. First, we applied our method to artificial landscapes in order to illustrate the effect of matrix heterogeneity on the cost and spatial distribution of dispersal routes. Second, we studied the effect of small, localized disturbance on

large-scale dispersal routes. This was performed using data from the highly fragmented Brazilian Atlantic forest (Morellato and Haddad 2000). Last, we discussed how the approach proposed here can be refined and incorporated in animal movement studies and conservation initiatives.

## Methods

### The landscape graph

In this section, we describe the approach routinely employed to perform any type of distance calculations on grids. Most GIS software packages use graphs (Urban and Keitt 2001) to represent grid maps. Graphs are composed of vertices ( $V$ ) placed on cell centers, and edges ( $E$ ) that connect each vertex to its eight nearest neighbors (Fig. 1). Using this representation, we define two cost grids:

- Relative cost grid (Figs. 2a, 3a), also referred to as a friction layer (Verbeylen et al. 2003). Each vertex contains the relative cost to cross it in any direction.
- Cumulative cost grid (Figs. 2b, 3b). Consider a source ( $S$ ) composed of one or more vertices. Each vertex in the cumulative cost grid contains the minimum cumulative cost to reach  $S$ . This is calculated in two steps: first, the cost to move between pairs of vertices is stored as edge weights. The weight  $W$  for an edge connecting vertices  $V1$  and  $V2$  is calculated as:

**Fig. 1** The landscape graph. In most software packages, grid maps are internally represented as a graph. Vertices ( $V$ ) are located in cell centers. Each vertex is connected to its eight nearest neighbors by an edge ( $E$ ). Edge weights (not shown) hold information on the cost to move between pairs of vertices

**Fig. 2** Illustration of the procedure for calculating the CMTC. **a** Relative cost grid. **b** The cumulative cost grid for the target (*left*) and the source (*right*). Lighter shades indicate lower cumulative cost. **c** The two grids from (**b**) are added to produce the CMTC grid

$$W = [\text{Relative Cost (V1)} + \text{Relative Cost (V2)}] / 2 \quad (1)$$

For diagonal edges, edge weights  $W'$  are calculated as:

$$W' = W \times \sqrt{2} \quad (2)$$

Second, Dijkstra's breadth-first search algorithm (Cormen et al. 2001) is used to calculate the least-cost path between  $S$  and each vertex in the graph. The minimum cumulative cost between  $S$  and a given vertex ( $V$ ) is the sum of all edge weights in the least-cost path connecting  $S$  and  $V$ . To calculate the

**Fig. 3** Illustration of the procedure for locating MSPs. **a** Relative cost grid, **b** cumulative cost grid for the source. Lighter shades indicate lower cumulative cost. This was calculated after rebuilding the graph that represents the landscape, **c** with the cumulative cost grid, we trace the least-cost path between source and target, **b** and **c** are repeated 100 times to produce 100 least-cost paths

least-cost path between two habitat patches  $P1$  and  $P2$  we define all vertices in  $P1$  as sources and all vertices in  $P2$  as targets. The least-cost path between patches  $P1$  and  $P2$  will most likely link the two patches' most external vertices.

In the next two sections, we build on the above representation and describe two methods that extend Dijkstra's breadth-first search algorithm.

### Conditional minimum transit cost (CMTC)

Consider a vertex ( $V$ ) located between groups of source vertices ( $S$ ) and target vertices ( $T$ ). The Conditional Minimum Transit Cost (CMTC) for  $V$  is the cost-weighted distance to move from  $S$  to  $T$ , conditional on the route forming the shortest passage between  $S$  and  $T$  while passing through  $V$ . It is calculated as (Fig. 2):

$$\text{CMTC}(V, S, T) = \text{Cumulative cost}(V, S) + \text{Cumulative cost}(V, T) \quad (3)$$

The final CMTC grid was obtained by masking out all cells with CMTC values larger than the minimum CMTC value plus 10% (Fig. 2c). The remaining values were then divided by the grid's maximum CMTC. According to Forman (1995), a corridor is "a narrow strip of land that differs from the matrix on either side". We assume that areas within the 10% threshold form corridors, but emphasize that our choice of corridor width was arbitrary.

Our analysis generates corridors that are highly heterogeneous. Visually inspecting the CMTC grid (Fig. 2c) enables identification of contiguous cells with low CMTC value. We refer to these cell groups as "dispersal routes", while recognizing that distinction between routes that are close together is arbitrary. The least-cost path is invariably located within one dispersal route.

In practice, obtaining a CMTC grid is straightforward with modules such as spatial analyst within ArcGIS (Esri, California). Some conservation biologists strongly advocate the CMTC approach for designing wildlife corridors (Majka et al. 2007). But to our knowledge, the relationship between matrix heterogeneity and the distribution of dispersal routes as predicted by the CMTC has not yet been explored.

### Multiple shortest paths (MSPs)

We developed a stochastic version of Dijkstra's algorithm (Fig. 3) that outputs multiple realizations of the least-cost path, or Multiple Shortest Paths (MSPs). As described above, the least-cost path is obtained from a relative cost grid. Dijkstra's breadth-first search algorithm (Cormen et al. 2001) proceeds by iteratively marking vertices in the order of their cumulative distance from the source. At each step, the algorithm must identify the set of neighbors

associated with the marked vertices. Standard algorithms use a static definition of the neighborhood, typically the nearest eight cells on a rectangular grid (Fig. 1). Our approach is to redefine the neighborhood as a stochastic function such that adjacency is non-deterministic and is instead determined randomly in proportion to edge weights. The algorithm proceeds as follows (Fig. 3):

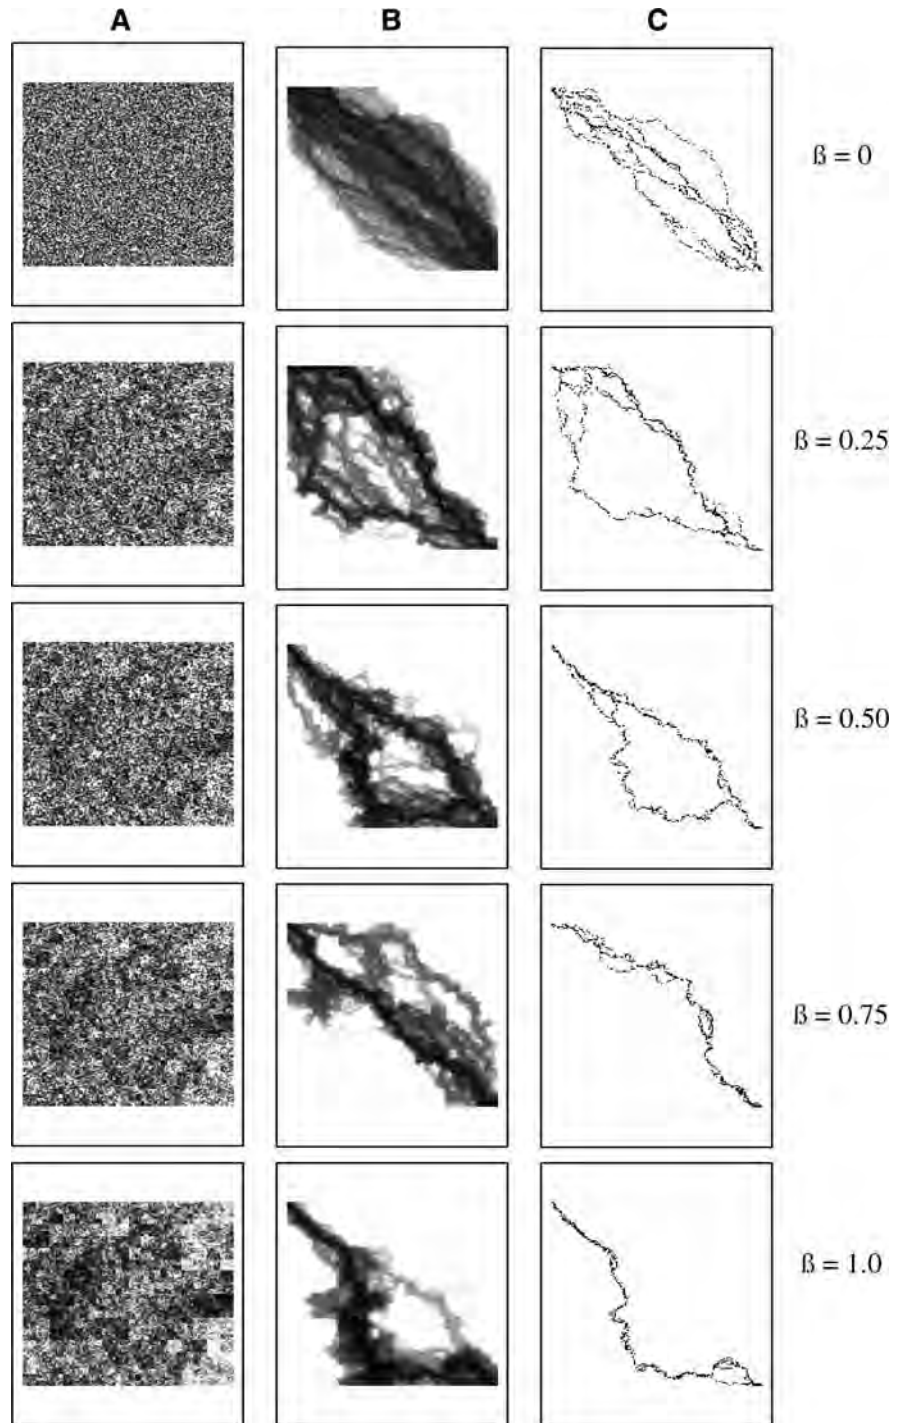

1. Draw a number ( $U$ ) between 0 and 1 from a random uniform distribution.
2. Delete edges in the graph. An edge with weight  $W$  connecting two adjacent vertices  $V1$  and  $V2$  is deleted if  $W > U$ . That is, connections with lower costs are more likely to be maintained.

A program implementing Dijkstra's algorithm (with the above modification) was run 100 times in order to produce 100 MSPs for each study case (Fig. 3c shows one path). The cumulative cost associated with each path is a measure of effective distance and is calculated by adding the weights of all edges in the path. The programs used to obtain both CMTCs and MSPs were written in the Java programming language.

### Applications to artificial landscapes

We generated artificial landscapes with different degrees of spatial autocorrelation using the method of wavelet synthesis (Keitt 2000). We started with a grid containing values between 0 and 1, drawn from a random uniform distribution. Using this grid, each landscape was created in four steps: (a) apply the discrete Haar wavelet transform; (b) obtain wavelet coefficients; (c) multiply coefficients by  $2^{-L} \beta$ , where  $L$  is the coefficient level (higher levels representing low-frequency variation); (d) apply the inverse Haar wavelet transform on the modified coefficients; (e) map results to a random uniform distribution (min = 0; max = 1). The last step is taken to ensure that the distribution of quality values is consistent across all landscapes. The values of the parameter  $\beta$  were 0, 0.25, 0.50, 0.75, and 1. A  $\beta$  value of zero generates a white noise landscape with no spatial autocorrelation. Increasing  $\beta$  produces autocorrelated landscapes, where clusters of favorable habitat can be identified. Each artificial landscape represents one relative cost grid that served as input in calculations of CMTC and MSPs (Fig. 4a). We used ANOVA to test for differences among landscapes, in terms of

**Fig. 4** Relative cost grids generated with the use of wavelet transforms (a), and the values of CMTC (b) and location of MSPs (c) for each landscape. A  $\beta$  value of 0 is a landscape with no spatial autocorrelation in habitat quality values, and landscapes become “patchier” as  $\beta$  values increase

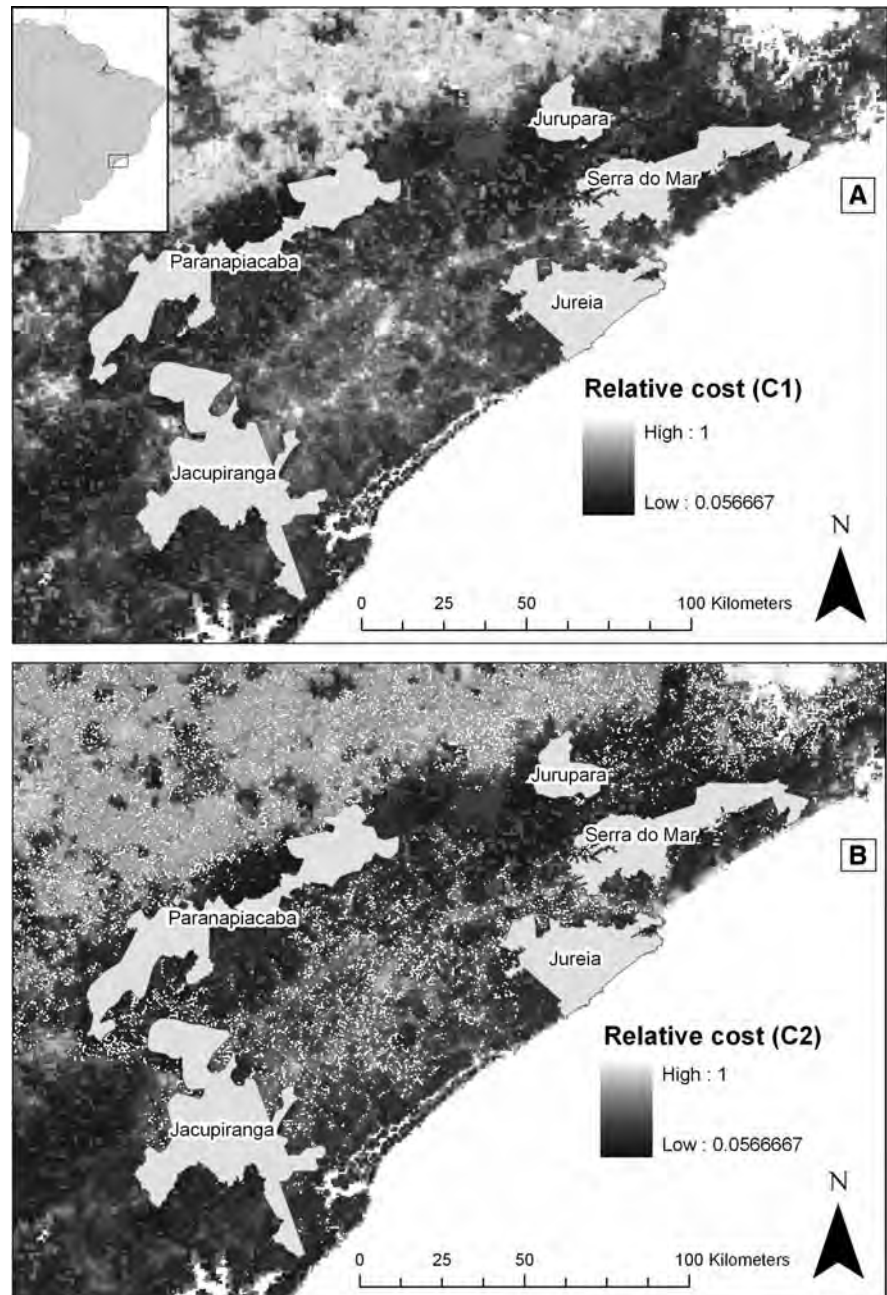

cumulative costs associated with MSPs and mean CMTC. The generation of artificial landscapes and ANOVA tests were performed using the R programming language (R Core Development Team 2008).

#### Applications to real landscapes

We studied a real landscape (Fig. 5) that covers 111 km<sup>2</sup> of the Brazilian state of São Paulo (upper

**Fig. 5** Study site in the Brazilian Atlantic forest, showing conservation units in Sao Paulo State. **a** Relative cost values for scenario C1. **b** Relative cost values for scenario C2 (after deletion of small forest fragments)

left coordinates: 23.60S, 49.00W; lower right coordinates: 25.40S, 46.20W). Remaining forests are part of the Atlantic forest biome (for a description, see Oliveira-Filho and Fontes 2000). Despite its location in highly industrialized São Paulo state, the study area still contains large forest tracts and rural properties. A recent vegetation map (Eva et al. 2002) estimates that 11.1% of the study area is devoted to intensive agriculture, 7% contains a mix of

agriculture and degraded vegetation, 23% is a mix of agriculture and degraded forest, and 46% is covered with forest. Excluding São Paulo's metropolitan area, human populations per municipality range in size from 3,403 to 412,243 (mean = 60,410; IBGE 1991). Five conservation units are considered here: Pedro de Toledo Nucleus within Serra do Mar State Park (868 km<sup>2</sup>), Jureia-Itatins Ecological Reserve (801 km<sup>2</sup>), Jurupara State Park (259 km<sup>2</sup>),

Jacupiranga State Park (1,552 km<sup>2</sup>), and the contiguous units Intervales State Park, Carlos Botelho State Park, Ecological Station Xitué, and Alto do Ribeira Touristic State Park (1,282 km<sup>2</sup>), referred together here as “Paranapiacaba” due to their location along the Paranapiacaba Valley.

Our analyses consisted of modeling dispersal routes between all pairs of conservation units. We have built a relative cost map in an attempt to capture the habitat preferences of species that move in forested areas and suffer higher mortality when crossing disturbed habitat. In the discussion, we describe how more detailed models can be built and refined to reflect the habitat preferences of a particular species. Three land use/land cover maps were the main input for our analyses (Table 1).

1. The Modis continuous fields, (Hansen et al. 2003) contains estimates of percent tree cover. Values were manipulated (Table 1) in order to obtain a grid with values ranging between 0 (=100% tree cover) and 1 (=no tree cover).
2. The human footprint map (Sanderson et al. 2002) is a global dataset with estimates of anthropogenic impact ranging from 0 (pristine land) to 100 (most disturbed land), normalized per ecosystem. These estimates were based on patterns of human population density, land use, and transportation networks. We divided original values by 100 (Table 1) to obtain a grid with values ranging from 0 (=pristine land) to 1 (=most disturbed land).
3. The South American vegetation map (SAVM; Eva et al. 2002) contains information on forest distribution, degree of forest disturbance, and mixture with agricultural lands. We assigned

each class in the SAVM grid (Table 1) a relative cost value ranging from 0 (=closed or dense forest) to 1 (intensive land use or non-forested ecosystems).

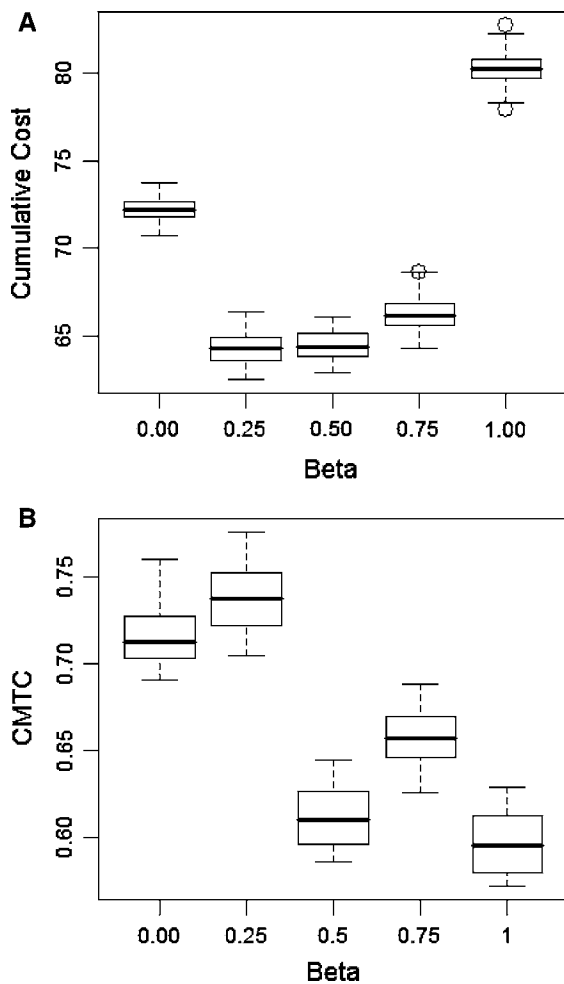

The Footprint and SAVM grids were rescaled so as to bring their spatial resolution to 500 m. The first relative cost map (C1; Fig. 5a) was obtained by averaging the values in the three grids described above (Table 1). As a result, we obtained a grid where cell values ranged from 0.057 (minimum relative cost to cross) to 1 (maximum relative cost to cross).

The second cost map (C2; Fig. 5b) simulated the removal of small forest fragments from C1, which could result from clear cutting, selective logging, or road construction. Results do not necessarily reflect actual land cover changes taking place in the Atlantic forest, but they enable us to explore the effect of small, localized disturbance on regional connectivity patterns. The C2 map was built in three steps. First, we produced a binary map with areas classified as “forest” or “non-forest” based on the SAVM map. This binary map was eroded and dilated (Serra 1982) by 0.5 pixel, resulting on the deletion of fragments with area <5 ha and linear elements (such as riparian corridors) <500 m wide. Last, C2 was obtained by assigning the maximum relative cost (1) to the deleted cells. All other cells contained the same values as C1, and the range of relative cost values for the entire grid remained unchanged (0.057–1). It was assumed that individuals could not move through water, thus a cost value of positive infinity was assigned to cells representing water bodies in both C1 and C2 scenarios. Finally, we calculated the CMTC and MSPs for both C1 and C2 scenarios. All GIS layers were processed using programs written in Java

**Table 1** Grids used to construct the relative cost maps used in the present study, their original spatial resolution (pixel size), period of data collection, and operations performed on original grid values

Layer	Resolution (m)	Years	Operations performed on the original raster values
South America vegetation map	1,000	1995–2000	0 = closed, dense, transitional forest 0.25 = open forest 0.5 = mosaic agriculture/degraded forest 0.75 = shrubland, savannah, grassland 1 = intensive agriculture, mosaic agriculture/ degraded vegetation, desert, urban
Human footprint	1,000	1960–2001	Final value = (original value)/100
Modis continuous fields, % tree	500	2000–2001	Final value = (100 – original value)/100

**Fig. 6** The distribution of values of **a** Multiple Shortest Paths **b** and Conditional Minimum Transit Costs. A  $\beta$  value of 0 is a landscape with no spatial autocorrelation in habitat quality values, and landscapes become “patchier” as  $\beta$  values increase

programming language, and illustrations were produced in ArcMap (Esri, California).

## Results

### Artificial landscapes

The two graph theory approaches proposed here outlined the influence of matrix heterogeneity on dispersal routes. We detected a significant difference in mean cumulative costs associated with Multiple Shortest Paths (MSPs) among the five artificial landscapes (ANOVA,  $F = 6,934.5$ ;  $P < 0.001$ ). MSPs with lowest costs were observed when

landscapes had intermediate patchiness (Fig. 6a; Tukey multiple comparisons of means, 95% family-wise confidence level,  $P < 0.001$ ). We also observed significant differences in mean Conditional Minimum Transit Cost (CMTC) values (ANOVA,  $F = 474,104$ ;  $P < 0.001$ ). The most autocorrelated landscapes produced the lowest CMTC values (Fig. 6b; Tukey multiple comparisons of means, 95% family-wise confidence level;  $P < 0.001$ ). In addition, we observed differences in the spatial distribution of dispersal routes. Landscapes with little autocorrelation in relative habitat quality produced redundant corridors with more alternative dispersal routes (Fig. 4;  $\beta$  closer to 0). As clusters of favorable habitat started to form, corridors became restricted to fewer routes (Fig. 4;  $\beta$  closer to 1). This was evidenced in the outputs of both the CMTC and MSPs calculations.

### Real landscapes

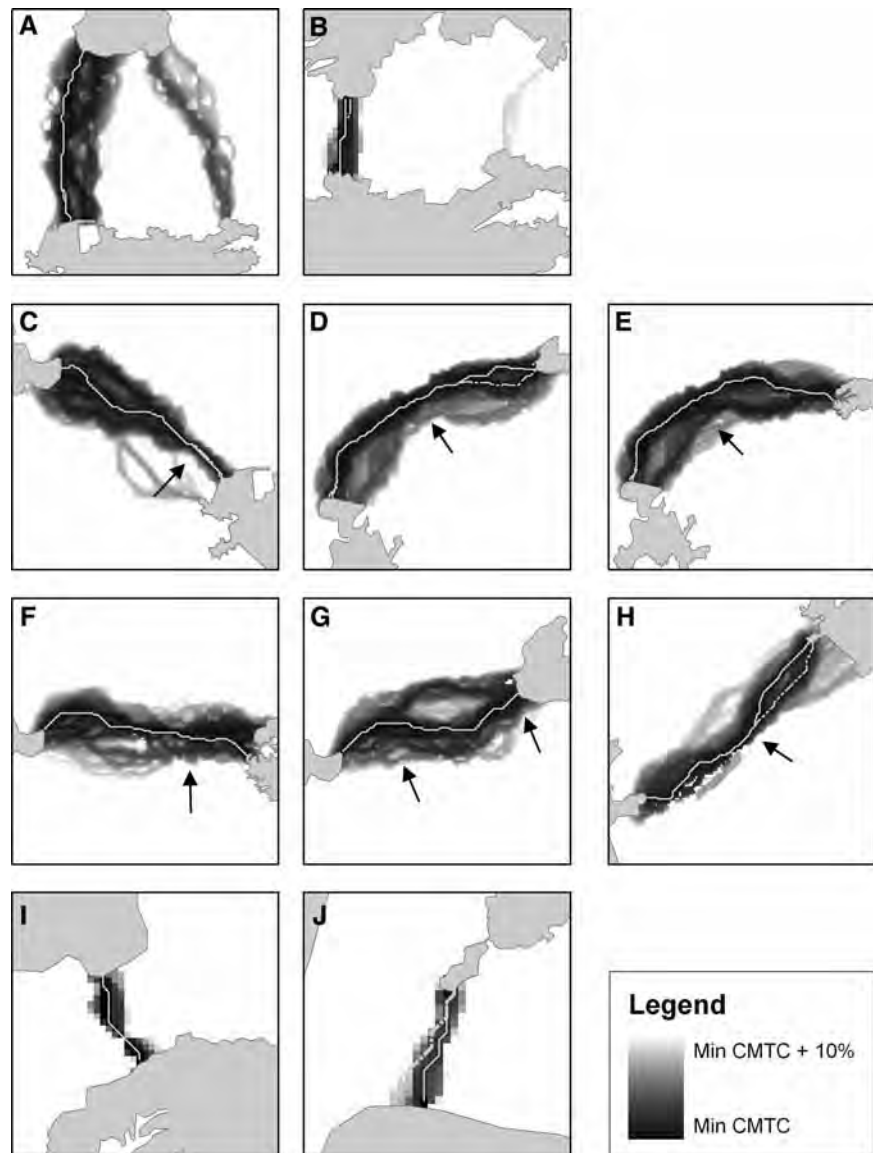

We tested the influence of small, localized disturbance on corridors connecting five conservation units in the Brazilian Atlantic forest (Fig. 5). There were no significant differences in mean cumulative path costs calculated from MSPs, or in mean CMTC values ( $t$ -test,  $P > 0.05$ ) between scenarios C1 and C2. But in most cases, simulated fragment removal influenced the spatial distribution of dispersal routes. Since small fragments were not homogeneously distributed in the study area, corridors obtained under scenario C1 were differentially affected by simulated fragment removal in scenario C2 (Table 2).

**Table 2** Conservation units included in the present study

	Jacupiranga	Jurupará	Serra do Mar	Paranapiacaba
Juréia	72.321	35.391	6.905	3.993
	5	3.6	10.4	5.5
Jacupiranga		115.502	104.800	7.868
		4.0	5.0	21.0
Jurupará			7.263	43.739
			2.0	1.2
Serra do Mar				51.183
				2.3

Each unit in a pair can serve as a source or a target for dispersing organisms. The first line contains the straight-line distance between units (in kilometers), and the second line shows the percentage of 500-m<sup>2</sup> cells deleted from the corridor as a result of simulating fragment removal

**Fig. 7** CMTC grids for the corridor connecting conservation units in São Paulo, Brazil. The pairs are: **a** Jurupará–Juréia, **b** Juréia–Serra do Mar, **c** Juréia–Paranapiacaba, **d** Jacupiranga–Jurupará, **e** Jacupiranga–Serra do Mar, **f** Paranapiacaba–Serra do Mar, **g** Paranapiacaba–Jurupará, **h** Juréia–Jacupiranga, **i** Serra do Mar–Jurupará, **j** Paranapiacaba–Jacupiranga. *Gray lines* show the least-cost path. *Solid lines* represent least-cost paths obtained for scenarios C1 and C2, whereas *interrupted lines* represent sections of the least-cost path obtained for scenario C2 only. *Arrows* indicate potential dispersal bottlenecks

In most cases, the CMTC grid displayed more than one alternative route between conservation units, one of them being the least-cost path (Fig. 7a–h). When conservation units were close, the distance between them was small with respect to the variation in their shape. In this case, the CMTC grid produced narrow corridors, coinciding with the links representing the shortest Euclidian distance (Fig. 7b, i, j). When corridors contained alternative routes, these were rarely disjoint (Fig. 7a, b). The constriction zones where dispersal routes merged represented potential dispersal bottlenecks (Fig. 7c–h). In most cases, the

location of the least-cost path did not change substantially as a result of small fragment removal (Fig. 7a–c; e–g; i, j). But in two cases, the least-cost path for scenario C2 was displaced to an alternative route located a few kilometers away from the least-cost path for scenario C1 (Fig. 7d, h).

We also identified the MSPs between pairs of conservation units. Compared to the CMTC calculation, this tool provided a better assessment of the impact of fragment removal on corridor redundancy. Examining the MSPs produced for the scenarios C1 and C2, we observed two trends. In some cases,

**Fig. 8** Location of the first 100 least-cost paths connecting conservation units in São Paulo, Brazil.

**a** Jacupiranga–Serra do Mar, scenario C1; **b** Jacupiranga–Serra do Mar, scenario C2; **c** Juréia–Paranapiacaba, scenario C1; **d** Juréia–Paranapiacaba, scenario C2; **e** Serra do Mar–Paranapiacaba, scenario C1; **f** Serra do Mar–Paranapiacaba, scenario C2

fragment removal led to the disappearance of external dispersal routes; corridors became narrower and less redundant (Fig. 8). In other cases, new, more external routes emerged after fragment removal (Fig. 9).

## Discussion

Analyses of artificial landscapes show the influence of matrix heterogeneity on landscape connectivity. Redundant corridors with multiple alternative dispersal routes emerged in white noise landscapes, where favorable habitat is randomly distributed (Fig. 4,  $\beta$  closer to 0). As patches of favorable habitat started forming, corridors became narrower and less redundant (Fig. 4,  $\beta$  closer to 1). The cumulative cost of MSPs was on average lower in landscapes with intermediate degree of

autocorrelation (Fig. 6a). This is because paths in white noise landscapes will often cross areas of high cost, whereas the presence of contiguous habitat patches in autocorrelated landscapes can lead to longer, more tortuous paths (Fig. 4c). The CMTC was on average lower in autocorrelated landscapes (Fig. 6b). This follows from our choice of CMTC value used to delimit corridors—under a 10% threshold, white noise landscapes produced wider corridors with higher CMTC values.

In addition to studying artificial landscapes, we illustrated our methods using data from a real landscape in the Brazilian Atlantic forest. In this region, a complex landscape matrix produced dispersal routes that were not apparent in land use/land cover maps (Fig. 7a–f, h–j), with the exception of the pair Paranapiacaba–Jurupará that is separated by an artificial dam (Fig. 7g). CMTC maps revealed highly

heterogeneous corridors displaying bottlenecks to animal movement (indicated by arrows in Fig. 7c–h). Removing small fragments did not produce a significant increase in the mean cumulative cost of MSPs but led to changes in their spatial distribution (Figs. 8, 9). Our work illustrates two possible large-scale effects of small, localized disturbance on the landscape matrix. Narrower corridors were produced (Fig. 8), and the importance of external dispersal routes increased (Fig. 9). The latter case included the two pairs of conservation units with the largest amount of deleted habitat in the scenario C2 (Table 2; Fig. 9c–f).

Results of least-cost path analyses are strongly dependent on the selection of relative cost grids (Adriaensen et al. 2003; Rae et al. 2007). Our choice of relative cost grids (Table 1) was made as an attempt to approximate the habitat preferences of a

forest specialist. Relative cost grids can be further refined and validated for a particular species using patch occupancy data (Verbeylen et al. 2003) or from ecological niche modeling and tools such as the Mahalanobis distance (Farber and Kadmon 2003). In addition to habitat preference estimates, an important issue is the time scale over which individuals are expected to disperse. Here, we were not concerned with the time interval or number of generations that individuals (or populations) took to move between source and target fragments (conservation units). More realistic models can be obtained by adjusting the maximum Euclidian distance allowed between source and target fragments so as to match the maximum distance that can be crossed by a species given a particular time interval (Keitt et al. 1997). The issue of time scale is related to the question of whether corridors should function as habitat or as

**Fig. 9** Location of the first 100 least-cost paths connecting conservation units in São Paulo, Brazil. **a** Serra do Mar–Jurupara, scenario C1; **b** Serra do Mar–Jurupará, scenario C2; **c** Paranapiacaba–Jacupiranga, scenario C1; **d** Paranapiacaba–Jacupiranga, scenario C2; **e** Juréia–Serra do Mar, scenario C1; **f** Juréia–Serra do Mar, scenario C2

conduits (Hess and Fischer 2001)—i.e., individuals are expected to spend more time in habitat corridors. Corridor width can be adjusted by increasing the CMTC threshold to ensure that corridors contain minimum habitat requirements.

The ability to identify multiple dispersal routes can be desirable in conservation studies, for three main reasons. First, least-cost paths have been employed in the design of linked reserve systems (Hector et al. 2000; Schadt et al. 2002; Larkin et al. 2004). This approach, however, can lead to very narrow linkages (Alagador and Cerdeira 2007) that might not be located in land tracts available for purchase. Second, dispersal routes that appear similar may differ in terms of their conservation value. For example, field studies in Canada (Clevenger et al. 2001) show that drainage culverts can act as habitat linkages for several mammal species, but culverts near roads with higher traffic volume and noise levels are less commonly used. Third, the approach shown here enable the visualization of functionally unique landscape structures (Manning et al. 2006): narrow corridors or dispersal bottlenecks within corridors (e.g., Fig. 7).

Considerable attention has been given to quantifying the role played by agroecosystems in conservation (i.e., Bestelmeyer and Wiens 1996; Reitsma et al. 2001; Mas and Dietsch 2003). Agricultural lands can help support wild populations by providing critical habitat (Moguel and Toledo 1999) and influencing neighboring fragments, in which case potential outcomes depend on the spatial configuration and degree of mixture with pristine habitat (Perfecto and Vandermeer 2002; Perfecto et al. 2003; Tscharrntke et al. 2005). Our study of the Brazilian Atlantic forest shows that private lands can collectively influence ecological processes occurring at large spatial scales and supports the assertion that small fragments can potentially shape regional patterns of gene flow (Bodin et al. 2005). This raises the necessity to view agricultural lands' contribution to biodiversity in a larger context.

Movement behavior is a key aspect in functional connectivity studies, but detailed data on animal movement remains hard to collect, especially for large spatial scales. In fact, the ability to produce accurate movement models has long been recognized as one of the main challenges of population biology

studies (Turchin 1998). There is no consensus on the amount of biological detail that should be used in functional connectivity studies. It has been suggested that movement models ought to increase in complexity in order to capture the behavior of particular species (Goodwin 2003). At the same time, conservation biologists have raised the need for rigorous methods that predict the location of dispersal routes for many species (Boitani et al. 2007). Clearly a compromise is needed, which requires determining how much simplification can be made before losing predictive power (Baguette and Van Dyck 2007). Least-cost path predictions can be derived for many species, given the ever growing maps of habitat quality produced by ecological niche modeling. Also, rigorous protocols already exist to compare least-cost predictions with field data (Driezen et al. 2007).

## Conclusions

In the present paper, we extended the graph theory algorithm that serves as the basis for least-cost path calculations. The two outputs are the Conditional Minimum Transit Cost (CMTC) and the Multiple Shortest Paths (MSPs). Our goal was to integrate information on habitat preferences to model dispersal patterns across a heterogeneous matrix. In addition to the path of least resistance between two points, the methods presented here outlined additional paths with similar length and relative cost. Results from artificial landscapes show that the location and relative cost of dispersal routes are strongly influenced by the spatial distribution of favorable habitat in the matrix. In addition, study of a real landscape shows that small, localized disturbance such as removal of small fragments can affect large-scale dispersal routes. Models producing multiple dispersal routes present a practical advantage over models assuming optimum behavior. Although the choice of number of dispersal routes or their location is application specific (and beyond the scope of this paper), our results suggest that the least-cost path is a flexible approach with a wide range of applications.

---

**Abstract:** *Urbanization and habitat fragmentation are major threats to wildlife populations, especially mammalian carnivores. We studied the ecology and behavior of bobcats (*Lynx rufus*) and coyotes (*Canis latrans*) relative to development in a fragmented landscape in southern California from 1996 to 2000. We captured and radiocollared 50 bobcats and 86 coyotes, determined home ranges for 35 bobcats and 40 coyotes, and measured their exposure to development ("urban association") as the percentage of each home range composed of developed or modified areas. Both species occupied predominantly natural home ranges. Adult female bobcats had low levels of urban association, significantly lower than coyotes, adult male bobcats, and young female bobcats. Home-range size was positively correlated with urban association for coyotes and adult male and young female bobcats, suggesting that human-dominated areas were less suitable than natural areas in some important way. Animals more associated with non-natural areas had higher levels of night activity, and both bobcats and coyotes were more likely to be in developed areas at night than during the day. Survival rates were relatively high and were not related to urban association, at least for animals >6-9 months of age. Mortality rates from human-related causes such as vehicle collisions and incidental poisoning were also independent of urban association. In this region, even the few animals that had almost no human development within their home range were vulnerable to human-related mortality. Carnivore conservation in urban landscapes must account for these mortality sources that influence the entire landscape, including reserves. For bobcats, preserving open space of sufficient quantity and quality for adult females is necessary for population viability. Educating local residents about carnivores is also critical for conserving populations in urban areas.*

Efectos de la Urbanización y la Fragmentación del Hábitat sobre Gatos Silvestres (*Lynx rufus*) y Coyotes en el Sur de California

**Resumen:** *La urbanización y la fragmentación del hábitat son las amenazas más grandes para las poblaciones de animales silvestres, especialmente de mamíferos carnívoros. Estudiamos la ecología y conducta de gatos silvestres (*Lynx rufus*) y coyotes (*Canis latrans*) en relación al desarrollo en un paisaje fragmentado del sur de California entre 1996 y 2000. Capturamos y colocamos collares de radiotelemetría en 50 gatos silvestres y 86 coyotes, y determinamos los rangos de hogar para 35 gatos y 40 coyotes y medimos su exposición al desarrollo urbano ("asociación urbana") como el porcentaje de cada rango de hogar compuesto por áreas desarrolladas o modificadas. Ambas especies ocuparon rangos de hogar naturales en su mayoría. Las hembras adultas de gatos silvestres mostraron niveles bajos de asociación urbana, significativamente menores que los coyotes, los machos adultos y las hembras jóvenes de gatos silvestres, lo cual sugiere que estas áreas dominadas por humanos fueron notablemente menos adecuadas que las áreas naturales. Los animales más estrechamente asociados con áreas no naturales, gatos adultos machos y coyotes, tienen niveles más altos de actividad nocturna y mayor probabilidad de ocupar áreas urbanizadas durante la noche que durante el día.*

Paper submitted September 28, 2001; revised manuscript accepted June 12, 2002.

*Las tasas de supervivencia fueron relativamente altas y no se relacionaban con la asociación urbana, al menos para animales >6-9 meses de edad. Las tasas de mortalidad por causas relacionadas con la población humana, tales como el atropellamiento por vehículos y el envenenamiento accidental también fueron independientes del desarrollo urbano. En esta región, los pocos animales que casi no incluían áreas urbanizadas en sus rangos de hogar, eran vulnerables a la mortalidad causada por humanos. La conservación de carnívoros en paisajes urbanos debe tomar en cuenta estas fuentes de mortalidad que afectan a todo el paisaje, incluyendo las reservas. Para la preservación de la viabilidad poblacional de gatos silvestres, hace falta conservar suficiente espacio abierto de calidad para hembras adultas. Es también de importancia crucial educar a los residentes locales sobre los carnívoros para conservar poblaciones en áreas urbanas.*

## Introduction

Conversion of natural habitat to human uses, including urban development, agriculture, and extractive industries such as mining and intensive forestry reduces the amount of intact natural habitat and fragments what remains (Saunders et al. 1991). Wide-ranging and low-density species such as mammalian carnivores are particularly vulnerable to the processes of habitat loss and fragmentation (Noss et al. 1996; Gittleman et al. 2001).

Some carnivores have adapted well to the presence of humans. Raccoons (*Procyon lotor*; Riley et al. 1998), skunks (*Mephitis mephitis*, Rosatte et al. 1990), and red foxes (*Vulpes vulpes*; Harris 1981) reach their highest densities in urban areas, and Crooks (2002) found that the relative abundance of gray foxes (*Urocyon cinereoargenteus*) and opossums (*Didelphis virginianus*) is highest in the smallest habitat fragments. Other species, however, are less able to coexist with humans. Large carnivores come into conflict with humans and their domestic animals, and more-specialized species may not benefit from human-associated foods such as ornamental fruit or garbage. Mammalian carnivores, although often controversial (Kellert et al. 1996), generate public interest and are often the focus of conservation. As top predators in many terrestrial ecosystems, carnivores may also affect other carnivores (Palomares & Caro 1999) and populations in lower trophic levels (Sovada et al. 1995; Crooks & Soulé 1999).

Bobcats (*Lynx rufus*) and coyotes (*Canis latrans*) are common predators throughout North America, yet little is known about how they respond to urban development and habitat fragmentation. A few studies have examined urban or suburban coyotes in southern California (Gill & Bonnett 1973), around Seattle, Washington, (Quinn 1997a; 1997b), in Tucson, Arizona (McClure et al. 1995; Bounds & Shaw 1997; Grinder & Krausman 2001a, 2001b), and in British Columbia (Atkinson & Shackleton 1991). Although interesting results have been obtained, particularly for urban coyote diets, the radiotracking components of these studies have all included <10 animals and have been of short duration, except for the study by Grinder and Krausman (2001a) which addressed largely younger animals (13 of 16). Harrison (1998) inter-

viewed residents in a rural residential area about bobcat sightings, and Riley (1999) studied bobcats and gray foxes in unfragmented habitats adjacent to urban areas in northern California. Studying bobcats and coyotes in an urban area allows an evaluation of how two relatively adaptable but also quite different carnivores are affected by urbanization. Although both bobcats and coyotes range across the entire continent and utilize a variety of habitats, coyotes are larger, more social, and more omnivorous than bobcats.

We studied the use of a fragmented urban landscape by bobcats and coyotes to better understand the conservation of carnivores in the face of urbanization. We estimated the level of exposure to development of these two carnivores by measuring the percentage of developed and altered area within their home range, or their "urban association." Our goals were to determine whether exposure to urban areas was related to species, age and sex class, homerange size, degree of nocturnal or diurnal activity, survival rates, and causes of mortality.

## Methods

### Study Area

Our study area was in the central Santa Monica Mountains and Simi Hills of southern California, west of the city of Los Angeles (Fig. 1). Natural vegetation varied and included mixed chaparral, coastal sage scrub, oak woodland and savanna, riparian areas, and introduced annual grasslands. Human land uses included commercial development, low- to high-density residential development, golf courses, landscaped areas in parks and adjacent to office buildings, agricultural land, and a 120-ha landfill. An 8- to 10-lane freeway (U.S. Route 101) and numerous secondary roads intersected the study area (Fig. 1).

### Animal Capture and Radiotelemetry

Bobcats and coyotes were captured with padded foothold traps and necksnare. Captured animals were fitted with radiocollars with activity/mortality sensors that indicated whether animals were active, inactive, or dead

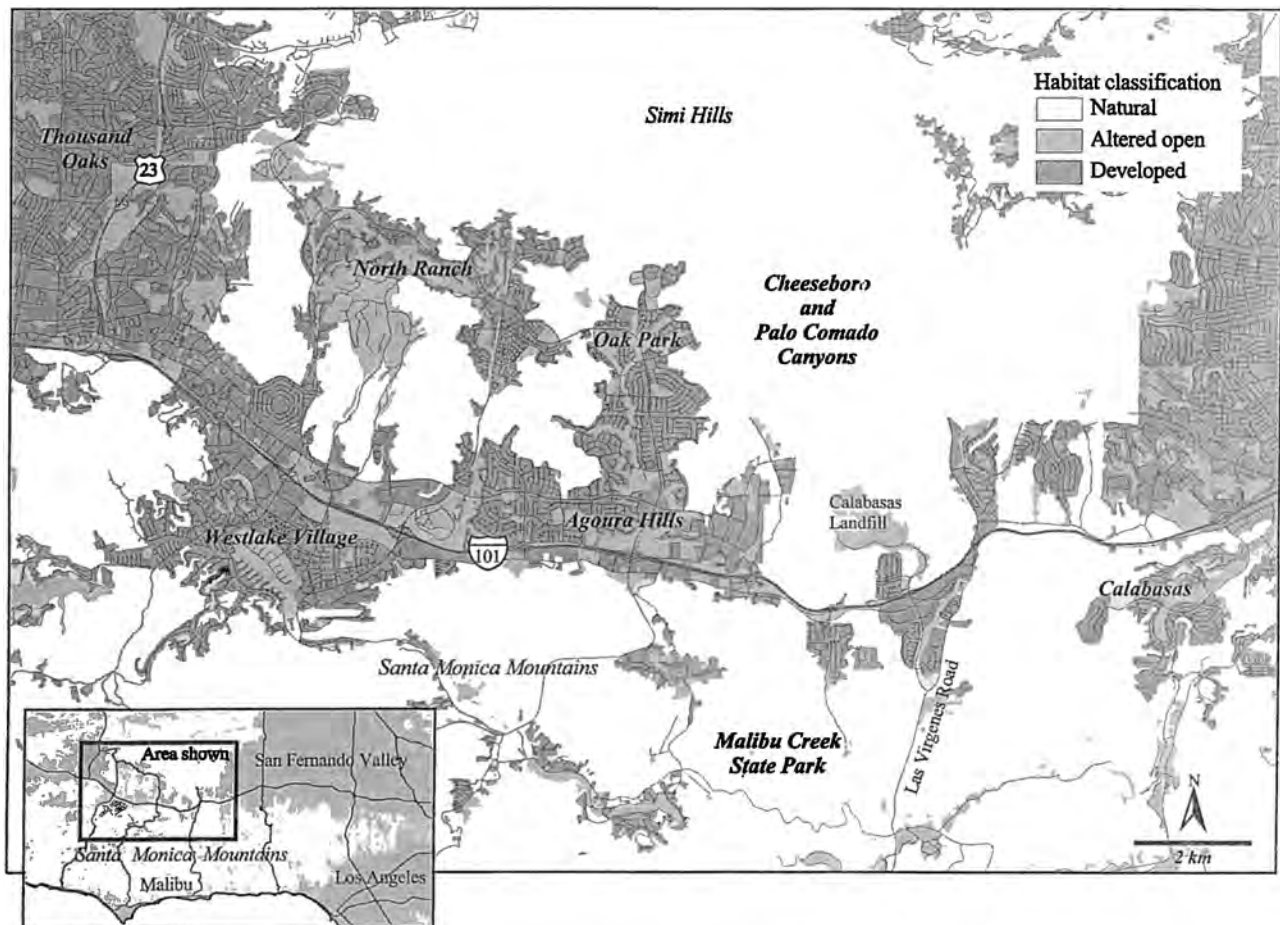

Figure 1. Land-use classification of bobcat and coyote study area in Los Angeles and Ventura Counties, California. The landscape within the study area was classified according to three land-use types: developed areas, altered open areas, and natural areas.

by variation in signal frequency (Advanced Telemetry Systems, Isanti, Minnesota, and Telemetry Solutions, Concord, California). We recorded sex, weight, morphological measurements, and age (juvenile, yearling, adult) for each animal. Juvenile animals were equipped with radiocollars with compressible polyurethane foam inserts to accommodate growth. “Young” animals included juveniles (0–1 year) and yearlings (1–2 years). To locate radiocollared animals by ground triangulation, observers recorded azimuths and their own location. We measured the accuracy of the radiotelemetry with test collars by comparing geographic positioning system locations of the collars to triangulated locations. Mean error distance was 42.4 m (SD = 50.2). This measure may underestimate the error of some locations, because test collars were generally close to the observers. However, we minimized the distance between observers and collared animals to acquire accurate locations, especially near land-use edges. We rechecked locations in or near the urban edge before conducting analyses, and we discarded those locations for which the observer was not

positioned along the urban edge because we could not know with certainty on which side of the edge the animal was located.

#### Estimates of Home Range

We used minimum convex polygon (MCP) home ranges (Hayne 1949) for our analyses because they more accurately characterized the landscape used by radiocollared animals in our study area. The highly fragmented nature of the landscape produced clumps of locations in disjunct areas, and kernel home ranges for these animals often included separate polygons with no utilized area in between, but these areas were potentially important. Our study area also had many linear boundaries, such as roads and freeways, across which many animals rarely or never moved, and kernel home ranges included areas on the far side of such boundaries, whereas MCPs did not. Home-range area-observation curves reached asymptotes around 20 locations, so we determined home ranges for each animal with  $\geq 20$  radiolocations. Over

our 4-year study, some animals made home-range shifts. If an animal completely shifted its area of use, we computed the home range based on the area that was used for the longest period. We estimated two different home ranges for one male bobcat that spent substantial time in two distant areas. We compared home-range size between species and age and sex groups with Mann-Whitney *U* tests.

### Urban Association

To classify land use in the study area, we generalized a digital land-use map (Southern California Association of Governments 1993) into three types of land use: natural areas, developed areas, and altered open areas (Fig. 1). "Natural areas" consisted of large, contiguous areas of natural vegetation. "Developed areas" included commercial and residential areas with at least one house per 0.40 ha (1 acre). "Altered open" areas included golf courses; the Calabasas Landfill; graded areas (e.g., future construction sites); landscaped lawns such as office parks, playing fields, and city parks; low-density residential areas (one house per 2 ha), and small patches or strips of natural vegetation within high-density residential development (e.g., stream corridors). These altered open areas were potentially more attractive to carnivores than developed areas.

We measured urban association as the percentage of each animal's home range consisting of these non-natural types of land use. Land-use association can also be measured by calculating the percentage of locations that occurred in the different types of land use (e.g., Mannan & Boal 2000), and contrasting the percentage of locations with the home range or the percentage of the home range with the study area could illuminate habitat selection (*sensu* Johnson 1980). However, we focused on the extent to which animals were exposed to urban areas, regardless of whether they "selected" them or not. We believe that the percentage of the home range is the best measure of this exposure.

With Arc-Info (Environmental Systems Research Institute, Redlands, California), we overlaid the 95% MCP home ranges for each animal onto the land-use classification map and measured the percentage of its home range consisting of development, altered open areas, or both. We refer to the combined developed and altered open areas as "non-natural areas." We also counted the number of animals that had no non-natural area within their home range as animals with no urban association. For logistic reasons there was probably some bias against developed areas in our trap locations, but we believe it unlikely that we missed any strictly urban bobcats or coyotes, or that this bias compromised our results.

We used Mann-Whitney *U* and Kruskal-Wallis tests to evaluate differences in degree of urban association between species and sexes, and Fisher exact tests to test

for differences in the number of animals with no urban association. We used Spearman rank correlations with two-sided tests of significance to determine the relationship between urban association and home-range size.

### Survival and Cause-Specific Mortality Rates

We monitored radiocollared animals at least weekly to assess survival. When a mortality signal was discovered, we attempted to determine cause of death in the field. If this was not possible, carcasses were sent to the California Department of Fish and Game Wildlife Investigations Laboratory. We used the program MICROMORT (Heisey & Fuller 1985) to calculate survival rates. For both sexes of each species we calculated survival and cause-specific mortality rates annually, during wet (November–April) and dry (May–October) seasons and over relevant life-history periods. If radio contact was lost and the animal's fate was unknown, the animal was excluded from the analysis.

We tested for differences in survival rates and cause-specific mortality rates with the chi-square methods of Sauer and Williams (1989) and the program CONTRAST (Hines & Sauer 1989). We examined the relationship between survival rate and urban association by classifying bobcats and coyotes into three groups based on breaks in the histogram of the percentage range non-natural. We then computed survival rates for the animals in those categories and tested for differences between groups with multiple comparisons and Bonferroni corrections. Because we computed urban association by using home ranges and we only computed home ranges for animals with >20 locations, many radiocollared animals were not included. Animals with few locations may have died sooner, potentially producing a bias toward high survival rates. To detect this bias, we used the percentage of locations in non-natural areas (because we did not compute home ranges for these animals) to determine urban association for the 26 coyotes and five bobcats with 5–19 locations. We tested survival rates based on these 66 coyotes and 40 bobcats for a relationship between urban association and survival rate and compared the results with those from the animals with  $\geq 20$  locations. We also used this larger group of animals to look for a relationship between cause-specific mortality rates and urban association, this time using the histogram of percentage points non-natural to split bobcats into three groups and coyotes into four groups for computing mortality rates based on urban association.

### Activity

When an animal was located, its activity level was recorded as active or inactive and time of day was classified as night (between 2200 and 0500 hours, the period during which human activity was significantly decreased)

or day (other hours). On the level of the individual animal, we used Spearman rank correlation to determine the relationship between urban association and the percentage of nocturnal locations that were active. To summarize the relationship between urban association, time of day, and activity across animals, for each animal we computed (separately for both active and inactive locations) the percentage of locations in the different types of land use that occurred at night or during the day. We then took the mean of these percentages across bobcats and coyotes, a procedure that uses individual animals as independent sampling units and avoids pseudoreplication.

We used an  $\alpha$  of 0.10 as the level of significance for all statistical tests because of our small sample sizes and the need to use nonparametric tests, both of which reduced statistical power. Statistical analyses were performed with the program SYSTAT.

## Results

We captured and radiocollared 50 bobcats (23 males; 27 females) and 86 coyotes (49 males; 37 females). We computed 95% MCP home ranges for 35 bobcats and 40 coyotes (Table 1) with  $\geq 20$  radiolocations (coyotes: mean = 48 locations, SD = 22, range = 20–177; bobcats: mean = 49 locations, SD = 30, range = 23–147). Males had significantly larger home ranges than females for both bobcats ( $U = 66.5, p = 0.005$ ) and coyotes ( $U = 119, p = 0.054$ ). These sex differences were also significant within age class for bobcats (adults:  $U = 40, p = 0.068$ ; young:  $U = 2, p = 0.041$ ) but not for coyotes (adults:  $U = 67, p = 0.262$ ; young:  $U = 8, p = 0.123$ ). Adult and

young home ranges were not different for bobcats ( $U = 141.5, p = 0.736$ ) or coyotes ( $U = 160, p = 0.951$ ).

## Urban Association

Male bobcats were significantly more urban-associated than female bobcats (Table 1; Fig. 2; range developed:  $U = 86, p = 0.027$ ; range non-natural:  $U = 68.5, p = 0.006$ ). This difference was most striking for adult males and females (range developed:  $U = 16, p = 0.001$ ; range non-natural:  $U = 17.5, p = 0.002$ ). Young females were not significantly more urban-associated than young males (range developed:  $U = 19, p = 0.149$ ; range non-natural:  $U = 12, p = 1.00$ ). However, adult males were more urban-associated than young males (range developed:  $U = 35, p = 0.036$ ; range non-natural:  $U = 34.5, p = 0.043$ ), and adult females were less urban-associated than young females (range developed:  $U = 15, p = 0.014$ ; range non-natural:  $U = 24, p = 0.098$ ). Only two bobcats, one adult female and one young male, had no urban association, so we did not test for sex or age differences in this measure. More adult females than adult males had no developed area in their home range (adult females, 6 of 11; adult males, 1 of 13; Fisher's test,  $p = 0.023$ ). However, the proportion of young females with no urban association did not differ from the proportion of adult females (Fisher's test,  $p = 0.147$ ) or the proportion of adult males (Fisher's test,  $p = 1.00$ ).

Male coyotes were more urban-associated than females by percentage range developed ( $U = 135, p = 0.085$ ), although not for percentage range non-natural ( $U = 142, p = 0.128$ ). Young animals were not significantly more urban-associated than adults (range developed:  $U = 115, p = 0.116$ ; range non-natural:  $U = 124, p = 0.194$ ).

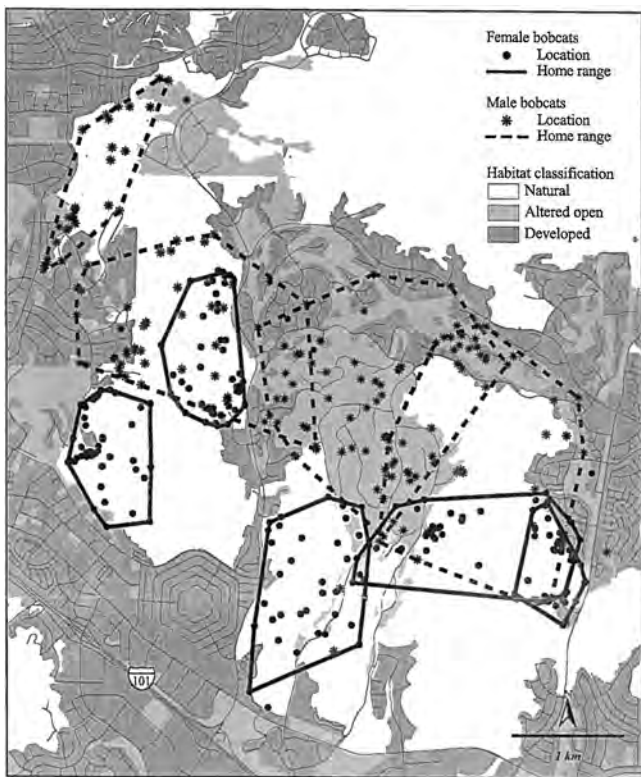

**Table 1.** Home range size and urban association<sup>a</sup> of bobcats and coyotes in the Santa Monica Mountains and Simi Hills.

Species	n	95% MCP <sup>b</sup> home range size (km <sup>2</sup> ) mean $\pm$ SD	Developed area in home range (%)	Altered open area in home range (%)	Natural area in home range (%)	Number of animals with	
						no developed area in home range	no non- natural <sup>c</sup> area in home range
Bobcats	35		7.6	11.5	80.9	10	2

young animals	12	4.18 $\pm$ 3.66	22.3	11.9	65.8	0	0

<sup>a</sup> Urban association is measured by the percentage of the home range that is made up of developed and altered open habitats.

<sup>b</sup> Minimum convex polygon (Hayne 1949).

<sup>c</sup> Non-natural area = developed area + altered open area.

**Figure 2.** Home ranges (95% minimum convex polygons) of male and female bobcats relative to land use in the Simi Hills region, Ventura County, California. Altered open areas include low-density residential areas, golf courses, and small vegetated patches or strips.

Sexes were not different within ages, and ages were not different within sexes.

Only 4 of 40 coyotes, all adults, had no non-natural area within their home range. There was no difference between males and females (Fisher's test,  $p = 0.705$ ) in the proportion of coyotes with no developed area in their home ranges.

To compare urban association among species, we separated adult male, adult female, and young female bobcats, excluded young male bobcats because of small sample size ( $n = 3$ ), and considered coyotes as one group. Kruskal-Wallis tests showed a significant effect of species-age-sex group on urban association (range developed:  $H = 11.415$ ,  $p = 0.010$ ; range non-natural:  $H = 8.105$ ,  $p = 0.044$ ). To specifically compare each bobcat group with coyotes, we carried out three contrasts with an overall  $\alpha$  of 0.075. Adult female bobcats were significantly less urban-associated than coyotes (at  $\alpha = 0.025$ , critical difference = 13.97, range developed difference = 23.24, range non-natural difference = 17.66), but adult male bobcats (critical difference = 13.10, range developed difference = 0.12; range non-natural difference = 4.26) and young female bobcats (critical difference = 15.88, range developed difference = 5.99, range non-natural difference = 7.36) were not.

More adult female bobcats than coyotes had no developed area in their home range (adult female bobcats: 6 of 11, coyotes: 9 of 40; Fisher's test,  $p = 0.061$ ), but neither adult male bobcats (Fisher's test,  $p = 0.419$ ) nor young female bobcats (Fisher's test,  $p = 1.00$ ) were different from coyotes in this measure.

### Urban Association and Home Range Size

For all bobcats, home range size was larger for animals with higher urban association, particularly for percent range non-natural ( $n = 35$ , range developed:  $r_s = 0.319$ ,  $0.10 > p > 0.05$ ; range non-natural:  $r_s = 0.681$ ,  $p < 0.001$ ). This positive relationship was significant for adult males ( $n = 13$ ;  $r_s = 0.484$ ,  $p = 0.10$ , for percent developed;  $r_s = 0.302$ ,  $0.50 > p > 0.20$ , for percent non-natural) and young females ( $n = 8$ ;  $r_s = 0.548$ ,  $0.20 > p > 0.10$ , for percent developed;  $r_s = 0.643$ ,  $p = 0.10$ , for percent non-natural). The relationship was not significantly negative for adult females ( $n = 11$ ;  $r_s = -0.484$ ,  $0.20 > p > 0.10$ , for percent developed;  $r_s = -0.368$ ,  $0.50 > p > 0.20$ , for percent non-natural). We could not compute a relationship for young males ( $n = 3$ ).

For all coyotes ( $n = 39$ ), home range size increased with percent range non-natural ( $r_s = 0.275$ ,  $0.10 > p > 0.05$ ) but not with percent range developed ( $r_s = 0.210$ ,  $p = 0.20$ ). For adult male coyotes ( $n = 15$ ; range developed:  $r_s = 0.481$ ,  $0.10 > p > 0.05$ ; range non-natural:  $r_s = 0.593$ ,  $0.05 > p > 0.02$ ) the relationship was stronger.

### Survival and Mortality Causes Relative to Urban Association

Average annual survival rates were similar between species (bobcats,  $n = 50$ , survival rate = 0.761, vs. coyotes,  $n = 86$ , survival rate = 0.742;  $\chi^2_1 = 0.093$ ,  $p = 0.760$ ) and between sexes within species (male bobcats,  $n = 21$ , survival rate = 0.822, vs. female bobcats,  $n = 29$ , survival rate = 0.745;  $\chi^2_1 = 0.910$ ,  $p = 0.340$ ; male coyotes,  $n = 49$ , survival rate = 0.770, vs. female coyotes,  $n = 37$ , survival rate = 0.730;  $\chi^2_1 = 0.392$ ,  $p = 0.531$ ). Survival rates were higher in the sample of animals for which we computed home ranges (those with  $>20$  locations; Table 2).

With the expanded sample of 66 coyotes and 40 bobcats with  $>5$  locations, survival rates did not vary with urban association (Table 3; bobcats:  $\chi^2_2 = 4.46$ ,  $p = 0.107$ ; coyotes:  $\chi^2_3 = 1.38$ ,  $p = 0.709$ ). Similarly, for those animals with  $>20$  locations (Table 2), average annual survival rates were not related to urban association for bobcats ( $\chi^2_2 = 3.91$ ,  $p = 0.142$ ) or coyotes ( $\chi^2_2 = 0.362$ ,  $p = 0.830$ ). Vehicles, other carnivores, and toxins—specifically anticoagulant rodenticides—were the principal causes of death for bobcats and coyotes (Table 3). For bobcats, the average annual vehicle mortality rate was related to urban association ( $\chi^2_2 = 6.20$ ,  $p = 0.045$ ), but

**Table 2.** Average annual survival rates of bobcats and coyotes in urban Southern California, 1996–2000, relative to urban association.<sup>a</sup>

	Urban association (%)	n	Average annual survival rate <sup>b</sup>	Total no. radio days	No. deaths

<sup>a</sup>Urban association is measured by the percentage of the home range that consists of developed and altered open areas.

<sup>b</sup>Survival rates based on the 34 bobcats and 40 coyotes with  $\geq 20$  locations.

Bonferroni-corrected pairwise comparisons were not significant, even between the groups with the most and least urban association (0.141 vs. 0.00;  $\chi^2_1 = 3.91$ ,  $p = 0.048$ ). The mortality rate from predation was not related to urban-association group ( $\chi^2_2 = 1.41$ ,  $p = 0.494$ ).

For coyotes, the vehicle mortality rate was not related to urban association ( $\chi^2_3 = 0.837$ ,  $p = 0.841$ ), but both the predation mortality rate ( $\chi^2_3 = 11.43$ ,  $p = 0.0096$ ) and the toxin mortality rate ( $\chi^2_3 = 11.39$ ,  $p = 0.010$ ) were. Although the group with the highest urban association had the highest average annual mortality rate from toxins (Table 3), there was no consistent relationship between urban association and toxin mortality, and corrected pairwise comparisons were not significant. The predation mortality rate in the animals with no urban association was higher than that in animals with some non-natural area in their home range ( $\chi^2_1 = 16.49$ ,  $p < 0.001$ ). Bobcats and coyotes did not differ in their average annual vehicle mortality rate ( $\chi^2_1 = 0.193$ ,  $p = 0.661$ ).

### Activity and Urban Association

Coyotes as a group were more active at night (66% of points active) than during the day (51% of points active).

For bobcats there was little difference between day and night in the percentage of points active (night, 64% active; day, 60% active).

Based on the analysis of all radiolocations for each species, both coyotes and bobcats shifted their use of altered open areas, and particularly of developed areas, to the night. Based on only bobcat locations recorded as active, 75% of developed-area locations, 47% of altered-open-area locations, and 27% of natural-area locations occurred at night (average percentages across 40 bobcats). For inactive locations, on average 77% of developed-area locations, 58% of altered-open-area locations, and 21% of natural-area locations occurred at night. On average overall, 25% of all locations, 28% of active locations, and 26% of inactive locations were recorded at night.

Coyotes exhibited the same pattern. Of coyote radiolocations recorded as active, on average 80% of developed-area locations, 60% of altered-open-area locations, and 29% of natural-area locations occurred at night (averages across 66 coyotes). For inactive locations, on average 66% of developed-area locations, 80% of altered-open-area locations, and 23% of natural-area locations occurred at night. On average overall, 25% of all locations, 32% of active locations, and 25% of inactive locations were recorded at night.

**Table 3.** Average annual cause-specific mortality rates for bobcats and coyotes in urban southern California relative to urban association,<sup>a</sup> 1996–2000.<sup>b</sup>

	Urban association (%)	Radio days	Survival rate	Vehicle mortality rate (no. deaths)	Predation mortality rate (no. deaths)	Toxin mortality rate (no. deaths) <sup>c</sup>	Gunsbot mortality rate (no. deaths) <sup>c</sup>	Unknown/miscellaneous mortality rate (no. deaths)

<sup>a</sup>Urban association is based on the percentage of radiolocations in developed and altered open areas.

<sup>b</sup>Survival and mortality rates are for the 66 coyotes and 40 bobcats with fewer than five locations.

<sup>c</sup>The na indicates that no bobcats ever died of this cause, so we did not compute mortality rates for bobcats for these causes.

At the individual animal level there was a relationship between urban association and night activity. For adult female bobcats ( $n = 11$ ), level of night activity increased with percent range non-natural ( $r_s = 0.454$ ,  $0.10 > p > 0.05$ ) but not with percent range developed ( $r_s = 0.345$ ,  $0.25 > p > 0.10$ ). The percentage of night points active increased with urban association for adult male bobcats ( $n = 13$ ) for percent range non-natural ( $r_s = 0.643$ ,  $0.01 > p > 0.005$ ), although not for percent range developed ( $r_s = 0.308$ ,  $0.25 > p > 0.10$ ). For young female bobcats ( $n = 8$ ), neither relationship was significant, although both were positive.

For coyotes there were strong relationships between urban association and night activity. The relationship was significant for both urban-association measures for all coyotes ( $n = 39$ ) (range developed:  $r_s = 0.306$ ,  $0.05 > p > 0.025$ ; range non-natural:  $r_s = 0.286$ ,  $0.05 > p > 0.025$ ) and for adult male coyotes ( $n = 22$ ; range developed:  $r_s = 0.453$ ,  $0.05 > p > 0.025$ ; range non-natural:  $r_s = 0.444$ ,  $0.10 > p > 0.05$ ). For adult female coyotes ( $n = 17$ ) there was a significant relationship between percentage of night points active and percent range developed ( $r_s = 0.450$ ,  $0.10 > p > 0.05$ ) but not for percent range non-natural ( $r_s = 0.375$ ,  $0.25 > p > 0.10$ ).

## Discussion

Even though these carnivores utilized developed areas, all groups including coyotes and adult male bobcats were predominantly associated with natural areas (Table 1). Natural area was also the largest component of home ranges of coyotes in Tucson (Grinder & Krausman 2001a), and coyotes in Seattle preferred the least-disturbed habitats, even when they were scarce within the animal's home range (Quinn 1997a). Although coyotes are omnivorous and can take advantage of human-related food items, including ornamental fruit, garbage, pet food, and pets (McClure et al. 1995; Quinn 1997b; Fedriani et al. 2001), even in the most "humanized" part of their study area. Fedriani et al. (2001) found that at most 25% of the coyote diet consisted of anthropogenic food. Coyotes are opportunistic animals that find available resources in a disturbed landscape, but they still largely inhabit natural areas and subsist on natural foods.

For bobcats, age and sex affected sensitivity to urbanization. Similar sex differences were also found when individual bobcats were intensively monitored in the study area (Tigas et al. 2002). The low level of urban association of adult female bobcats may be related to the species' polygynous social system, in which females care for the young. Areas frequented or modified by humans may be perceived by female bobcats as unsafe for raising young. In Golden Gate National Recreation Area in northern California, female bobcats also appear to be more sensitive to urbanization because they maintain

home ranges only in the interior of the park, whereas males range out to the park edge (Riley 1999). Our findings that young female bobcats were more urban-associated than adult females whereas young male bobcats were less urban-associated than adult males, although currently based on a small sample of animals, is in accordance with bobcat social behavior. Female bobcats are generally territorial by prior rights land tenure (Bailey 1974; Anderson 1987), and in high-density populations young females searching for a territory may be willing to utilize marginal habitats. Dispersing Iberian lynx (*Lynx pardinus*) use lower-quality habitat than residents (Palomares et al. 2000). Adult male bobcats have larger home ranges that generally increase in size over time in order to encompass more females (Connor et al. 1999), and their greater willingness to move through developed areas may allow more mating opportunities.

For some predators such as red foxes (Harris 1981), raccoons (Riley et al. 1998), and Cooper's Hawks (*Accipiter cooperii*; Mannan & Boal 2000), density increases and home range size decreases in urban areas, presumably because of high-density food supplies and sufficient habitat requirements. Fedriani et al. (2001) suggest that coyote density may be enhanced by human-related food items in this study area, and, in comparison with other populations, the home ranges of bobcats and coyotes in our study were small. The high productivity of environments in coastal California may allow bobcats and coyotes to meet metabolic requirements with small home ranges, but the constraints of urban habitat fragmentation may also restrict home range size. Of the three bobcat studies that have reported home ranges of a similar size (Lembeck & Gould 1979; Miller & Speake 1979), one was also in an urban area (Riley 1999), and female home ranges were significantly smaller there than in a nearby rural area. Coyote home ranges can also be small in urban areas (Atkinson & Shackleton 1991; but see Bounds & Shaw 1997).

Although developed and altered open areas may offer increased food resources, we observed a positive relationship between home range size and urban association. This suggests that non-natural areas are less suitable than natural areas in some important aspect. Secure resting and denning locations may be more dispersed in developed areas, and although coyotes, adult male bobcats, and young female bobcats may forage in the neighborhoods, they may be less willing to rest there. For adult male bobcats, the significant relationship with percentage range developed but not with percentage range non-natural may indicate that the altered open areas are more equivalent to natural areas. In general, bobcats had consistently higher association with altered open areas than with developed areas (Table 1).

A decreased sense of security around humans would also explain the shift toward nocturnal use of more-developed areas in both bobcats and coyotes. Urban coyotes in Seattle

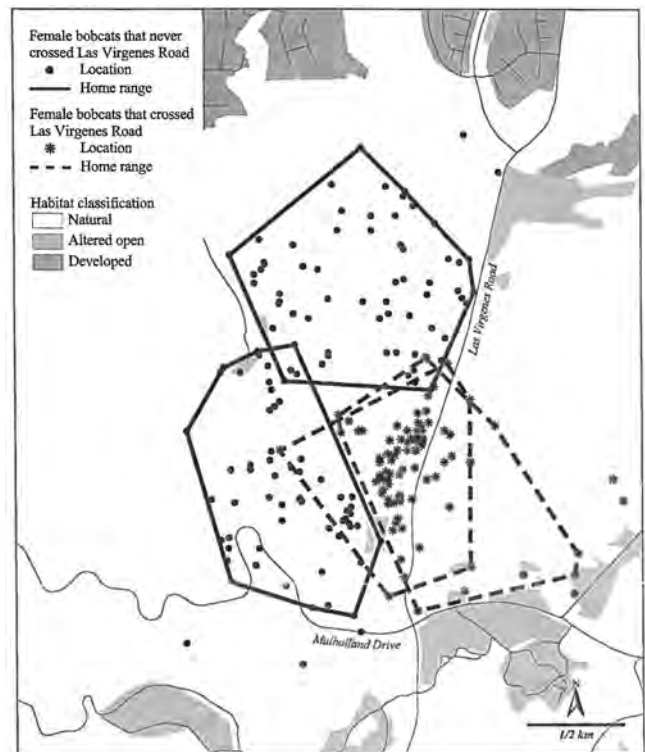

move through developed habitats more at night than during the day (Quinn 1997a), and coyotes in a suburban area in Wyoming have also shifted to less diurnal activity than animals in nearby Grand Teton National Park (McClennen et al. 2001). Coyotes in southeastern Colorado are more active during the day since population exploitation and harassment have ceased (Kitchen et al. 2000).

The survival rates for bobcats and coyotes in our study were similar to those reported in other unexploited populations (Gese et al. 1989; Fuller et al. 1995; Chamberlain et al. 1999; Grinder & Krausman 2001b) and higher than those in harvested populations (Davison 1980; Fuller et al. 1985; Windberg et al. 1985). Contrary to our expectations, there were no differences in survival rate relative to urban association. Although our sample of animals for which we could determine home ranges may have been biased toward higher survival, we found no more of a relationship between survival rate and urban association with animals found at  $\geq 5$  locations. We followed mostly full-grown animals that were at least 6–9 months old, so differences in survival rate could be more evident in young animals. Perhaps when bobcats and coyotes have negotiated their first few months in the urban landscape, the lack of human exploitation or larger carnivores produces high survivorship.

Still, if there were mortality sources associated with urbanization and fragmentation, such as vehicle collisions, nuisance animal trapping, or contaminant build-up, animals with more contact with developed areas should have lower survivorship. In Tucson, humans—specifically, their vehicles—accounted for most coyote mortality (Grinder & Krausman 2001b). In our study area almost every animal lives in a fragmented and urbanized landscape: only 4 of 40 coyotes and 2 of 35 bobcats had home ranges consisting entirely of natural area. Consequently, nearly every bobcat and coyote was potentially affected by human-associated mortality sources.

Similarly, mortality rates from human-related causes were not positively related to urban association. For bobcats, the vehicle death rate was highest in animals with the least urban association. In this landscape roads are omnipresent, and even if they are denser in urban zones, those traversing open space can be particularly dangerous, especially if used by many vehicles traveling at high speed. Animals most exposed to urban areas may also gain familiarity with roads and develop the ability to safely navigate them. Las Virgenes Road, a throughway between the 101 freeway and the town of Malibu, bisects significant natural area. Radiocollared animals in this area had low or no urban association, but a number of collared and uncollared animals were killed on this road. Four female bobcats were radiotracked in the vicinity of Las Virgenes road. Two that never crossed the road each survived for over 5 years. The two that were located on both sides of the road were each struck and killed by vehicles <15 months after capture (Fig. 3).

*Figure 3. Home ranges (95% minimum convex polygons) of four female bobcats along Las Virgenes Road, Los Angeles County. Risk of vehicle mortality was not related to urban association, as illustrated by these four female bobcats with low urban association (<4% for each). The two bobcats that crossed the road (dashed lines) were killed by vehicles, whereas the other two were not.*

The coyote mortality rate from anticoagulant poisoning was also not related to urban-association. Anticoagulant poisoning deaths were generally caused by brodifacoum, a chemical designed and designated as an indoor rodent poison (Hosea 2000). Although the highest mortality rate was among coyotes with the highest urban association, animals with the lowest urban association also died from anticoagulant poisoning. Although coyotes may have been exposed to poisons in residential areas or on golf courses, even animals in large natural zones may consume prey that have ingested poisons.

Woodroffe and Ginsburg (1998) suggest that minimizing carnivore mortality at the boundaries of nature reserves may be more important for conserving carnivores than the size of the reserve. Our results further indicate that in fragmented urban landscapes, human-caused mortality may affect all animals. Carnivore conservation efforts in these landscapes must account for the pervasive effects of humans and development, even within reserves.

Bobcats are more sensitive to urbanization than omnivorous canids such as coyotes and gray foxes (Riley 1999; Crooks 2002; Tigas et al. 2002; this study). The

higher sensitivity of adult female bobcats in particular is important for bobcat population viability because lands that are inhospitable to females cannot produce new animals. The most marginal areas used by bobcats may be a population sink (*sensu* Pulliam 1988) if dispersing bobcats reach these areas from nearby source populations but do not reproduce there. Source-sink dynamics can have critical implications for the long-term prospects of felid populations (Gaona et al. 1998). An important management issue then becomes the minimum requirements for adult female bobcats to survive and successfully reproduce. Adult female home ranges averaged 1.7 km<sup>2</sup>, and we know that fragments of 3.15 and 4.45 km<sup>2</sup> supported at least three female bobcats. The habitat quality of a particular patch is important, however, and intensive human alteration will limit its value. We do not know the reproductive success of bobcats in habitat fragments or how it compares with that in nearby wildlands. We also know from concurrent scat, track, and camera surveys (Tigas 2000) that bobcats utilize fragments as small as 0.4 km<sup>2</sup>. But whether only males use these smallest patches, whether and how bobcats move between these patches, and finally whether reproduction occurs in them are open questions.

Even the highly adaptable coyote utilizes natural areas more than developed areas, expands its home range in increasingly urbanized areas, shifts its use of developed areas to periods of decreased human presence, and is vulnerable to vehicle collisions and poison. Ultimately, we must not only learn the requirements of carnivore species in developing landscapes, we must also educate people to value carnivores and promote their conservation by preserving open space, using rodenticides sparingly and correctly, providing usable crossing points under freeways and major roads, driving slower where carnivores cross roads, and living with rabbits in the yard and in the park.

## Acknowledgments

We thank Canon U.S.A. (through the National Park Foundation's *Expedition into the Parks* program), the National Park Service, California Department of Parks and Recreation, Southwest Parks and Monuments Association, Los Angeles County Sanitation District, and the Biological Resources Division of the U.S. Geological Survey for funds and equipment. Many dedicated people contributed field work, particularly K. Asmus, D. Jones, S. Kim, S. Ng, G. Pasrich, P. Roby, L. Tigas, and A. Vashon. Research access and permits were provided by the National Park Service, California Department of Parks and Recreation, Mountains Recreation and Conservation Authority, Rancho Simi Recreation and Park District, Conejo Open Space and Conservation Agency, Los Angeles County Sanitation District, City of Calabasas, and Ahmanson Land Company. We extend special thanks to A.

Eck and W. Smeck of the Santa Monica Mountains National Recreation Area for unwavering support of the research, and to D. Van Vuren and J. Fedriani for ongoing interest and help. We thank L. Lee for help with the figures, and we thank K. Crooks, B. Sacks, three anonymous reviewers, and especially P. Beier and E. Main for helpful comments on the manuscript.

## FAST-TRACK

# A southern California freeway is a physical and social barrier to gene flow in carnivores

## Abstract

Roads present formidable barriers to dispersal. We examine movements of two highly mobile carnivores across the Ventura Freeway near Los Angeles, one of the busiest highways in the United States. The two species, bobcats and coyotes, can disappear from habitats isolated and fragmented by roads, and their ability to disperse across the Ventura Freeway tests the limits of vertebrates to overcome anthropogenic obstacles. We combine radio-telemetry data and genetically based assignments to identify individuals that have crossed the freeway. Although the freeway is a significant barrier to dispersal, we find that carnivores can cross the freeway and that 5–32% of sampled carnivores crossed over a 7-year period. However, despite moderate levels of migration, populations on either side of the freeway are genetically differentiated, and coalescent modelling shows their genetic isolation is consistent with a migration fraction less than 0.5% per generation. These results imply that individuals that cross the freeway rarely reproduce. Highways and development impose artificial home range boundaries on territorial and reproductive individuals and hence decrease genetically effective migration. Further, territory pile-up at freeway boundaries may decrease reproductive opportunities for dispersing individuals that do manage to cross. Consequently, freeways are filters favouring dispersing individuals that add to the migration rate but little to gene flow. Our results demonstrate that freeways can restrict gene flow even in wide-ranging species and suggest that for territorial animals, migration levels across anthropogenic barriers need to be an order of magnitude larger than commonly assumed to counteract genetic differentiation.

## Introduction

Roads are the primary threat to dispersal between habitat patches in urban landscapes (Forman & Alexander 1998) and, without dispersal, isolated populations may be doomed to extinction (Brown & Kodric-Brown 1977; Hanski *et al.* 1996). Roads can also isolate populations

previously in genetic communication, and the resulting genetic erosion may contribute to population decline (Saccheri *et al.* 1998; Westemeier *et al.* 1998). Empirical data on the frequency of dispersal across roads and its effect on genetic variation and population persistence are few and limited to small and relatively abundant species with low vagility (e.g. frogs, Reh & Seiz 1990; voles, Gerlach & Musolf 2000; beetles, Keller & Largiadér 2003). In contrast, the ability of large carnivores to disperse long distances could mitigate the effects of genetic isolation. However, for carnivores, population densities are low and home range

E-mail: seth\_riley@nps.gov

sizes and dispersal distances are large (Sunquist & Sunquist 2001), so their persistence should be strongly influenced by the isolating effects of roads and development. Additionally, carnivores are susceptible to the deleterious genetic effects of inbreeding in small populations (O'Brien *et al.* 1985; Roelke *et al.* 1993; Vila *et al.* 2003; Liberg *et al.* 2005). Although conservation biologists have focused on the importance of connectivity for carnivores, actual demonstrations of the genetic consequences of roads for such long-lived and mobile species have been lacking.

We studied dispersal and genetic differentiation in coyote (*Canis latrans*) and bobcat (*Lynx rufus*) populations separated by a wide and heavily travelled freeway in the highly urbanized landscape of southern California. To obtain a direct estimate of dispersal, we radio-tracked animals on both sides of the freeway over seven years, from 1996 to 2003. To obtain a genetic estimate of dispersal, we genotyped individuals using highly variable microsatellite loci and then used genetic assignment tests based on the composite genotypes to assign animals genetically to each side of the freeway. We then assessed levels of genetic differentiation between populations on the same and different sides of the freeway to measure the effect of the road on gene flow (genetically effective migration). Finally, we determined whether levels of observed migration were consistent with levels of gene flow estimated by a coalescent model based on the number of generations since the freeway was established. The use of both radio-tracking information and genetic data to monitor migration and gene flow allows an assessment of the long-term genetic consequences of roads and other anthropogenic barriers on genetic diversity and can lead to the development of plans to mitigate their effects.

## Materials and methods

We studied coyote and bobcat populations separated by the Ventura Freeway (US101), a congested 10–12 lane road in the San Fernando Valley 40 km from downtown Los Angeles. More than 150 000 vehicles use the road daily and the presence of a meridian fence largely restricts dispersal to underpasses and culverts (Fig. 1A) (Ng *et al.* 2004). The freeway was established in 1949 from a relatively undeveloped secondary road with minimal traffic (B. Marquez, personal communication), and there are no other natural barriers such as rivers or topographic features following the freeway that would have historically restricted gene flow. The study area consisted of 358 km<sup>2</sup> of chaparral, grassland, and oak woodland habitat (Table S1, Supplementary material) interspersed with secondary roads and housing developments. The 28.4-km length of the freeway connects the towns of Agoura Hills and Thousand Oaks that have a combined population of 200 000. The area is considered a critical habitat corridor connecting the Santa Monica Mountains with extensive natural habitat to the north (Penrod *et al.* 2001).

## Animal capture and radiotelemetry

Bobcats and coyotes were captured with padded foothold traps in 1996–1998 and with box traps (bobcats) and neck snares (coyotes) in 2000–2003. We also genotyped a population of bobcats from northern California where bobcats were captured with box traps from 1992 to 1995 (Riley *et al.* 2004). Captured animals were aged, sexed, weighed, measured, ear-tagged, radio-collared, and released at the capture site. Blood, hair, scat, and in some cases tissue samples were taken for genetic analyses.

Animals were radio-located by triangulation using three consecutive or two simultaneous compass directions obtained with a peak directional antenna. Locations were obtained throughout the 24-h daily cycle. We computed 95% minimum convex polygon home ranges for animals with at least 20 locations. Home range overlap was computed for animals that were radio-tracked concurrently. We computed overlap as the total percentage of the home range that intersected with any other animals of the same sex.

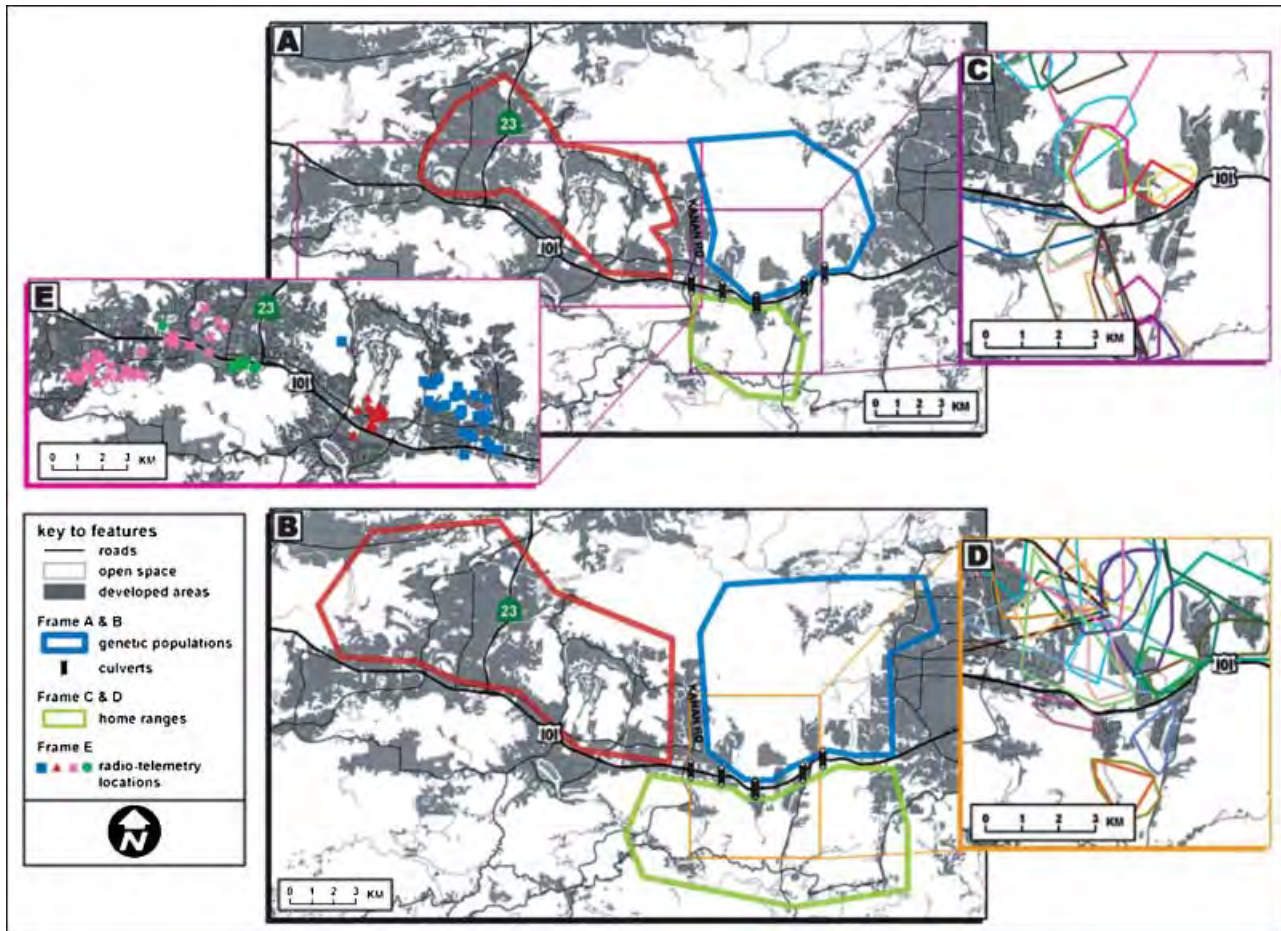

## Genetic sampling

All bobcat and coyote DNA samples were extracted from blood or tissue (ear punch) samples taken at time of capture. Standard phenol–chloroform extraction methods were utilized. Seven dinucleotide microsatellite loci developed for the domestic cat (Menotti-Raymond *et al.* 1999) and validated for polymorphism in the bobcat (Ernest *et al.* 2000) were used to genotype all bobcat specimens (FCA026, FCA043, FCA045, FCA077, FCA090, FCA096, and FCA132). Seven tetranucleotide microsatellite loci developed for the domestic dog (Breen *et al.* 2001) and validated as polymorphic for the coyote by the authors were used to type all coyote specimens (FH2001, FH2137, FH2422, FH2062, FH2226, FH2293, and PEZ19). Polymerase chain reactions (PCR) utilized either (i) a fluorescent dye-labelled forward primer, or (ii) a hybrid combination of forward primers consisting of the published forward primer with the M13F (–20) sequence (16 bp) added to the 5' end and a fluorescent dye labelled M13F (–20) primer. The unlabelled reverse primer was used in both cases. We used the PCR conditions for the hybrid combination primer (a two-step cycle) (Boutin-Ganache *et al.* 2001). Primer dye labelling utilized BeckmanCoulter dye D4 and PCR products were sized on the BeckmanCoulter CEQ2000XL DNA Analysis System.

## Genetic analysis

Observed and expected heterozygosities, allelic diversity, and deviation from Hardy–Weinberg equilibrium were assessed with GENEPOP (Raymond & Rousset 1995; Table S2, Supplementary material). Bonferroni corrections to significance levels were applied to account for multiple

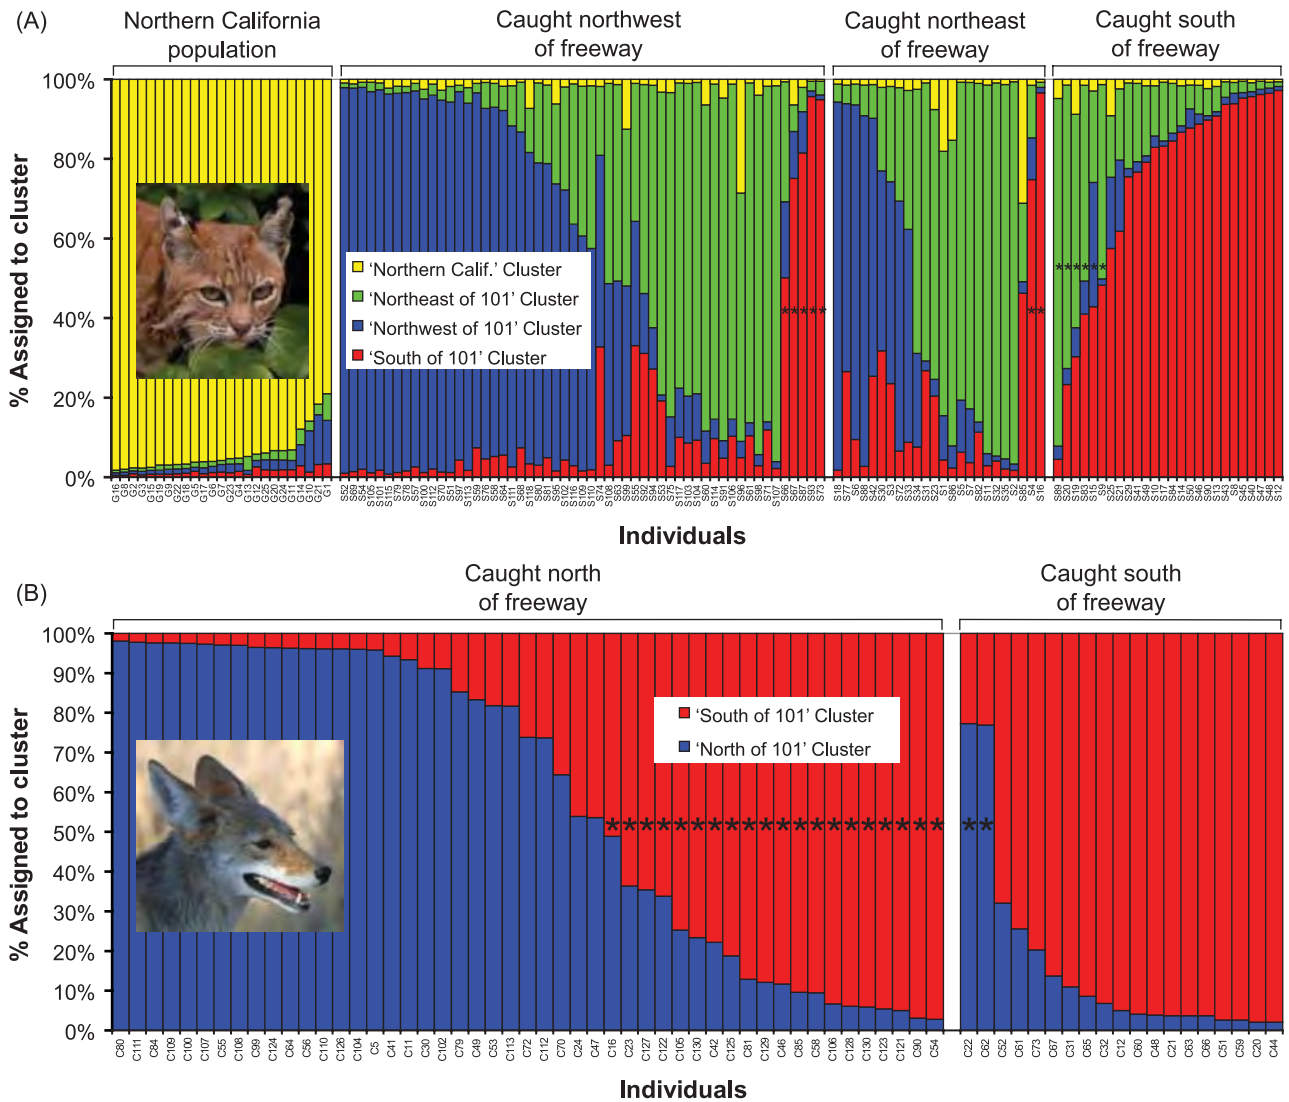

**Fig. 1** Study populations, home ranges and radio-locations of bobcats and coyotes near the Ventura Freeway in southern California. Bobcat (A) and coyote (B) study populations are located north and south of the Ventura Freeway. The north side populations are further divided by Kanan road into northeast and northwest populations. 95% minimum convex polygon (MCP) home ranges are shown for all radio-tracked bobcats (C) and coyotes (D) near the freeway between the south and northeast populations. In (E), radio-telemetry locations are shown for four bobcats with locations north and south of the freeway that were captured north of the freeway but assigned genetically to the population south of it (see Fig. 2).

tests in the determination of heterozygote deficiency/excess (Rice 1989). Coyote samples were grouped into two populations north and south of the freeway, whereas bobcats were divided into three populations, two north and one south of the freeway according to *STRUCTURE* results (see Results and discussion).

To obtain a genetic estimate of dispersal, we used assignment tests based on the composite microsatellite genotypes. Assignment tests identify the population of origin for each individual, and thus individuals assigned to a population other than the one in which they were caught can be considered migrants (Berry *et al.* 2004). We used the program *STRUCTURE* (Pritchard *et al.* 2000) to assign individuals to populations. *STRUCTURE* is a Bayesian clustering algorithm that uses multilocus genotypes to infer population structure and assign individuals to populations. All individuals were combined into one data set for analysis,

without any a priori population assignments. We utilized a burn-in of 50 000 iterations, followed by 500 000 iterations of the Gibbs sampler. Admixture was allowed. We evaluated  $K$  values, the number of assumed populations, from 1 to 6. Each value of  $K$  was run a minimum of three times to evaluate stability. For the highest likelihood  $K$  value, we then evaluated the cluster assignment results for each individual with respect to its capture location.

For potential migrants identified in the initial *STRUCTURE* analysis, we modified the *STRUCTURE* input data file to reassign them to their putative population of genetic origin based on the cluster assignment results. We then calculated the posterior probability of correct population assignment with this revised data set in *STRUCTURE* using the ancestry model with admixture, incorporating population information with the migration parameter set to  $v = 0.1$  (Table S5, Supplementary material).

**Fig. 2** Genetic assignment results from the program STRUCTURE for bobcat (top) and coyote (bottom) populations. Individuals are grouped according to capture location. Genetic population clusters are coded with different colours and the fraction of colour for each individual represents the probability of assignment to the cluster with that colour. Four clusters were found in bobcats, corresponding to a northern California group (yellow), two groups on the north side of the freeway (blue and green) and one group on the south side of the freeway (red). In coyotes, two clusters are supported by STRUCTURE, corresponding to a north (blue) and south (red) cluster. Asterisks denote misassigned individuals (individuals with greater than 50% assignment to a cluster different from the capture location) that are potential migrants.

We measured population differentiation by calculating population pairwise  $F_{ST}$  values and significance ( $g$ -test) using the program FSTAT (Goudet 2002). We estimated gene flow as the number of genetic migrants ( $Nm$ ) between populations from  $F_{ST}$  values [ $F_{ST} \approx 1/(1 + 4Nm)$ ; Wright 1921]. Population membership was based on the capture location north or south of the Ventura Freeway. The northern population was additionally split into northwest and northeast populations to measure differentiation between populations on the same side of the freeway. Computing  $F_{ST}$  between these two populations north of the

freeway allows us to compare the amount of genetic differentiation across the freeway with that over the same or greater distance without the barrier. The east and west populations were divided by Kanan Road, a secondary road, and surrounding development (Fig. 1A,B).

We also computed the pairwise relatedness coefficient,  $R$  between individuals, (Queller & Goodnight 1989) using the program KINSHIP (Goodnight 2005). We identified pairs of individuals significantly related ( $\alpha = 0.05$ ) at the  $R \geq 0.25$  level by first performing a simulation in KINSHIP using the complete population data set at  $R = 0.25$ , followed

by log-likelihood calculations for all possible pairs. Based on the three defined populations, two north and one south of the freeway, for both bobcats and coyotes, we then determined the percentage of number of close relatives ( $R \geq 0.25$ ) across the freeway, across a similar distance on the same side of the freeway, and within each population (Fig. S1, Supplementary material).

We used coalescent simulation to generate predicted levels of genetic differentiation based on a population isolation event with the program SIMCOAL (version 1.0) (Excoffier 2004). SIMCOAL is a computer program for the simulation of molecular genetic diversity in an arbitrary number of diploid populations based on a retrospective coalescent approach. SIMCOAL was utilized to estimate expected population pairwise  $F_{ST}$  values for both bobcat and coyote microsatellite results, based on the time since the freeway was built. A sensitivity analysis was performed on the parameter space of inference for the simulations by varying population effective sizes, sample sizes, migration rates, number of generations since a historical event (population separation), and microsatellite mutation rate. The microsatellite mutation rate was varied from  $10^{-3}$  to  $10^{-2}$  based on observed mutation rates for dinucleotide and tetranucleotide microsatellites for the domestic dog (Francisco *et al.* 1996). Effective population sizes ( $N_e$ ) were estimated as the number of territorial adults in the study area based on telemetry observations. This calculation assumes that all territorial individuals reproduce equivalently; however, sensitivity analysis showed that results were not sensitive to small changes in  $N_e$  or sample size. One thousand analysis iterations were performed for each combination of input parameters. SIMCOAL output results were then analysed using ARLEQUIN (Schneider *et al.* 2000) for pairwise population  $F_{ST}$  estimation.  $F_{ST}$  values were determined by averaging the  $F_{ST}$  values of all 1000 iterations. Because sensitivity analysis showed that population effective size and sample size had minimal effect on  $F_{ST}$  within the range of our study values, they were held constant at 200/50 (population effective size/sample size) for bobcats and 75/25 for coyotes. The number of generations since separation was varied from 25 to 100, and migration rate was varied from 0 to 10% of source population. We assume a 2-year generation time for coyotes and bobcats (Knick *et al.* 1985; Bekoff & Wells 1986).

## Results and discussion

We captured bobcats and coyotes on the north and south sides of the freeway and placed radio-telemetry collars on 110 (92 north side, 18 south side) coyotes and 87 (64 north side, 23 south side) bobcats. Using radio-telemetry, from 1996 to 2003 five (4.5%) radio-collared coyotes and 10 (11.5%) radio-collared bobcats were observed to cross the

freeway, whereas 58 (52%) coyotes and 40 (45%) bobcats crossed major secondary roads. Because a principal study objective was to understand the effects of roads, and in particular the freeway, on carnivore movement, all radio-collared animals were captured within dispersal distance, and many within an average home range diameter, of both the freeway and secondary roads. However, only 213 (2.3%) of 9311 bobcat locations and 19 (0.4%) of 4565 coyote locations were on the opposite side of the freeway from the capture location of the individual.

Home range perimeters followed but did not cross roads such as the freeway, implying that they functioned as artificial territorial boundaries (Fig. 1C, D). For both male and female bobcats, home ranges that bordered on hard boundaries such as the freeway or development were significantly smaller than those that did not (males:  $t = -1.919$ , one-sided  $P = 0.033$ ; females:  $t = -2.186$ , one-sided  $P = 0.018$ ). Also, for adult female bobcats, the age class most important for reproduction, home range overlap was three times higher among individuals with home ranges adjacent to development and the freeway than in those with nonadjacent home ranges (38.8% vs. 12.4% overlap;  $t = -1.77$ , one-sided  $P = 0.045$ ). For coyotes, we did not radio-track a sufficient proportion of territorial individuals throughout the study area to reliably measure territory overlap. Overall, the freeway was a significant barrier to movement as only about 5–10% of individuals crossed in the 7 years of observation, and home range boundaries, overlap, and size were affected by its proximity.

We genotyped 68 (49 north side, 19 south side) coyotes and 108 (82 north side, 26 south side) bobcats for variation in seven microsatellite loci. Microsatellite loci were highly polymorphic for both species (Table S2, Supplementary material). We also typed a population of 25 bobcats from Golden Gate National Recreation Area in the San Francisco Bay Area, a geographically remote and genetically distinct population (Riley *et al.* 2004). For bobcats, the STRUCTURE assignment test results determined that four populations best fit the data (Table S3, Supplementary material), with the northern California population clearly separated from those in southern California and two populations located north and one south of the freeway (Fig. 2A). All bobcats from northern California were assigned correctly to that population. However, seven bobcats caught north of the freeway, five to the west and two to the east, were assigned genetically to the south side population with assignment probabilities and posterior probabilities of greater than 50% (Fig. 2A; Table S5, Supplementary material). We had radio-telemetry observations on six of these seven bobcats, and four of the six were located south of the freeway at least once (Fig. 1E), corroborating their status as migrants. Six bobcats assigned north of the freeway were captured to the south (Fig. 2A). None of these bobcats were found north of the freeway based on

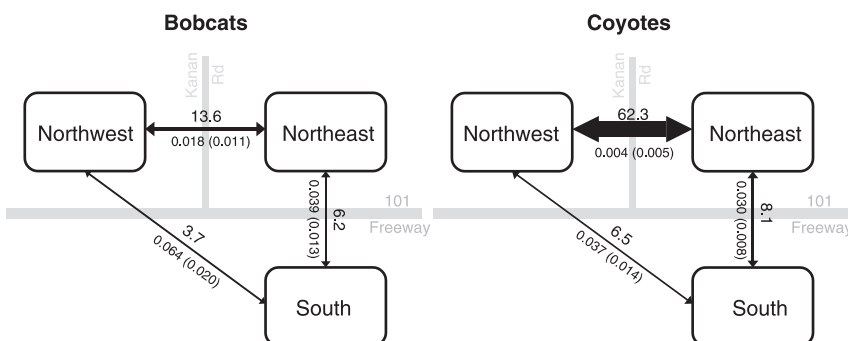

radio-telemetry observations, although three were located within 500 m of it, and two within 100 m. Therefore, based on genetic assignment and in part supported by telemetry observations, 9% (7 of 80) of the bobcats sampled from the north side of the freeway and 23% (6 of 26) of the bobcats sampled from the south side are putative migrants (see Fig. 2A). Considering the limited sampling of activity provided by radio-telemetry, the genetically derived estimate of migration (13 of 106 individuals or 12.3%) and that based on telemetry (10 of 87 individuals or 11.5%) are remarkably similar and suggest that about 12% of the sampled bobcat population crossed the freeway over the 7-year study period, or 3.4% per generation.

For coyotes, the assignment test determined that two populations best fit the observed data, one north and one south of the freeway (Fig. 2B; Table S3, Supplementary material). Two of 19 individuals (11%) captured south of the freeway were assigned to the north side population with assignment probabilities and posterior probabilities of greater than 50% (Fig. 2B; Table S5). Radio-telemetry observations were available for one of these two coyotes, and none of the 107 locations were north of the freeway, although six of the first seven locations were within 1.5 km of it, indicating that this coyote may have dispersed from the north. Twenty of the 49 coyotes (41%) captured on the north side of the freeway were assigned to the south side. We had radio-telemetry observation on 18 of these coyotes, and none showed evidence of crossing the freeway, although 11 of 18 were observed within 1 km of it. Consequently, the genetic results suggest that 10% of the South side population and as much as 41% of the north side population may be migrants. This implied migration fraction of 32% (22 of 68 individuals) or 9.1% per generation is much larger than the value of 4.5% or 1.3% per generation based on telemetry observations. Considering higher assignment thresholds of 80% and 90%, 21% (14 of 68) or 5.9% per generation and 10% (7 of 68) or 2.9% per generation, respectively, are still misassigned and likely to be migrants. The discrepancy between genetic- and telemetry-based estimates may reflect the unlikely probability of observing dispersal with limited radio-telemetry

observations or the difficulty of classifying migrants in genetically similar populations. The use of assignment tests to measure dispersal requires a modest degree of genetic differentiation between populations, otherwise historical gene flow will confound the assessment of recent dispersal events (Berry *et al.* 2004). However, two observations argue for a higher dispersal rate than suggested by telemetry observations. First, coyotes generally disperse farther than bobcats (Van Vuren 1998), which had higher observed and implied rates of migration (see above). Second, of the 22 coyotes that were genetically misclassified, 14, or 64%, were juveniles or yearlings, the ages when coyotes typically disperse (Gese *et al.* 1989). This compares to 39% juveniles or yearlings in the population of coyotes that were not misclassified.

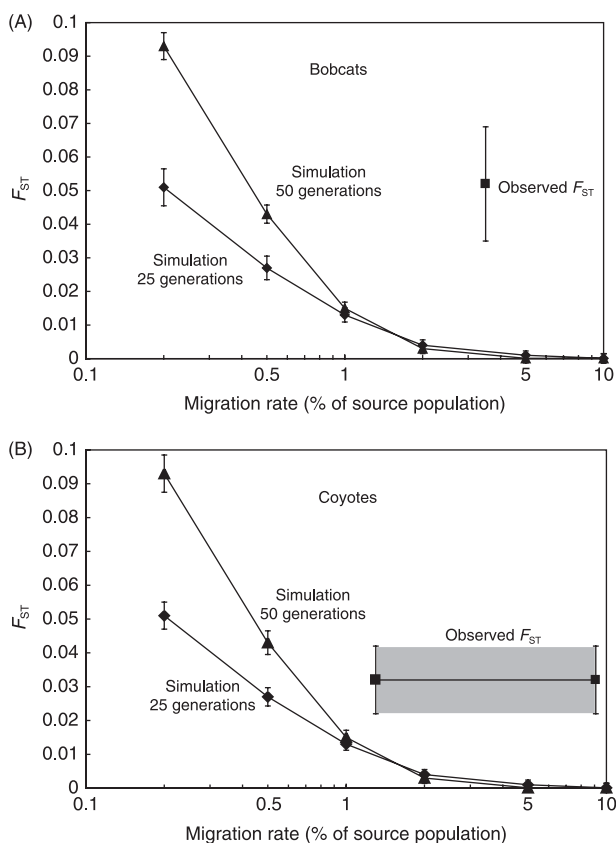

Although the freeway is a barrier to movement, rates of migration of 3.4% per generation for bobcats and from 1.3% to 9.1% per generation for coyotes as suggested by telemetry or genetic data imply high rates of gene flow sufficient to counteract drift (Mills & Allendorf 1996; Vucetich & Waite 2000). To assess levels of differentiation, we measured  $F_{ST}$ , the fixation index, for the seven microsatellite loci. For both species, we found that  $F_{ST}$  values between populations on different sides of the freeway were two to nine times larger (and  $Nm$  2–9 times smaller) than those between populations on the same side, although the latter populations were separated by greater distances (Figs 1A, B and 3). Additionally, 39.2% of alleles for coyotes and 23.6% of alleles for bobcats were unique to one side of the freeway (Table S4, Supplementary material). For coyotes, both pairwise  $F_{ST}$  values across the freeway ( $F_{ST} = 0.030$  northwest-south,  $F_{ST} = 0.037$  northeast-south) were significantly different from zero ( $P < 0.003$ ), whereas the  $F_{ST}$  values between the two subpopulations on the same side of the freeway (0.004, northwest-northeast) was not ( $P = 0.134$ ). For bobcats all three pairwise  $F_{ST}$  values were significantly different from zero ( $F_{ST} = 0.064$  northwest-south,  $F_{ST} = 0.039$  northeast-south,  $F_{ST} = 0.018$  northwest-northeast) ( $P < 0.003$ ), suggesting that Kanan Road, a busy secondary road, and the wide development corridor flanking it, may also be a significant barrier to gene flow for bobcats

**Fig. 3** The number of genetic migrants ( $Nm$ , above line) and levels of genetic differentiation ( $F_{ST}$ , below line, standard error in parentheses) between populations across the freeway (northwest vs. south and northeast vs. south) and on the same side of the freeway (northeast vs. northwest) for bobcats and coyotes. Arrow widths are proportional to  $Nm$  values.

(Fig. 3). Relatedness values also indicated substantially more closely related pairs of animals ( $R \geq 0.25$ ) between populations on the same side of the freeway (northeast vs. northwest) than across it (northeast vs. south) (Fig. S1, Supplementary material). Overall, these results clearly show that the Ventura Freeway is an imposing barrier to gene flow for both species.

To assess if these levels of genetic differentiation were consistent with population history and the observed and implied migration rates, we used coalescent simulation modelling to estimate north side–south side pairwise  $F_{ST}$  indices resulting from the division of a single population by the creation of the freeway in 1949. The simulation results (Fig. 4) showed that a genetically effective migration rate of approximately 0.5% per generation or less is required to explain the observed level of population differentiation for both carnivore species. Consequently, given

**Fig. 4** Comparison of predicted genetic divergence ( $F_{ST}$ ) using coalescence simulations (Y-axis) with observed  $F_{ST}$  values as a function of migration rate (X-axis) between bobcat (A) and coyote (B) populations north and south of the freeway. Migration rates for observed  $F_{ST}$  values are based on radio-tracking observations and genetic assignment tests (see text). Error bars for  $F_{ST}$  values represent one standard error. Observed genetic differentiation is consistent with a migration rate of 0.5% or less for both species given 25 or 50 generations since isolation.

that our observations span a period of about three generations (Knick *et al.* 1985; Bekoff & Wells 1986), the genetically effective migration rates estimated by the coalescent simulation are approximately 3–18 times lower than migration rates between populations separated by the freeway based on direct observation or genetic population assignment.

The disparity between observed migration rates and inferred gene flow likely reflects the lack of reproductive success of migrants. For example, 6 of the 10 bobcats that were found on both sides of the freeway were located across it less than four times, and of the four that stayed across, the two females were known not to have produced kittens the following spring. Of the five coyotes radio-tracked across the freeway, four did not reproduce since they were located six or fewer times across the road and over only a short period of time outside the reproductive season. Further, of the potential migrants observed by telemetry and implied by genetic results, 54% were classified as less than 2 years old. In undisturbed populations, young dispersers enter a matrix of occupied and unoccupied territories, reflecting natural mortality of territorial adults. However, in our study area, home ranges follow the freeway boundary (Fig. 1C, D) and consequently, territorial and reproductive individuals contribute genes to the population on one side of the freeway only. Additionally, in our urban study area, mortality from hunting and trapping is low or nonexistent, and carnivore survival rates were high (Riley *et al.* 2003). High survival rates, small home ranges, high home range overlap, and the barrier effect of roads and development all resulted in territory packing along hard boundaries such as the freeway. This territory pile-up likely produced a formidable social and behavioural barrier to genetically effective dispersal because dispersers are unlikely to obtain and hold territories near the freeway. This unique genetic-isolating effect of roads and other artificial boundaries likely applies to other territorial species.

Conceivably, genetic differences may also correspond to changes in habitat composition across the freeway. For example, continent-wide climate and habitat changes have been associated with genetic structure in grey wolves (*Canis lupus*; Geffen *et al.* 2004), and regional-scale biome changes, e.g. between mountainous regions and flat valley expanses, were associated with genetic structure in coyotes (Sacks *et al.* 2004). However, both the geographic scale and diversity in habitats sampled by these studies far exceed the habitat differences observed throughout the area that we studied. Both sides of the freeway consist of a similar mix of the three dominant types of vegetation in the Santa Monica Mountains and Simi Hills including mixed scrub (64–85%), grassland (8–26%) and riparian and oak woodland (2–11%; Table S1, Supplementary material). There is variation in the amounts of specific

types of scrub communities (e.g. coastal sage scrub, dominated by *Salvia* spp. and *Artemisia californica*, and chaparral, dominated by *Adenostoma fasciculatum* or *Ceanothus* spp.) across the entire study area, but coyotes and bobcats on both sides of the freeway used both of these scrub communities, indicating a lack of ecological specialization. Coyotes and bobcats are generalist carnivores, and we feel such small-scale ecological differences are an unlikely explanation of our results. Unfortunately, there are too few historical specimens from our study area in museum collections to directly assess genetic differentiation prior to the construction of the freeway.

Roads are a primary threat to the persistence of animal populations in urban landscapes. This threat is caused directly through vehicle mortality or indirectly by increasing the probability that isolated populations will become extinct through random demographic processes (Forman 2003). Our results show that the genetic effects of roads can also be substantial even for large, highly mobile species. Levels of differentiation between coyote and bobcat populations isolated for about 50 years are as large as those between coyote populations separated by several hundred kilometres (Roy *et al.* 1994). These levels of differentiation were found even between high-density populations of bobcats and coyotes. The isolating effects of roads would likely be even more severe for very small populations and rare species (Spielman *et al.* 2004). An additional insidious factor is the effect of roads in decreasing gene flow well below that expected from migration rates or existing between similarly spaced populations on the same side of the freeway. We suggest this decrease may be caused by: (i) roads acting as home range boundaries for terrestrial and reproductive individuals, and thus decreasing the migration rate of genes, and (ii) home range pile-up near roads that make it less likely that dispersing individuals can find territories. To counteract such genetic isolation, corridors across freeways could conceivably include more natural habitat so that home ranges could extend across the freeway and rates of genetic exchange might be increased. Five of the six potential crossing points in our study (Fig. 1A, B) were unvegetated culverts or paved underpasses. Finally, our results imply that observed migration rates across anthropogenic barriers may be poor surrogates for gene flow, and that molecular genetic studies of even recently isolated populations may provide new insights for conservation.

### Acknowledgements

We thank the National Park Service and the National Park Foundation through a grant from the Canon Foundation for funding, Lena Lee for help with Fig. 1, and many dedicated technicians, interns, and volunteers for help with fieldwork. We thank T. B. Smith, B. N. Sacks, L. Rieseberg, and four anonymous reviewers for comments on earlier drafts of the manuscript.

### Supplementary material

The supplementary material is available from <http://www.blackwellpublishing.com/products/journals/suppmat/MEC/MEC2907/MEC2907sm.htm>

**Table S1** Percentage of different habitat types in the sampled areas, determined by overlaying the polygons for each population (Fig. 1) on a vegetation map of the Santa Monica Mountains and Simi Hills (Franklin 1997). Chaparral consists of scrub habitat dominated by chamise (*Adenostoma fasciculatum*) and ceanothus (*Ceanothus* spp.); coastal sage scrub consists of scrub habitat dominated by sage (*Salvia* spp.) and California sagebrush (*Artemisia tridentata*); grassland is mostly introduced annual grasses; woodland consists of oak and riparian woodlands and some walnut woodlands.

**Table S2** Observed and expected heterozygosities, allelic diversity and deviations from Hardy–Weinberg equilibrium (significant deviations indicated by  $\pm$ ).

**Table S3** Likelihood values for inferred number of genetic clusters ( $K$ ) from STRUCTURE (3 iterations per value of  $K$ ).

**Table S4** Private alleles as percentage of total alleles per locus in each population.

**Table S5** Cluster assignment and posterior probability of correct genetic population assignment of potential migrants.

**Fig. S1** Comparison of the percentage bobcat and coyote pairs that were closely related genetically, as defined by having an  $R$  value of 0.25 or greater between populations across the freeway (south vs. northwest and northeast) and on the same side of the freeway (across Kanan road, northwest vs. northeast). Bar widths are proportional to percentage values.

**Fig. S2** Sensitivity of the SIMCOAL simulation algorithm for  $F_{ST}$  as a function of microsatellite mutation rate ( $\mu$ ), migration rate, and number of generations since population separation (since construction of the freeway).

**ABSTRACT** Humans introduce many toxicants into the environment, the long-term and indirect effects of which are generally unknown. We investigated exposure to anticoagulant rodenticides and evaluated the association between notoedric mange, an ectoparasitic disease, and anticoagulant exposure in bobcats (*Lynx rufus*) and mountain lions (*Puma concolor*) in a fragmented urban landscape in southern California, USA. Beginning in 2002, an epizootic of notoedric mange, a disease previously reported only as isolated cases in wild felids, in 2 years reduced the annual survival rate of bobcats from 0.77 (5-yr average) to 0.28. Anticoagulants were present in 35 of 39 (90%) bobcats we tested, multiple compounds were present in 27 of these 35 (77%), and total toxicant load was positively associated with the use of developed areas by radiocollared animals. Mange-associated mortality in bobcats showed a strong association with anticoagulant exposure, as 19 of 19 (100%) bobcats that died with severe mange were also exposed to the toxicants, and for bobcats with anticoagulant residues >0.05 ppm, the association with mange was highly significant ( $\chi^2 = 10.36, P = 0.001$ ). We speculate that concomitant elevated levels of rodenticide exposure may have increased the susceptibility of bobcats to advanced mange disease. Bobcats were locally extirpated from some isolated habitat patches and have been slow to recover. In 2004, 2 adult mountain lions died directly from anticoagulant toxicity, and both animals also had infestations of notoedric mange, although not as advanced as in the emaciated bobcats that died with severe disease. Two other mountain lions that died in intraspecific fights also exhibited exposure to 2–4 different anticoagulants. These results show that the effects of secondary poisoning on predators can be widespread, reach even the highest-level carnivores, and have both direct and possibly indirect effects on mortality. Further research is needed to investigate the lethal and sub-lethal effects of anticoagulants and other toxicants on wildlife in terrestrial environments. (JOURNAL OF WILDLIFE MANAGEMENT 71(6):1874–1884; 2007)

DOI: 10.2193/2005-615

**KEY WORDS** anticoagulant rodenticides, bobcat, fragmentation, mountain lion, multiple stressors, notoedric mange, southern California, synergistic effects, toxicology, urbanization.

The conversion of land for urban or agricultural uses has obvious impacts on natural populations by eliminating, fragmenting, and altering habitat. However, human activity, including the introduction of toxicants into the environment, can have other unintended and more cryptic consequences for wildlife populations. Determining the nature and extent of these effects can be difficult, particularly if multiple stressors are involved. In recent years, laboratory and artificial pond experiments on aquatic amphibians have revealed that anthropogenic stressors can interact with natural ones to have a much greater influence on survival, growth, and population persistence than either factor in isolation (Kiesecker et al. 2001, Kiesecker 2002, Relyea 2003). However, there have been few similar demonstrations in terrestrial systems or in more natural field situations (e.g., Gervais and Anthony 2003).

Anticoagulant rodenticides are widely used in both urban and agricultural settings to control rodent populations.

There are 6 anticoagulant rodenticides registered by the Environmental Protection Agency for control of rats and mice in and around buildings. They are often formulated as grain-based food baits, typically pellets, although other formulations are used, and all are sold over-the-counter and are therefore available to the general public. Warfarin, chlorophacinone, and diphacinone were developed earlier and are referred to as first-generation anticoagulants. They generally require multiple feeding by the target species and are less toxic to birds. They are also more readily metabolized and are much less persistent in the body. The other 3 anticoagulants, brodifacoum, bromadiolone, and difethialone, are commonly referred to as second-generation anticoagulants. They exhibit very high toxicity to birds and mammals, can provide a lethal dose in a single feeding, and can remain in body tissues for long periods (months) because they are highly persistent and are not readily metabolized (Eason et al. 2002, Erickson and Urban 2004, Berny et al. 2006).

Secondary anticoagulant poisoning of nontarget animals has been well-documented in a wide range of birds and mammals (Eason and Spurr 1995; Stone et al. 1999, 2002;

<sup>1</sup> E-mail: seth\_riley@nps.gov

<sup>2</sup> Present address: Big Horn Canyon National Recreation Area, 20 Highway 14A East, Lovell, WY 82431, USA

Hosea 2000; Eason et al. 2002) including owls (Mendenhall and Pank 1980), buzzards (Berny et al. 1997), coyotes (*Canis latrans*; Riley et al. 2003), feral cats (*Felis catus*; Alterio 1996), mountain lions (*Puma concolor*; Littrell 1988), otters (*Lutra lutra*), endangered European mink (*Mustela lutreola*), and polecats (*Mustela putorius*; Fournier-Chambrillon et al. 2004). However, the vast majority of this poisoning undoubtedly remains undetected for several reasons. Most importantly, testing for the presence of anticoagulants requires necropsy and analysis of liver tissue (using high-performance liquid chromatography [HPLC]). Unless an animal is being tracked through radiotelemetry, finding deceased animals in a nondecomposed state is rarely possible in the field (Wobeser 2006). Another problem is that many animals do not exhibit any outward signs of poisoning, so toxicants go undetected without specific testing (e.g., McDonald et al. 1998).

When testing is done, anticoagulant occurrence is often high. Shore et al. (1996) found that 31% of polecats tested in Britain had anticoagulants present, Hosea (2000) found that 70% of the mammals (including coyotes and bobcats [*Lynx rufus*]) tested in California, USA, had been exposed to anticoagulants, and anticoagulants were detected in 49% of the raptors tested in New York, USA, from 1998 to 2001, including in 81% of the great horned owls (*Bubo virginianus*; Stone et al. 2002). Although some predators die directly from anticoagulant toxicity, many others do not. For example, 86% of the raptors exposed to anticoagulants in New York did not show evidence of death from direct toxicity. However, according to Stone et al. (2002:37), “the impact of anticoagulant exposure must extend well beyond those cases in which acute lethal hemorrhage is the proximal cause of death.” Little is known about what constitutes a lethal dose for wildlife species, what the sub-lethal, chronic effects may be, or what kinds of interactions may occur between anticoagulants and other factors.

We investigated the association between anticoagulants and the natural stressor of disease, specifically notoedric mange. Mange is not an uncommon disease in carnivore populations, but most reports of population-level effects are from sarcoptic mange infestation, often in canids (Pence and Ueckermann 2002). Notoedric mange has generally only been reported as isolated cases in wild felids (e.g., Pence et al. 1995, Ryser-Degiorgis et al. 2002) including both bobcats (Penner and Parke 1953, Pence et al. 1982) and captive Florida panthers (*Puma concolor coryi*; Maehr et al. 1995), although there are reports of epizootics in coatis (*Nasua narica*; Valenzuela et al. 2000) and in a feral cat population in Florida, USA (Foley 1991). The mite, *Notoedres cati*, occurs as a treatable ear parasite in domestic cats and may be more common in veterinary practices in Southern California (Brooks 2000), although it occurs in urban areas throughout the United States (K. Kwochka, DVM Pharmaceuticals, personal communication). Mange cases may become severe and result in dehydration, emaciation, and eventually death (Pence and Ueckermann 2002). However, by itself, the occurrence of mange mites,

including *Sarcoptes*, on a healthy animal would not be considered fatal but can develop into lethal disease when other factors are also present (Samuel 1981). Consequently, the prevalence of mange increases in times of increased environmental stress such as drought or winter or in animals under social or nutritional stress (Pence and Ueckermann 2002).

Following results from previous research about the occurrence of anticoagulant toxicity in coyotes (Riley et al. 2003) and more recent observations of mange-associated mortality in bobcats, we began investigating anticoagulant exposure and the potential for interactive effects of this exposure in bobcats and mountain lions. Specifically, we measured the frequency and amount of anticoagulant exposure and notoedric mange incidence in both species, and we assessed the potential association between anticoagulant exposure and susceptibility to severe mange infestation. We also evaluated the degree to which anticoagulant exposure was related to the use of development by radiocollared bobcats and the impact of the mange epizootic on the local bobcat population.

## STUDY AREA

Our study was conducted in the coastal mountain ranges north and west of the city of Los Angeles in southern California, including the Santa Monica Mountains, Simi Hills, and Santa Susana Mountains (Fig. 1). The area had a Mediterranean climate with cool, wet winters and hot, dry summers. Predominant habitat types included mixed chaparral, coastal sage scrub, oak woodland and savanna, riparian areas, and introduced annual grasslands. Human land-uses included commercial development, low- to high-density residential development, golf courses, landscaped areas in parks and adjacent to office buildings, agricultural land, and a 120-ha landfill. An 8–10-lane freeway (United States Route 101), 2 4–6-lane freeways (State Routes 23 and 118), and numerous secondary roads intersected our study area (Fig. 1). For bobcats, we focused on the southern Simi Hills area, including habitat fragments, and the portions of the Santa Monica Mountains immediately across the 101 freeway (see bobcat study area, Fig. 1). For mountain lions, our study area included all of the Santa Monica Mountains, Simi Hills, and Santa Susana Mountains.

## METHODS

### Bobcat and Mountain Lion Capture and Radiotracking

We captured bobcats using foothold traps and snares (1996–1998) and cage traps (2000–2004) and captured mountain lions using foot-snares, cage-traps, and hound-capture. We chemically immobilized all animals with ketamine hydrochloride and xylazine hydrochloride in a 5:1 ratio, and then weighed, measured, and marked them with ear-tags. We fitted adult bobcats with very high frequency (VHF) radiotransmitters (Telonics Inc., Mesa, AZ; Telemetry Solutions, Concord, CA; Advanced Telemetry Systems, Isanti, MN). We fitted mountain lions with combination VHF and Global Positioning System (GPS) collars (Tele-

**Figure 1.** Study area for bobcats and mountain lions near Los Angeles, California, USA, 1996–2006. Inset: home ranges (95% min. convex polygons) of 6 bobcats in an isolated habitat patch in Westlake Village, California. Five of 6 radiocollared bobcats in this patch died of mange between March 2002 and March 2003, and contact was lost with the sixth animal. Based on trapping and scat surveys, little or no evidence of bobcat activity has been seen in this patch since.

vilt, Lindesberg, Sweden). All radiocollars were equipped with mortality sensors. We obtained the necessary permits for animal capture and handling.

We located bobcats by ground telemetry using triangulation (3 compass azimuths obtained within 15 min) 2–5 times per week throughout the 24-hour cycle. Locations used for home range analysis were separated by >12 hours. We tested radiotelemetry accuracy using test collars (see Riley et al. 2003) and it averaged 42.4 m (SD = 50.2). We calculated 95% minimum convex polygon home ranges using the home range extension in the program ArcView. We calculated bobcat survival rates with the techniques of Heisey and Fuller (1985) using the program MICRO-MORT.

We calculated the urban association (the relative amt of potential interaction with human development) of bobcats by determining the percentage of developed land and the percentage of altered land (areas that are not natural habitat, but are potentially more conducive to wildlife use than developed areas) present in the home range (see also Riley et al. 2003). Developed land included commercial areas and residential areas with  $\geq 1$  house per 0.4 ha. Altered land included golf courses, landscaped areas such as office or city parks, a landfill, small strips or patches of habitat, and low-density ( $\leq 1$  house/2 ha) residential areas. We define unnatural area as developed areas plus altered areas.

We radiotracked mountain lions 2–3 times per week by VHF ground telemetry, and we obtained 100–150 GPS collar locations each month by remote download. Potential mountain lion prey kill-sites were identified by examining each month's GPS locations for clusters of locations (Anderson and Lindzey 2003) encompassing a period of 24 hours or more. Potential kill sites were investigated and prey remains were identified to species, age, and sex, when possible.

#### **Bobcat Distribution and Relative Abundance**

We collected scat on established transects each month. Over multiple years, changes in the numbers of scat collected over time allowed us to monitor changes in bobcat distribution and relative abundance. Transects were cleared in March 2001, and then all bobcat scat was collected each month through December 2004, except for 3 months in 2002. We identified bobcat scat by size and shape (Murie 1954). Verification of species identification of bobcat scat in the same region using faecal genotyping revealed approximately 90% accuracy using field characteristics (Kohn et al. 1999, Fedriani et al. 2000), although for examining trends over time, consistency of technique is most important.

#### **Necropsy and Diagnostic Analysis**

When we detected mortality signals, we immediately located the carcasses of radiocollared animals. We determined cause

of death by necropsy and, when possible, by using associated ancillary tests including routine histology, bacteriology, virus isolation, and toxicology. We transported the first 4 bobcats that showed indications of mange to the California Animal Health and Food Safety Laboratory (CAHFS) San Bernardino Branch, where full necropsies were performed. We treated skin scrapings from these animals with 10% potassium hydroxide and examined them microscopically for mites, and we examined mites as whole mounts in glycerin. We identified future cases of mange in bobcats by visual examination and by the distinctive pattern of disease progress for notoedric mange. We performed a field necropsy on the first mountain lion that died, an adult female. We transferred her liver, head, and pelt and the complete carcasses of the other 3 mountain lions, an adult male, an adult female, and a yearling female, to CAHFS for examination. We also obtained skin scrapings and mites from the 2 mange-infested mountain lions, which we processed as described for the bobcats.

### Anticoagulant Testing

We collected liver samples from radiocollared bobcats that died and were recovered intact. We also collected livers from unmarked bobcat carcasses encountered in the field and from 2 bobcats collected by the City of Los Angeles. We froze all liver samples at  $-20^{\circ}\text{C}$  and shipped them to the CAHFS laboratory (Davis Branch), where they were tested for the presence of 7 anticoagulants: warfarin, bromadiolone, coumachlor, brodifacoum, diphacinone, chlorophacinone, and difethialone. We also collected blood samples from 3 bobcats that were afflicted with mange when live-captured. For 2 of these animals, we measured prothrombin time of blood samples to determine anticoagulant presence. These samples were analyzed by Idexx Veterinary Services (San Bernardino, CA). Normal prothrombin time was considered to be 7.0–12.7 seconds, based on values for domestic cats. The third animal was B108, a female bobcat that also had an early stage case of mange and was kept at the California Wildlife Center for rehabilitation (see Results). Partial thromboplastin time was determined for this bobcat (Idexx Veterinary Services). Between 10 seconds and 28 seconds was considered normal partial thromboplastin time, again based on values for domestic cats.

We analyzed liver samples using a previously published method for the analysis of anticoagulant rodenticides in serum (Palazoglu et al. 1998) modified for tissue analysis. We acidified 5-g liver samples with acetic acid and homogenized them with 5% ethanol in ethyl acetate. We cleaned up the samples using gel-permeation chromatography (GPC). We then exchanged the GPC eluent to methanol and reduced the volume of methanol to 0.5 mL. We analyzed the methanol extracts by HPLC using diode-array and fluorescence detectors in series. Identification was by comparison with diode-array and fluorescence spectra from known standards. In cases in which diode-array and fluorescence spectra were ambiguous, we performed qualitative confirmation analysis using liquid chromatography–mass spectrometry. We performed quantification by com-

parison of analyte response in samples with that of known standards. Minimum detectable levels were 0.05 ppm for warfarin, bromadiolone, and coumachlor, 0.01 ppm for brodifacoum, and 0.25 ppm for diphacinone, chlorophacinone, and difethialone.

### Statistical Analyses

We measured the association between severe notoedric mange and anticoagulant exposure using a chi-square test. We assessed the relationship between mange and urban association of radiocollared bobcats with nonparametric Mann–Whitney  $U$  tests, measured the relationship between the total concentration of anticoagulants (ppm) and urban association with simple linear regression, and compared the total concentration of anticoagulants between mange-infected and uninfected bobcats with a 2-sample  $t$ -test. We report statistical results with a  $P$ -value of  $\leq 0.10$ . We performed statistical tests with the program SYSTAT (SPSS Inc., Chicago, IL).

## RESULTS

We tested the livers from 39 bobcats, including animals with and without mange and that died both before and after the mange epizootic. Anticoagulant toxicants were present in 35 of 39 (90%) bobcat livers, and 27 of these 35 (77%) revealed exposure to  $\geq 2$  compounds. We detected brodifacoum in 31 of the liver samples at levels ranging up to 0.56 ppm, bromadiolone in 25 livers at levels up to 0.82 ppm, diphacinone in 12 livers up to 0.58 ppm, and difethialone in 10 livers at trace levels ( $< 0.25$  ppm; Table 1). Prothrombin times for the 2 bobcats whose blood we tested were 17.3 seconds and  $> 100$  seconds (normal time: 7.0–12.7 sec). The livers of all 4 mountain lions we tested indicated high levels of the 2 compounds most common in bobcats, and one mountain lion also had significant levels of difethialone and trace levels of diphacinone. In the 2 mountain lions that died of anticoagulant toxicity (see below), we detected bromadiolone at 1.27 ppm and brodifacoum at 0.57 ppm in the liver of the male (P3) and bromadiolone at 0.51 ppm and brodifacoum at 0.31 ppm in the female (P4). Two other mountain lions were killed in August 2005 (ad F P2) and June 2006 (yearling F P7) by an adult male lion. We detected bromadiolone at 0.37 ppm and brodifacoum at 0.32 ppm in the liver of P2 and bromadiolone at 0.66 ppm, brodifacoum at 0.32 ppm, difethialone at 0.66 ppm, and diphacinone at trace levels in P7.

Mange-afflicted bobcats and mountain lions exhibited severe mite encrustation on the head and shoulders (Fig. 2) in the form of proliferative dermatitis with hyperkeratosis, epidermal scaling and multiple mites, identified as *Notoedres cati*, on the surface in keratin tunnels (see also Uzal et al. 2007). In the bobcats the mange often extended over much of the body, including the hind legs. The bobcats became emaciated and increasingly diurnal in many cases, and eventually succumbed to the disease. With one exception, bobcats that died of mange did not show evidence upon necropsy of direct anticoagulant toxicity as a cause of mortality. Specifically, we did not find evidence of a

**Table 1.** Anticoagulant exposure of bobcats in the Santa Monica Mountains and Simi Hills, Ventura and Los Angeles Counties, California, USA, 1997–2003. Values indicate residues from liver samples (ppm). We captured and radiocollared all bobcats with identification (ID) numbers except for B050, which had an identification collar without a radiotransmitter. All bobcats with ID letters were recovered by other means, such as being recovered on a road, submitted to an animal control agency, or seen and reported by a homeowner. We also conducted tests for warfarin, coumachlor, and chlorophacinone, but we detected no residues except for a trace of warfarin (mdl = 0.05) in Bobcat 114.

<sup>a</sup> tr = positive, but amt < min. detectable limit (mdl) for that compound; nd = not detected.

coagulopathy (manifested by extensive internal hemorrhaging), indications that were seen previously in >8 coyotes and 1 bobcat that were determined to have died directly from anticoagulant toxicity (Hosea 2000, Riley et al. 2003). On the other hand, both mountain lions died directly from anticoagulant toxicity as demonstrated by the high levels of anticoagulants detected in the liver, multiple extensive hemorrhages on serosal surfaces and within body cavities, and the lack of evidence of trauma or other lesions to justify the bleeding. In addition, we obtained negative results from all the other ancillary tests performed.

Severe mange and anticoagulant exposure were highly associated as 19 of 19 bobcats with advanced mange had anticoagulant compounds in their liver, 18 at more than trace levels (Table 1). Including the 2 mountain lions, 21 of 21 wild felids (100%) with mange also had anticoagulant

toxicants present. The anticoagulant levels were also generally high in bobcats with mange, and for bobcats with anticoagulant residues >0.05 ppm, the association with mange was very high (Table 2;  $\chi^2 = 10.36$ ,  $P = 0.001$ ). By contrast, just 8 of 20 bobcats (40%) that died of other causes exhibited a similar level of anticoagulant exposure. Overall, the total anticoagulant level in bobcats that died with severe mange ( $\bar{x} = 0.39$ ) was higher than in bobcats that died of other causes ( $\bar{x} = 0.17$ ;  $t = 2.67$ ,  $P = 0.011$ ). There did not appear to be a specific, or threshold, level of anticoagulants in bobcats with mange because 3 of the bobcats that died with mange had 0.03 ppm, 0.07 ppm, and trace levels of anticoagulants, although it is impossible to know the level of toxicant present when the mange infestation began.

In November of 2003, we captured an adult female bobcat (B108) in the early stages of mange development that also

**Figure 2.** Bobcat with severe mange, Simi Hills, Ventura County, California, USA, 2002.

had a prolonged partial thromboplastin time (PTT) of 50.6 seconds indicative of anticoagulant exposure (normal time: 10–28 sec). She was held captive at a wildlife rehabilitation center (California Wildlife Center, Calabasas, CA) and treated with vitamin K<sub>1</sub> for anticoagulant intoxication and 2 doses of ivermectin for mange. After 2 weeks, her PTT was still elevated (>100 sec), but after 4 weeks it was normal (21.0 sec) and she had no signs of mange. We released her at the capture site in December 2003, and she subsequently produced a large litter of 4 healthy kittens in the spring of 2004. However, she was apparently exposed again to mange, and she and her surviving kitten both died with severe mange infestations in the autumn of 2004.

Beginning in 2002, when the mange epizootic began, the bobcat survival rate fell from a high of 0.847 in 1999 and a 5-year average of 0.770 to 0.280 in 2003 (Table 3). Simultaneous scat surveys also showed a significant decrease in bobcat activity starting in the autumn of 2002 (Fig. 3). Finally, local extirpations of bobcats have occurred in some of the habitat fragments in the area, both large and small. In one larger patch that is surrounded by roads and development, we were radiotracking 6 bobcats (3 F, 3 M) at the beginning of 2002 (Fig. 1, inset). All 3 males and 2 of the females died with severe mange, and we lost contact with the third female's radiocollar. Scat surveys and intensive trapping for bobcats in 2004–2006 found little evidence of bobcat activity. In 2005, 2 radiocollared male bobcats occasionally visited this patch.

For bobcats in this fragmented landscape, use of developed areas was not significantly greater for bobcats with mange (% of the home range consisting of unnatural area: Mann–Whitney  $U = 234$ ,  $P = 0.351$ ). Although neither mange nor the presence of anticoagulants were associated with human development, the total concentration (ppm) of all anti-

**Table 2.** Relationship between notoedric mange and anticoagulant exposure of >0.05 ppm in bobcats in the Santa Monica Mountains and Simi Hills, Ventura and Los Angeles Counties, California, USA, 1997–2003. Two mountain lions also had both notoedric mange and high levels of anticoagulant exposure.

coagulants in the livers of radiocollared bobcats was related to their use of developed areas. Total concentration was positively related to the percentage of the home range made up of developed area ( $r^2 = 0.255$ ,  $F_{1,20} = 6.85$ ,  $P = 0.017$ ) or unnatural area ( $r^2 = 0.163$ ,  $F_{1,20} = 3.91$ ,  $P = 0.062$ ) and to the percentage of radiolocations in developed areas ( $r^2 = 0.310$ ,  $F_{1,20} = 8.97$ ,  $P = 0.007$ ) or unnatural areas (Fig. 4;  $r^2 = 0.249$ ,  $F_{1,20} = 6.64$ ,  $P = 0.018$ ).

The radiocollared mountain lions were generally less urban-associated than the bobcats, but both mountain lions (P3 and P4) diagnosed with anticoagulant intoxication died after spending the bulk of their last month in the most developed parts of their home ranges. For example, just prior to his death, there were multiple locations for the male mountain lion (P3) in the same habitat fragments used by many of the bobcats, only the third month in 16 that he utilized these patches (southern part of Simi Hills, see Fig. 1). The female mountain lion (P4) lived almost exclusively in the Santa Susana Mountains (Fig. 1), a large contiguous block of open space, and only used the more developed Simi Hills area during the month before she died. The other 2 lions (P2 and P7) that were killed in intraspecific fights lived exclusively south of the 101 Freeway in the less-developed Santa Monica Mountains (Fig. 1).

## DISCUSSION

We frequently detected anticoagulant rodenticides in the wild felids in this landscape; including the 4 mountain lions, 91% of the cats we tested were positive for  $\geq 1$  compound. Bobcats are strict carnivores and the cases were widespread geographically and temporally, so we expect that most if not all exposure is secondary, from bobcats consuming poisoned prey. The presence of multiple compounds in 27 of 35

**Table 3.** Survival rate of radiocollared bobcats in the Santa Monica Mountains and Simi Hills, Ventura and Los Angeles Counties, California, USA, from 1997 to 2003, showing decrease in survival rate caused by mange.

Yr	No. of bobcats	No. of deaths	No. of mange deaths	Survival rate
1997	22	3	0	0.836
1998	33	7	0	0.707
1999	19	3	0	0.847
2000	20	3	0	0.796
2001	34	8	1	0.685
2002	31	15	8	0.516
2003	25	15	10	0.280

**Figure 3.** Three-month running average of the number of bobcat scat collected on standardized scat transects from 2001 to 2004 in the Santa Monica Mountains and Simi Hills, Ventura and Los Angeles Counties, California, USA. The arrow indicates the beginning of the mange epizootic.

exposed bobcats and all 4 mountain lions tested also points to secondary exposure and to the potential for accumulation of toxicity as a result of multiple exposure events. Anticoagulants are highly persistent in tissue (Eason et al. 2002, Erickson and Urban 2004, Wobeser 2006), with liver retention times of up to 256 days for brodifalone, and >250 days for brodifacoum (see Eason et al. 2002, table 6 for review, references). Target rodents may also ingest a much larger than lethal dose in the days between initial bait ingestion and eventual death (Erickson and Urban 2004), in part because of the delayed onset of toxic effects (often 3–5 d) following ingestion (Murphy and Talcott 2006), thereby increasing the amount of toxicant available to a carnivore. The lack of a significant relationship between either mange or anticoagulant exposure and urban association suggests that even bobcats with low levels of development within their home ranges were close enough to developed or altered areas to be exposed to anticoagulants. Of particular concern is the finding that toxicant concentrations increased in bobcats that more frequently utilized developed areas. This is consistent with repeated exposures, and it also suggests that as development continues to encroach upon remaining habitat, anticoagulant exposure among carnivores may increase.

The compounds that we detected, brodifacoum, bromadiolone, diphacinone, and difethialone, are widely available as household and landscape rodenticides. In our study area, those known to have used anticoagulants to target rodents

**Figure 4.** Linear regression of total concentration of all anticoagulants (ppm) found in the livers of radiocollared bobcats and the percentage of radiolocations for those bobcats in unnatural areas (developed + altered areas), in the Santa Monica Mountains and Simi Hills, Ventura and Los Angeles Counties, California, USA, 1997–2003.

include private homeowners, golf courses, office parks, schools, water utilities, apartment complexes, and park agencies. Brodifacoum, bromadiolone, and difethialone, which represent 67 of the 79 anticoagulant detections, are registered specifically for use in or adjacent to buildings to control commensal rodent pests, specifically Norway rats (*Rattus norvegicus*) and house mice (*Mus musculus*). They are not designated for the control of species such as rabbits (*Sylvilagus audubonii*), woodrats (*Neotoma* spp.), pocket gophers (*Thomomys bottae*), and ground squirrels (*Spermophilus beecheyi*) that make up the dominant prey of bobcats in this area (Fedriani et al. 2000; C. S. Schoonmaker, National Park Service [NPS], unpublished data). The high prevalence of these compounds in wild carnivores suggests widespread exposure of native, free-ranging, nontarget (at least according to the regulations) species.

The deaths of 2 mountain lions as a direct result of anticoagulant toxicity (see also Uzal et al. 2007) and the exposure of all 4 lions tested indicate the pervasiveness of these toxicants across the landscape and that they are reaching the highest levels of the food chain (see also Littrell 1988). Rodents commonly constitute a significant component of bobcat diets (Anderson and Lovallo 2003), but mountain lions specialize on ungulate prey, and 157 (95.2%) of 165 known lion kills in our study (through 2004) were mule deer (*Odocoileus hemionus*). Anticoagulant residues have not been widely reported in ungulates (but see Stone et al. 1999, Eason et al. 2002), but we only recovered kills requiring  $\geq 1$  day to eat, so we would generally not detect smaller prey items. We did find coyotes killed by radiocollared lions, and coyotes made up 15% and 7% of the kills for the 2 lions that died of anticoagulant intoxication but only 4% of kills overall. Anticoagulant toxicity was previously documented as a leading cause of death for coyotes in this area (Riley et al. 2003), and if coyotes are retaining anticoagulants, a lion eating a coyote could ingest a large quantity of toxicant at once. Both mountain lions consumed coyotes during the last month before they died.

The association between anticoagulants and mange suggests that synergistic interactions between natural and anthropogenic stressors can occur in terrestrial ecosystems. In particular, bobcats that have been exposed to anticoagulant rodenticides appear highly susceptible to succumbing to severe mange infestations, although not all anticoagulant-exposed bobcats necessarily contract mange, presumably because not all bobcats encounter *Notoedres* mites. There has been much recent discussion in the ecological literature about the enhanced effects of multiple stressors and, in particular, of natural and human-caused stressors (e.g., Sih et al. 2004). However, the empirical work has generally been in aquatic systems and in laboratory or artificial pond settings (e.g., Mills and Semlitsch 2004, Rohr et al. 2004). Here, we have documented what appear to be significant population effects in the field.

The interaction between mange and anticoagulant rodenticides also appears to be critical because each stressor by

itself would likely not have the same impact based on available evidence and previous studies. Notoedric mange has been rarely reported in wild felids, never at epizootic levels, and never in free-ranging adult mountain lions (Uzal et al. 2007). In domestic cats, young animals and those debilitated by retroviral disease are more susceptible to mange (Sparger 1990, Guaguère 1999), suggesting that complicating factors are important in disease development. Pence et al. (1982) report cases in an adult male bobcat and a litter of kittens. Wassmer et al. (1988) found that 4 of 17 captured bobcats (24%) showed evidence of mange, one of which died of the disease. However, the other 3 bobcats had only bare patches “suggesting a current or former mild mange infestation” (Wassmer et al. 1988:176). This population was also experiencing a concurrent epizootic of feline panleukopenia virus, so this disease may have contributed to the mange incidence. Despite 5 deaths from mange (notoedric and sarcoptic) in an endangered lynx (*Lynx lynx*) population in Switzerland, Ryser-Degiorgis et al. (2002) conclude that an epidemic is unlikely because of the less social nature of felids. In our study, the appearance of severe, widespread mange in adult animals prompted us to look at other factors, including anticoagulants.

Anticoagulant poisoning alone also appears to be less of a direct threat to bobcats. Although it was the most common source of mortality in coyotes, we documented one case of potential anticoagulant poisoning in bobcats in the first 5 years of our project (Riley et al. 2003). Laboratory research on anticoagulants has determined that felids have up to 100 times greater resistance than canids to certain compounds, including brodifacoum (Roder 2001, Morgan et al. 2003, Erickson and Urban 2004). There is also previous evidence of the interactive effects of anticoagulants and other stressors in mammals. In laboratory experiments with rabbits, anticoagulant levels that produced zero mortality alone resulted in 40%–70% mortality when combined with other stressors (e.g., frostbite), and similar results were obtained with rats (Jacques 1959). In a more recent study of free-ranging merino sheep (*Ovis aries*; Robinson et al. 2005), anticoagulants had a greater effect than in a similar study of sedentary sheep, and stress (specifically shearing) in combination with anticoagulant exposure caused more mortality than anticoagulant exposure alone. Bobcats and mountain lions are certainly susceptible to direct mortality from anticoagulant toxicity as demonstrated by the deaths of 1 bobcat and 2 lions.

Although we have demonstrated a strong association between anticoagulant exposure and notoedric mange, this is not the same as establishing cause and effect. Experimental evidence would be ideal, but this kind of manipulative experiment would be logistically and ethically very difficult, if not impossible, to pursue with wild felids. Wobeser (1994), reviewing Susser (1973), discusses 5 criteria or guidelines for inferring causal relationships related to disease in wild animals: strength of association, specificity of association (one cause produces one effect), time sequence, consistency (similar results in other populations), and

coherence with current knowledge about the disease. In medicine and epidemiology, these five are sometimes broadened to nine, including biological gradient (a dose response), biological plausibility (similar to coherence), experimental evidence, and analogy (Hill 1965).

Many of these criteria will not be met even in cases where a cause does produce an effect (e.g., specificity: 1 cause can produce >1 effect, and vice versa), and they are often difficult to evaluate in wildlife populations. However, the criteria can be useful in evaluating the potential for a causal relationship, in this case whether exposure to anticoagulants causes increased susceptibility to advanced mange disease (not necessarily increased exposure to *Notoedres cati*). We believe that the strength and the specificity of the association are clear in this case, as every felid with mange was also exposed to anticoagulants, and there is a highly significant association between the two. There is also evidence of a biological gradient, as bobcats with mange had significantly higher levels of exposure to anticoagulants. We have less information for the other criteria, and there are potential alternative explanations for our results. We address both of these issues below. Further research is certainly needed to more fully resolve this question. However, we believe that the available evidence points to anticoagulant exposure contributing to advanced and fatal mange disease.

In the case of each bobcat, we do not know that the anticoagulant exposure preceded the infestation, or specifically the manifestation, of notoedric mange. It is possible that the bobcats contracted mange, the mange infestation became advanced, and the bobcats were then more likely to prey on animals contaminated with anticoagulants. Several factors argue against this alternative. If anticoagulant exposure was the result of animals with mange eating prey exposed to anticoagulants, we would not expect to find anticoagulant exposure in bobcats prior to the beginning of the mange epizootic. However, on the contrary, 7 of 9 tested bobcats that died before 2002 were positive for anticoagulant exposure (Table 1). Under this alternative, we would also not expect to find bobcats with significant anticoagulant levels that did not have mange. In fact 6 animals that died after the beginning of the mange epizootic, but had no evidence of mange, had high levels of anticoagulants. Finally, this alternative presumes that bobcats weakened by mange would eat prey weakened by anticoagulants but that healthy bobcats would not. There is no reason to believe that healthy bobcats would pass up potential prey animals, including ones that were less able to escape.

It is also possible that the mange and anticoagulant exposure were simply coincident. This alternative is also related to the consistency criterion: why has this interaction not been documented in the past? Given the paucity of studies of carnivores in urban areas, and specifically of bobcats, this is not surprising. Although other studies are underway, to date we know of 2 published studies of radiocollared bobcats in urban areas, one in the San Francisco Bay area (Riley et al. 2004, Riley 2006) and this

project. The northern California study also documented a case of mortality caused by anticoagulant poisoning (Riley 1999, Hosea 2000), although not any cases of mange. However, our study is the only long-term study of bobcats in urban areas and is, to our knowledge, the longest continuous radiotracking study of bobcats ever undertaken (E. M. Anderson, University of Wisconsin—Steven's Point, personal communication). Without intensive and long-term study, periodic changes in disease prevalence or interactions between a disease and toxicants would be very difficult to document. Moreover, although anticoagulants have been in use for a long time, the second-generation anticoagulants implicated here came into widespread use more recently (e.g., brodifacoum in the 1990s; Eason et al. 2002).

Another potential alternative is that the severe mange is related to exposure to other diseases. Advanced mange, both notoedric and sarcoptic, is generally associated with debilitation by some other factor (Samuel 1981, Pence and Ueckermann 2002), including disease. There was no evidence of other disease in the 4 bobcats upon which full necropsies (with ancillary tests, see Methods) were performed, although the general poor condition as a result of the advanced mange may have masked signs of other conditions. We have tested bobcats serologically for a number of viral diseases including feline panleukopenia virus, feline infectious peritonitis, feline herpes virus, and feline calicivirus (J. E. Foley, NPS, unpublished data), and there is no indication that animals that died of mange had greater evidence of exposure to these diseases.

Although we have not been able to investigate specific mechanisms that could be responsible for the potential interaction between mange and anticoagulants, it is certainly conceivable that anticoagulant exposure could increase the likelihood of severe mange infestation (the coherence and biological plausibility criteria). Anticoagulant poisoning causes a broad spectrum of clinical signs resulting from hypovolemia from hemorrhage, organ dysfunction, or bleeding into cavities (Searcy 2001). A sub-lethal, chronic anemia, in turn, may lead to increased susceptibility to disease and leave the animals more vulnerable to mange or other stressors. Other studies have also found sub-lethal effects of anticoagulants. For example, female sheep (*Ovis aries*) exposed to anticoagulants had more aborted or stillborn lambs (up to 50%), male sheep had lower sperm motility (Robinson et al. 2005), and barn owls (*Tyto alba*) fed difenacoum-killed rats exhibited sub-lethal hemorrhaging (Mendenhall and Pank 1980). Other chronic, sub-lethal effects have included decreased food intake in sheep (Oliver and Wheeler 1978), liver damage in brushtail possums (*Trichosurus vulpecula*; Jolly et al. 1994, Littin et al. 2002), and a decrease in body weight in brushtail possums (Littin et al. 2002). Decreases in feeding and weight in particular could affect overall condition and thereby disease resistance. Sub-lethal effects may also be more likely in a species such as bobcats that is less susceptible to direct, lethal coagulopathy than, for example, coyotes.

## MANAGEMENT IMPLICATIONS

At present, anticoagulant rodenticides are seen as an effective and inexpensive method of killing rodents. However, anticoagulant applicators, including homeowners, landscape professionals, pest control operators, and land and resource managers, should consider that these chemicals can have significant impacts on nontarget wildlife. Especially in areas of high anticoagulant use such as urban areas, exposure of nontarget carnivores to anticoagulant rodenticides may be extensive and can result in direct mortality and possibly sublethal effects, potentially including complex interactions with other factors such as our data suggest. Increased awareness and the use of alternative pest control methods should reduce risks to nontarget wildlife, including carnivores. Where species of conservation concern may be exposed, further regulation of the use of anticoagulant rodenticides may be warranted. Managers should also be aware that the effects of anticoagulant rodenticides may be difficult to document without intensive study, but that a range of species may be affected. Finally, our results indicate that severe notoedric mange in bobcats, previously undocumented as an epizootic, can have population-level effects, and that those effects may be particularly significant in fragmented landscapes where local extirpations can occur.

## ACKNOWLEDGMENTS

We thank E. C. York, J. S. Sikich, C. A. Schoonmaker, P. Roby, K. A. Asmus, J. Moriarty, and K. McCurdy for exceptional capture and field work; J. Moore of California Animal Health and Food Safety Laboratory for assistance with necropsies; L. F. S. Lee for help with figures; California State Parks, the Western Region of NPS, and the Los Angeles County Sanitation Districts for funding; and Conejo Open Space and Conservation Agency and Rancho Simi Parks and Recreation District for assistance. We thank M. Morrison and 3 anonymous reviewers for comments on earlier drafts of this manuscript. The opinions expressed in this paper are not intended to represent official positions or policies of NPS, the United States Government, or the State of California.

## Summary

Large carnivores can be particularly sensitive to the effects of habitat fragmentation on genetic diversity [1, 2]. The Santa Monica Mountains (SMMs), a large natural area within Greater Los Angeles, is completely isolated by urban development and the 101 freeway to the north. Yet the SMMs support a population of mountain lions (*Puma concolor*), a very rare example of a large carnivore persisting within the boundaries of a megacity. GPS locations of radio-collared lions indicate that freeways are a near-absolute barrier to movement. We genotyped 42 lions using 54 microsatellite loci and found that genetic diversity in SMM lions, prior to 2009, was lower than that for any population in North America except in southern Florida, where inbreeding depression led to reproductive failure [3–5]. We document multiple instances of father-daughter inbreeding and high levels of intraspecific strife, including the unexpected behavior of a male killing two of his offspring and a mate and his son killing two of his brothers. Overall, no individuals from the SMMs have successfully dispersed. Gene flow is critical for this population, and we show that a single male immigrated in 2009, successfully mated, and substantially enhanced genetic diversity. Our results imply that individual behaviors, most likely caused by limited area and reduced opportunities to disperse, may dominate the fate of small, isolated populations of large carnivores. Consequently, comprehensive behavioral monitoring can suggest novel solutions for the persistence of small populations, such as the transfer of individuals across dispersal barriers.

## Results

### Movements, Mortality, and Dispersal in an Urban Landscape

We captured, genotyped, and radio-tracked 26 mountain lions in the Santa Monica Mountains (SMMs;  $n = 21$ ) and Santa Susana Mountains (including the Simi Hills;  $n = 5$ ) from July 2002 through July 2012 (Figure 1). We also genotyped 17 other mountain lions from opportunistically collected samples,

including from Angeles National Forest and the Verdugo Hills. Large freeways, including the 101 freeway (Figure 2A), the 5 freeway (Figure 2B), and the 405 freeway (Figure 2A), were significant barriers to movement (i.e., were almost never crossed by mountain lions) and often acted as home-range boundaries. One smaller freeway, the 118 freeway between the Simi Hills and the Santa Susana Mountains (Figure 1), was crossed at least 23 times by two radio-collared mountain lions in an area with a large tunnel and natural habitat on both sides [6]. In February 2009, subadult male P12 crossed the 101 freeway into the SMMs, the only time that a radio-collared mountain lion crossed 101, which separates the SMMs from all areas to the north.

Fourteen radio-collared lions died during the study period: six from intraspecific strife, two from vehicles, two of anticoagulant toxicosis from ingesting rodenticides, one from poaching, one from starvation as a young kitten, and two from unknown causes. Overall, 50% of mortalities of known cause were from intraspecific strife. An uncollared young male was also killed by another lion, for a total of seven instances of intraspecific killing. In five of these cases we were able to identify the surviving individual, and in all five we found that an adult male killed his offspring, his brother, or a previous mate (Table S1 available online).

We tracked the fate of young mountain lions, especially males, to assess dispersal. In the SMMs, we radio-tracked ten subadult male mountain lions and sampled five others that originated there (Table S1). Not one of these 15 young males was known to disperse from the SMMs to a home range with mating opportunities. Of the 12 young males from the SMMs whose ultimate fates are known, 11 died before or during dispersal from intraspecific strife ( $n = 5$ ), vehicle strikes ( $n = 4$ ), control action by police ( $n = 1$ ), and unknown causes ( $n = 1$ ). The only young male to successfully disperse from the SMMs, P22, settled in Griffith Park, requiring the crossing of two freeways (405 and 101; Figure 1). For more than 2 years, this male inhabited a home range of 26 km<sup>2</sup>, as compared to 500 km<sup>2</sup> for adult male P1 (Figure 1). P22's home range was entirely bounded by freeways and urbanization, and he was its sole occupant.

North of 101, we radio-tracked three subadult males and sampled three others that were killed on roads (Table S1). All three collared animals successfully crossed roads and established home ranges as adults. P3 moved regularly between the Simi Hills and the Santa Susana Mountains across the 118 freeway. P12 crossed 101 and subsequently established himself as a dominant male in the SMMs. Perhaps most instructive, young male P16, who shared the eastern Santa Susana Mountains with his father, P21, dispersed north across highway 126 and established a home range (Figure 1). Among radio-collared animals of known fate, the least biased sample for mortality and dispersal, none of the seven subadult males from the SMMs successfully dispersed and established viable home ranges, while all three from the Santa Susana Mountains did.

### Population Genetics of a Small, Isolated Population

We found very low genetic diversity compared to large, contiguous populations in California and in other parts of the west

\*Correspondence: [seth\\_riley@nps.gov](mailto:seth_riley@nps.gov)

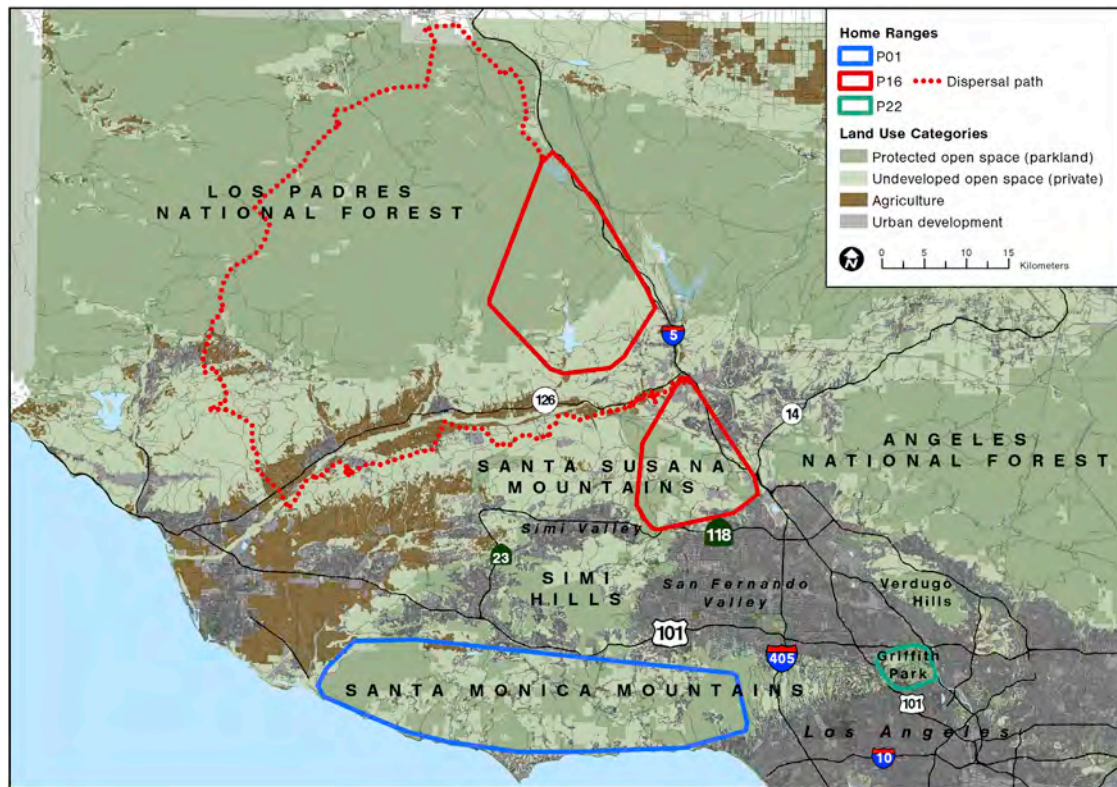

Figure 1. Study Area for Mountain Lion Movements and Population Genetics in and around Santa Monica Mountains National Recreation Area Northwest of Los Angeles

Large natural areas and major freeways are labeled. Home ranges are 100% minimum convex polygons for male P22 in Griffith Park, male P01 in the SMMs, and male P16 that dispersed from the eastern Santa Susana Mountains, across highway 126 to Los Padres National Forest. See also [Table S1](#).

([Tables 1](#) and [S2](#)). Genetic diversity was particularly low in the SMMs south of the 101 freeway, which is the largest and busiest road to the north (175,000 vehicles/day versus 115,000 for the 118 freeway and 22,000 for highway 126; [7]). This population is also farthest away from the putative source populations in Los Padres and Angeles National Forests. The expected heterozygosity ( $H_E$ ), total number of alleles ( $N_A$ ), and number of effective alleles ( $N_E$ ) were all significantly lower in the SMMs than north of the 101 freeway ([Table 1](#)). For private alleles (defined here as those present only in one study population), 67 of 172 discovered alleles were absent from the SMM population, and 78% of loci (42 of 54) had at least one private allele north of 101.

Genetic differences between local populations were also apparent from Bayesian cluster analyses ([Figure 3A](#)). Despite the small sample sizes, the program STRUCTURE [8] indicated strong clustering into three groups ( $K = 3$  by the Evanno  $\Delta K$  method [9]; [Figure S1](#)). The  $F_{ST}$  value between populations north and south of the 101 freeway was 0.12 ( $p < 0.05$ ), three times larger than that previously found for other carnivores in the area [10]. The SMM mountain lion population showed evidence of having experienced a genetic bottleneck based both on significant heterozygote excess (program Bottleneck [11]; single-step mutation probabilities of 90%,  $p = 0.00044$  and 78%,  $p = 0.00004$ ) and Garza and Williamson's  $M$  ratio test ([12]; average  $M = 0.75$ ; for single-step mutation proportion, 90%,  $p < 0.0001$ ). The current effective population size,  $N_E$ , for mountain lions south of 101 was just six individuals.

### The Influence of Specific Behavioral Events on Population Demography and Genetics

Our analysis of a genetically based pedigree showed that specific behavioral events greatly affected population dynamics and genetic composition ([Figure 3B](#)). For example, the migration into the SMMs of P12, who was genetically assigned to the population north of 101 ([Figure 3A](#), blue cluster) and had private northern alleles at 33% of microsatellite loci, demonstrated that the 101 freeway can be traversed. Critically, P12 then survived in the SMMs and bred with resident females, including female P13 twice and his daughter, P19 ([Figure 3B](#)). This was the second instance of father-daughter mating, as P13 was the result of male P01 mating with his daughter, female P06 ([Figure 3B](#)) [13].

The immigration and subsequent matings of male P12 increased the genetic diversity and decreased the internal relatedness (IR) of the SMM population ([Table 1](#)) and thus is an example of a genetic rescue. P12 possessed 20 private alleles from north of the freeway, 19 of which he passed on to his offspring, such that private alleles absent from the SMMs decreased from 67 to 47, loci with private alleles to the north decreased from 42 to 32, and monomorphic loci in the SMMs decreased from 13 to 9. Bayesian clustering analysis also clearly showed the impact of P12's immigration ([Figure 3A](#)). Ninety-seven percent of P12's genome was assigned to the Santa Susanna Mountain population, and he fathered eight offspring based on our pedigree ([Figure 3B](#)). Six of these, including the five with P13 (99% assigned to the SMMs) exhibited a near equal mix of the

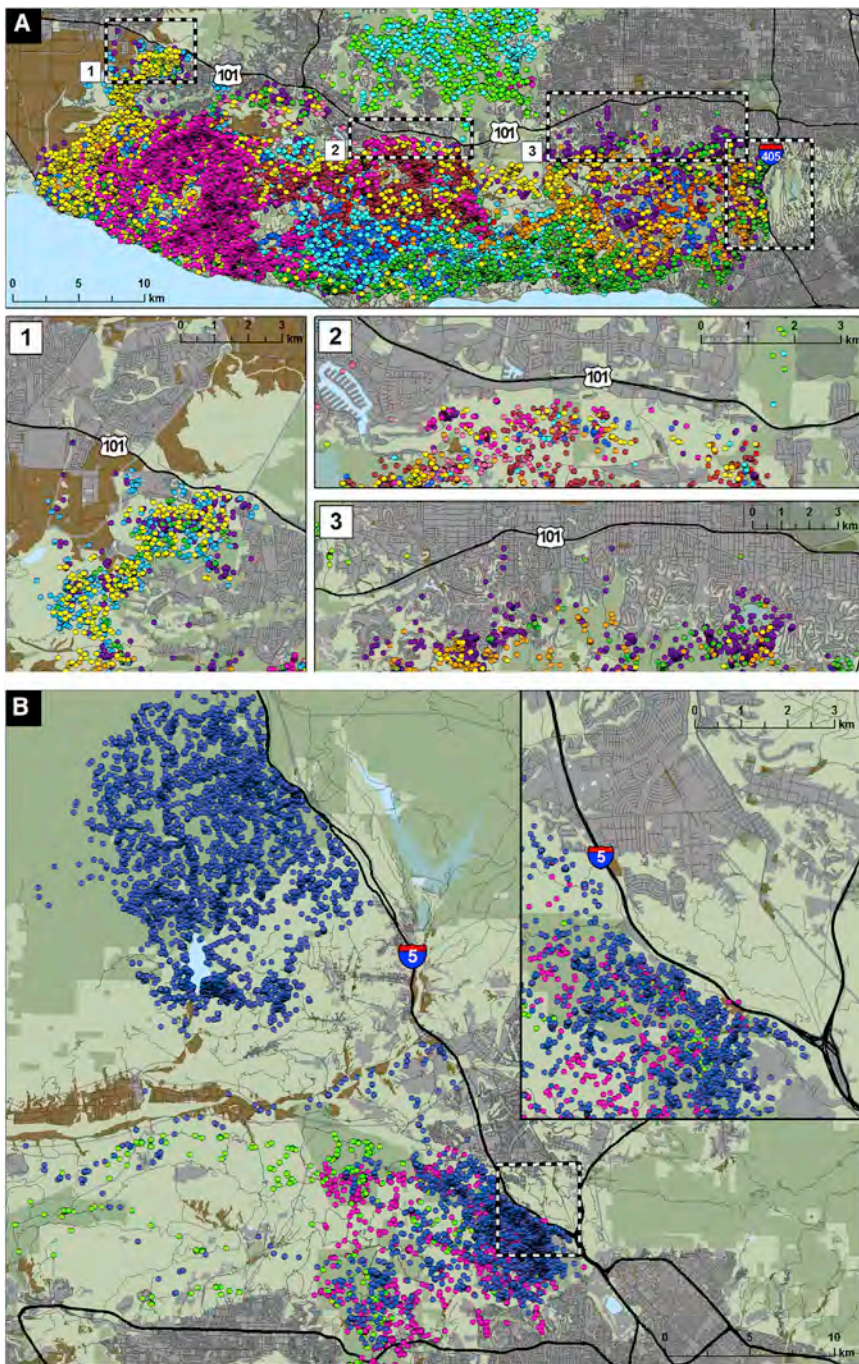

Figure 2. Locations of Mountain Lions along Freeways in Southern California from GPS Radio Collars, 2002–2012

(A) Locations near the 101 freeway, which runs east-west north of the Santa Monica Mountains. Because there is urban development along most of this freeway, in many areas (insets 2 and 3) animals do not approach the freeway. Toward the east end of the SMMs, the 405 freeway passes north-south through the mountains. This freeway is also a major barrier to mountain lion movement.

(B) Locations north of 101 in the Santa Susana Mountains and Los Padres National Forest near the 5 freeway, which runs north-south through the region.

the SMMs, and then rose again in 2013 after P12 bred with his daughter. Similarly, gene diversity showed the opposite pattern, decreasing after the first close inbreeding event, rising in 2010 after P12 bred, and then decreasing with the second inbreeding event (Table S3). The dramatic shifting values of these coefficients over short time periods demonstrate how important individual matings are to the levels of inbreeding and relatedness in the population (Figure S2).

Finally, the IR, a measure that has the potential to provide novel insight about inbreeding and genetic health [15], reflected both the initial bottleneck and the effects of the inbreeding and genetic rescue events. The mean IR for SMM animals dropped from 0.09 (SE = 0.014) to 0.03 (SE = 0.036) when P12 and his offspring were included, as IR values for the initial offspring of the genetic rescue event were low and averaged  $-0.16$  (range  $-0.10$  to  $-0.35$ ). For P23 and P24, the incestuous offspring of P12 and his daughter, IR values rose again to 0.10 and 0.09, indicating that one close inbreeding event may have reversed much of the value of the genetic rescue.

Our results from this small, isolated population also indicate how individual male mountain lions can monopolize breeding opportunities and

SMM (green) and Santa Susanna Mountain (blue) clusters (Figure 3A). Interestingly, P23 and P24, the offspring of P12 and his daughter, P19, each had about three-quarter assignment to the Santa Susana Mountains, as expected (Figures 3A and 3B).

The effects of individual mating events on population genetic measures were also evident as quantified with our pedigree by gene-drop analysis (program PMx [14]) applied for the first time to a wild population. Both the mean inbreeding coefficient (F) and mean kinship increased in 2007 after male P1 bred with his daughter, decreased in 2010 after migrant P12 began to produce offspring in

genetically dominate future generations. Two males, first P01 and later P12, had very high reproductive success based on the pedigree (Figure 3B). Specifically, P01 fathered  $\geq 15$  offspring, P12 fathered  $\geq 8$  offspring, and no individual in the SMM population was fathered by any other male. The pedigree and PMx analyses indicated that P01 had 22 descendants, including six of the seven animals known in the population in 2013, and that P12 had eight descendants, including four of the seven current animals; 33.9% of the copies of the genome in the current population are derived from P01 and 35.7% from P12 (see Table S4).

Table 1. Genetic Diversity Based on 54 Microsatellite Loci for Mountain Lions in and around the Santa Monica Mountains, California, 2002–2012

Population	N <sub>A</sub>	N <sub>E</sub>	Poly (%)	H <sub>E</sub>	H <sub>O</sub>	IR
Santa Monica Mountains only, south of the 101 freeway before P12 crossing (n = 17)	1.9 ± 0.2	1.6 ± 0.1	76%	0.31 ± 0.03	0.38 ± 0.04	0.09 ± 0.04
North and east of the Santa Monica Mountains, north of the 101 freeway (n = 15)	3.1 ± 0.1	2.1 ± 0.1	100%	0.48 ± 0.02	0.42 ± 0.02	0.17 ± 0.05
Santa Monica Mountains only, south of the 101 freeway after P12 crossing (n = 26)	2.3 ± 0.1	1.8 ± 0.1	83%	0.36 ± 0.03	0.36 ± 0.03	0.03 ± 0.04

Populations are from the SMMs before the genetic rescue event (the dispersal of subadult male P12 from north to south), from north of 101 in the Santa Susana Mountains and San Gabriel Mountains, and from in the SMMs after the genetic rescue event. N<sub>A</sub> is the total number of alleles, N<sub>E</sub> is the number of effective alleles, poly (%) is the percentage of loci that are polymorphic, H<sub>E</sub> is expected heterozygosity, H<sub>O</sub> is observed heterozygosity, and IR is individual heterozygosity or internal relatedness (see the [Supplemental Experimental Procedures](#) for details). N<sub>A</sub>, N<sub>E</sub>, and H<sub>E</sub> are significantly lower (nonoverlapping 95% confidence intervals) for the SMMs before P12 crossed than for north of the 101 freeway. Mean ± SE is shown. See also [Table S2](#).

## Discussion

### Individual Effects on Population Dynamics and Genetic Diversity

Urban environments are generally inhospitable for large carnivores. Therefore, it is remarkable that a population of a large carnivore extends into the metropolitan area of Los Angeles, one of 30 world megacities (metropolitan areas of >10,000,000 people). However, the challenges for the long-term persistence of this population are substantial. Freeways in the area are almost complete barriers to mountain lion movement ([Figure 2](#)). This severe isolation most likely caused a striking assignment of lions to a single genetic cluster in the SMMs ([Figure 3A](#)). SMM lions were also clearly differentiated from those east of the 5 freeway (red cluster in [Figure 3A](#)), which separates the Angeles National Forest from the Santa Susana Mountains and Los Padres National Forest ([Figure 1](#)). The F<sub>ST</sub> value of 0.12 across the 101 freeway is high given its relatively recent age (1949) and given that other studies of *Puma concolor* microsatellite loci have found F<sub>ST</sub> < 0.10 among 15 subpopulations across the state of Idaho (distances of ≥500 km; [16]) and an average F<sub>ST</sub> of 0.041 among 20 subpopulations from four southwestern states (700 by 700 km; [17]).

Genetic diversity in SMM mountain lions also is very low relative to populations north of the 101 freeway and elsewhere in California and the western US ([Table S2](#)). A measure that is less affected by sample size, the expected heterozygosity, is 0.31 for the SMMs before the immigration event, a value that is the lowest ever reported for western mountain lions, with the exception of another isolated population in the Santa Ana Mountains of Southern California that has comparable variability (H.B.E., unpublished data). The average number of alleles per locus (N<sub>A</sub>) was also lower in the SMMs than north of 101 and was one-half to two-thirds of the average value from other populations across the western range ([Table S2](#)). The sole population with lower genetic diversity than the SMM population across all of these measures is the Florida panther, *Puma concolor coryi*, a federally endangered subspecies that suffered from substantial inbreeding depression and had been isolated for more than a century before lions from Texas were introduced to alleviate inbreeding depression ([Table S2](#)) [4, 5].

In the small, isolated SMM population, individual behavioral events can have a significant impact on population dynamics and genetics. We documented only one movement across the 101 freeway, by subadult male P12. But after his establishment as a dominant breeding male, new alleles entered the

population, and, particularly for his mixed offspring, genetic diversity increased and measures of inbreeding decreased. However, first-order inbreeding events (father-daughter matings) by males P1 and P12 had the opposite effect, increasing inbreeding and reducing diversity. This kind of close inbreeding has only rarely been documented in mountain lions, specifically in the small and isolated southern Florida population [3, 4].

We also found significant effects of individual behavior on two other critical aspects of population dynamics, dispersal and mortality. Although typically every young male and half of young females disperse out of their natal range [18], not a single subadult mountain lion has successfully dispersed out of the SMMs. Instead, young males have died, principally from intraspecific strife and vehicles. In the one dramatic case, male P22 dispersed from the SMMs into the Hollywood Hills and has lived for 2 years in a home range of 26 km<sup>2</sup>, the smallest annual range ever reported for an adult male. In this range, P22 was surrounded by roads and development ([Figure 1](#)) and had no opportunity to mate. Male mountain lion home ranges are typically an order of magnitude larger, at 300–400 km<sup>2</sup> or more [18, 19], and overlap with those of multiple females. By contrast, all three of the young males that we radio-tracked in the Santa Susanna Mountains successfully dispersed and established home ranges.

Intraspecific strife, the most common cause of mortality, can also be important in other populations, particularly those that are not hunted [20, 21]. However, in the SMMs, we documented repeated cases of males killing their offspring, their brothers, and previous mates. Little has been reported about paternity or kin recognition in mountain lions [18, 22], but clearly this is rarely a sound evolutionary strategy as the survivorship of offspring or siblings is traded against the probability of future reproduction [23]. It is particularly hard to imagine an advantage from killing potential mates or female offspring ([Table S1](#)). In fact, in the Santa Susanna Mountains, we observed the opposite pattern. Male P21 was the father of subadult males P12 and P16 ([Figure 3B](#)), both of which successfully emigrated and established long-term home ranges: P12 south into the SMMs and P16 north across highway 126 ([Figure 1](#)). None of the young males originating in the SMMs, dominated by adult males P1 and P12, have lived beyond age 2, so with respect to male mountain lions, the SMMs are a population sink. In other aspects of ecology and behavior, including home-range size (males, 300–500 km<sup>2</sup>; females, 100–200 km<sup>2</sup>), diet (≥90% deer), annual adult survival (≥75%), and litter size (two to four) [6], the SMM lion population is similar to those throughout the southwest [20].

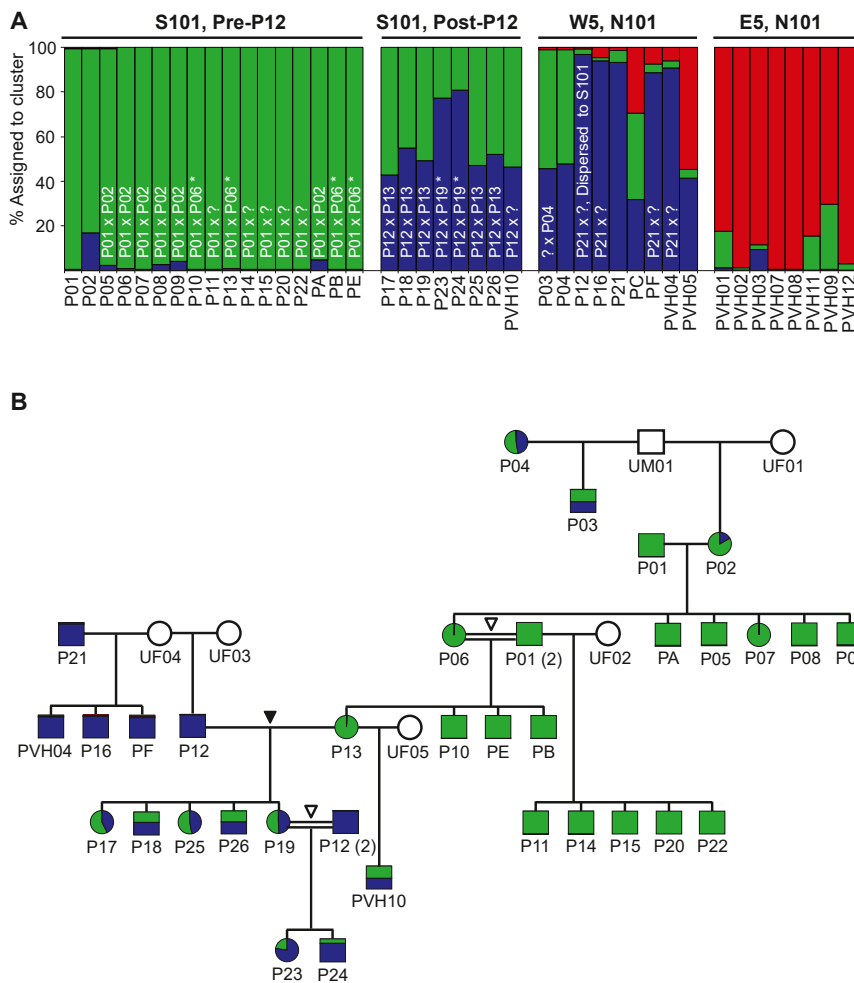

Figure 3. Genetic-Based Cluster Assignments and Recreated Pedigree Based on 54 Microsatellite Loci

(A) Results of program STRUCTURE for 42 mountain lions in the SMM region in Southern California, 2002–2012. The “S101, pre-P12” group is mountain lions from the SMMs, south of the 101 freeway (see Figure 1), before male P12 crossed the 101 freeway from the Simi Hills to the SMMs. The “S101, post-P12” group includes animals sampled in the SMMs that are the offspring of male P12 after he crossed the 101 freeway. “W5, N101” includes animals from the Simi Hills and Santa Susana Mountains, north of the 101 freeway. “E5, N101” includes mountain lions east of the 5 freeway in the San Gabriel Mountains and Verdugo Hills. White lettering for the first three groups indicates the known parentage based on the recreated pedigree. See also Figure S1.

(B) Pedigree for mountain lions in and around the SMMs, 2002–2012. The pedigree was constructed using the programs CERVUS and Colony (see the Supplemental Experimental Procedures). Colors for individual animals correspond to the genetic cluster assignments determined using STRUCTURE: green is the SMM cluster, and blue is the “W5, N101” or Santa Susana Mountains cluster. Symbols with two colors indicate animals with assignment to both clusters. Animals that were not sampled but whose presence is presumed are labeled “UF” for unknown females or “UM” for unknown males. Double lines and open triangles between animals indicate close inbreeding events, specifically father–daughter mating. The black triangle indicates the outbreeding event when P12, from north of the 101 freeway, bred with P13, from the SMMs. See also Figure S2 and Tables S3 and S4.

Very small populations are subject to Allee effects in which low growth rates result from low density, often caused by social disruption as individuals are too sparse to form social groups or find mates [24]. In the SMMs, the inverse has occurred as a small mountain lion population is at high density but lives in a spatially constrained area, resulting in social disruption through negative interactions between close relatives that normally would be rare or nonexistent. The result is reduced population health as indicated by low genetic diversity and increased inbreeding. Such “inverse Allee effects” leading to social disruption could be an important but largely unrecognized problem in isolated and densely packed urban environments.

#### Implications for Management and Conservation of Large Carnivores in Urban Landscapes

The importance of specific behavioral events such as dispersal, inbreeding, and killing of close relatives in this small, isolated mountain lion population has implications for conservation in fragmented landscapes. First, detailed behavioral and genetic monitoring may be critical for understanding the factors that threaten population persistence. Only through the collection of extensive demographic and behavioral data on most of the population were we able to identify the most important behaviors affecting population dynamics and genetic diversity.

Second, the maintenance and restoration of habitat connectivity is vital for small populations of large carnivores. Migration events between populations may not have to be frequent to maintain genetic diversity [25], and we have observed that one successful migrant can have a significant impact, especially in mountain lions, where individual males can have high reproductive success. However, the skewed reproduction in small mountain lion populations [26] can result in dominance of the gene pool by individual males, especially when close inbreeding is also occurring, which may be detrimental to population persistence. In the wolves at Isle Royale National Park, although a single male wolf immigrated into the population and increased genetic diversity, the effects were reversed by reproductive dominance of this individual and associated inbreeding [27, 28]. Connectivity is also important because stochastic effects, such as the loss of one dominant male through a vehicle collision, are more extreme and can result in extinction. Previous research on mountain lions in the Santa Ana Mountains suggested that an area of less than 1,100 km<sup>2</sup> was unlikely to support mountain lions without some immigration [29], and the SMMs are only about 660 km<sup>2</sup>. In highly developed areas, the conservation of natural habitat on both sides of freeways and effective corridors across them [30] or translocations may be necessary if large carnivores are to persist in proximity to the megacities of the future.

## Supplemental Information

Supplemental Information includes Supplemental Experimental Procedures, two figures, and four tables and can be found with this article online at <http://dx.doi.org/10.1016/j.cub.2014.07.029>.

## Acknowledgments

We thank K. Delaney for comments on an earlier draft, R. Sauvajot and C. Brigham for guidance and support throughout the project, L. Lee and J. Brown for assistance with databases and figures, and the UC Davis Veterinary Genetics Lab for technical assistance. We thank California State Parks, the Santa Monica Mountains Fund, SMMC/MRCA, and the Calabasas Landfill for funding support. We thank many NPS biologists and interns for hard work in the field on the mountain lion project, including J. Moriarty, J. Brown, C. Schoonmaker, E. Lara, C. Bromley, P. Roby, K. McCurdy, and especially E.C. York, 1970–2007, to whom we dedicate this paper and who was critical to the lion project and all of the carnivore projects at SAMO.

## EXECUTIVE SUMMARY

Roads can cause significant mortality for wildlife, but large roads like freeways can also form major barriers to wildlife movement and gene flow. Freeways are ubiquitous in southern California, and two freeways, Interstate 15 and U.S. 101, have been found to be barriers to wildlife passage and gene exchange, especially for mountain lions, between the Santa Ana Mountains and the Palomar Mountains and other mountains to the east (separated by Interstate 15), and between the Santa Monica Mountains and the Simi Hills, Santa Susana Mountains, and others to the north (separated by the 101 Freeway). We used two sources of information with the goal of bridging the gap between connectivity science and conservation practice. In early 2015 we engaged an independent panel of connectivity experts to evaluate possible locations and concepts for wildlife crossings along stretches of both freeways. We also developed and implemented an evaluation tool based on landscape characteristics and wildlife data to help prioritize locations for wildlife crossing infrastructure. The experts were asked to evaluate stretches of each freeway where wildlife studies have indicated that some connectivity potential remains due to the presence of natural habitat on both sides of the road, but where new or enhanced structures are likely required to restore lost connectivity. Multiple specific sites were examined along these stretches of each freeway. For I-15, both the Landscape and Expert scoring indicated that retention and enhancement of function under the Temecula Creek Bridge, and construction of a new under or overpass south of the bridge, were both likely needed for long term connectivity. For the 101 Freeway, the Landscape and Expert scoring both strongly concluded that West Liberty Canyon is the best location for a new wildlife crossing structure, with several other locations being sites where enhancements or new construction could serve the role of providing secondary crossings. The experts indicated that an overpass, over both 101 and the parallel Agoura Rd, was the best option here to provide connectivity for a range of species. The experts agreed that accompanying measures, such as effective wildlife fencing to funnel animals to crossing points and appropriate vegetative cover on and near structures were also important. They also recommended that, over the long term, more than one crossing structure should be enhanced or created for each linkage to assure sufficient movement of wildlife to accomplish gene exchange between populations in entire mountain ranges. Increasing connectivity across both freeways is critical for the long-term viability of local wildlife populations, especially for wide-ranging species such as mountain lions, and this analysis provides a concrete way forward.

## 1. INTRODUCTION

The protection of habitat connectivity is arguably one of the most salient global conservation problems of our day – how to keep from fragmenting intact natural landscapes with areas of intense human land use, and how to halt and reverse the cascading impacts of habitat fragmentation resulting from past land use decisions.

The threat of habitat fragmentation to biodiversity is well recognized in southern California. Here, coastal, montane, and desert ecosystems intersect to create an area renowned for its unique and diverse biota (Myers et al. 2000). It also is an area of intense human development with a growing population of nearly 24 million that threatens the persistence of the region’s natural habitats and species (State of California, Dept. of Finance 2017). Despite large expenditures of funds and effort to preserve biodiversity and conserve threatened or endangered species in the region, substantial challenges remain for persistence of some species.

The Santa Ana Mountains and Santa Monica Mountains are two of several large southern California landscapes (Figure 1) that, despite conservation investments in the hundreds of millions of dollars, remain at risk of isolation and fragmentation by roads and urban development (Riley et al. 2014, Ernest et al. 2014). Wildlife research studies have identified that major highways and associated development have severed connectivity between these coastal ranges and larger inland protected lands that are considered critical to protecting plant and animal species against climate change and other threats. Specifically, Interstate 15 (hereafter referred to as “I-15”) in western Riverside County has seriously reduced connectivity between the Santa Ana Mountains and the inland eastern Peninsular Ranges (with the Palomar Mountains being the most proximate portion of the Peninsular Ranges to I-15), and US Highway 101 (hereafter referred to as the “101 Freeway”) in northern Los Angeles County and Ventura County has seriously reduced connectivity between the Santa Monica Mountains and inland Santa Susanna and Sierra Madre Mountains to the north (Riley et al. 2014, Ernest et al. 2014). These concerns have been amplified by the findings of recent genetic analyses relating to both the Santa Ana Mountains’ and Santa Monica Mountains’ mountain lion (*Puma concolor*) populations, indicating significant genetic restriction and minimal evidence of migration into these populations in recent years. These studies indicate that genetic diversity for Santa Ana and Santa Monica mountain lions is very low (Riley et al. 2014, Ernest et al. 2014), lower than has been measured anywhere else in the west. Only in endangered Florida panthers, where severe genetic defects were present throughout the population before a genetic introgression program, has lower genetic diversity been found (Gustafson et al. 2017).

Both linkages have been prioritized for protection by the South Coast Missing Linkages Project, an effort to identify important landscape linkages throughout the State of California (Penrod et al. 2001). Subsequently, detailed linkage designs, including recommendations for highway crossing structures for the 101 and I-15 freeways, were developed (Penrod et al. 2006, South Coast Wildlands 2008). Both linkages were also identified as important in the California Essential Habitat Connectivity Project (2010), commissioned by Caltrans and the California Department of Fish and Wildlife.

Significant research and planning efforts have been conducted for both linkages to help address connectivity needs, which range from strategic land acquisition for conservation to the identification of locations and concepts for wildlife crossing structures for both freeways. Because of the rate and extent of past urbanization throughout southern California, opportunities for securing connectivity across

major freeways in both linkages are limited. Each of these areas presents unique challenges to accomplishing improved connectivity, with many improvements that have been proposed likely requiring significant financial investment, for both wildlife crossing structures and land protection, and significant political and public support.

As stated in the Wildlife Crossing Structure Handbook (2011): "There is currently an urgent need to provide transportation and other stakeholder agencies with technical guidance and best management practices on the planning and design of wildlife crossing mitigation measures. The siting of wildlife crossing structures is equally as important as their design. Identifying the proper location of crossing structures is critical for designing effective mitigation of the barrier effect caused by roads."

Given the challenges and level of financial investment required to secure connectivity for the Santa Ana to Palomar Mountains Linkage (Figure 2), and the Santa Monica to Sierra Madre Mountains Linkage (Figure 3), the National Park Service, The Nature Conservancy, and the UC Davis Karen C. Drayer Wildlife Health Center felt that both linkages would benefit from a collaborative effort to help bridge the gap between science and practice by: 1) engaging an independent panel of connectivity experts to evaluate possible wildlife crossing site locations and concepts for the I-15 and 101 Freeways; and 2) developing and implementing an evaluation tool based on landscape characteristics and wildlife knowledge to help prioritize locations for the siting of wildlife crossing infrastructure.

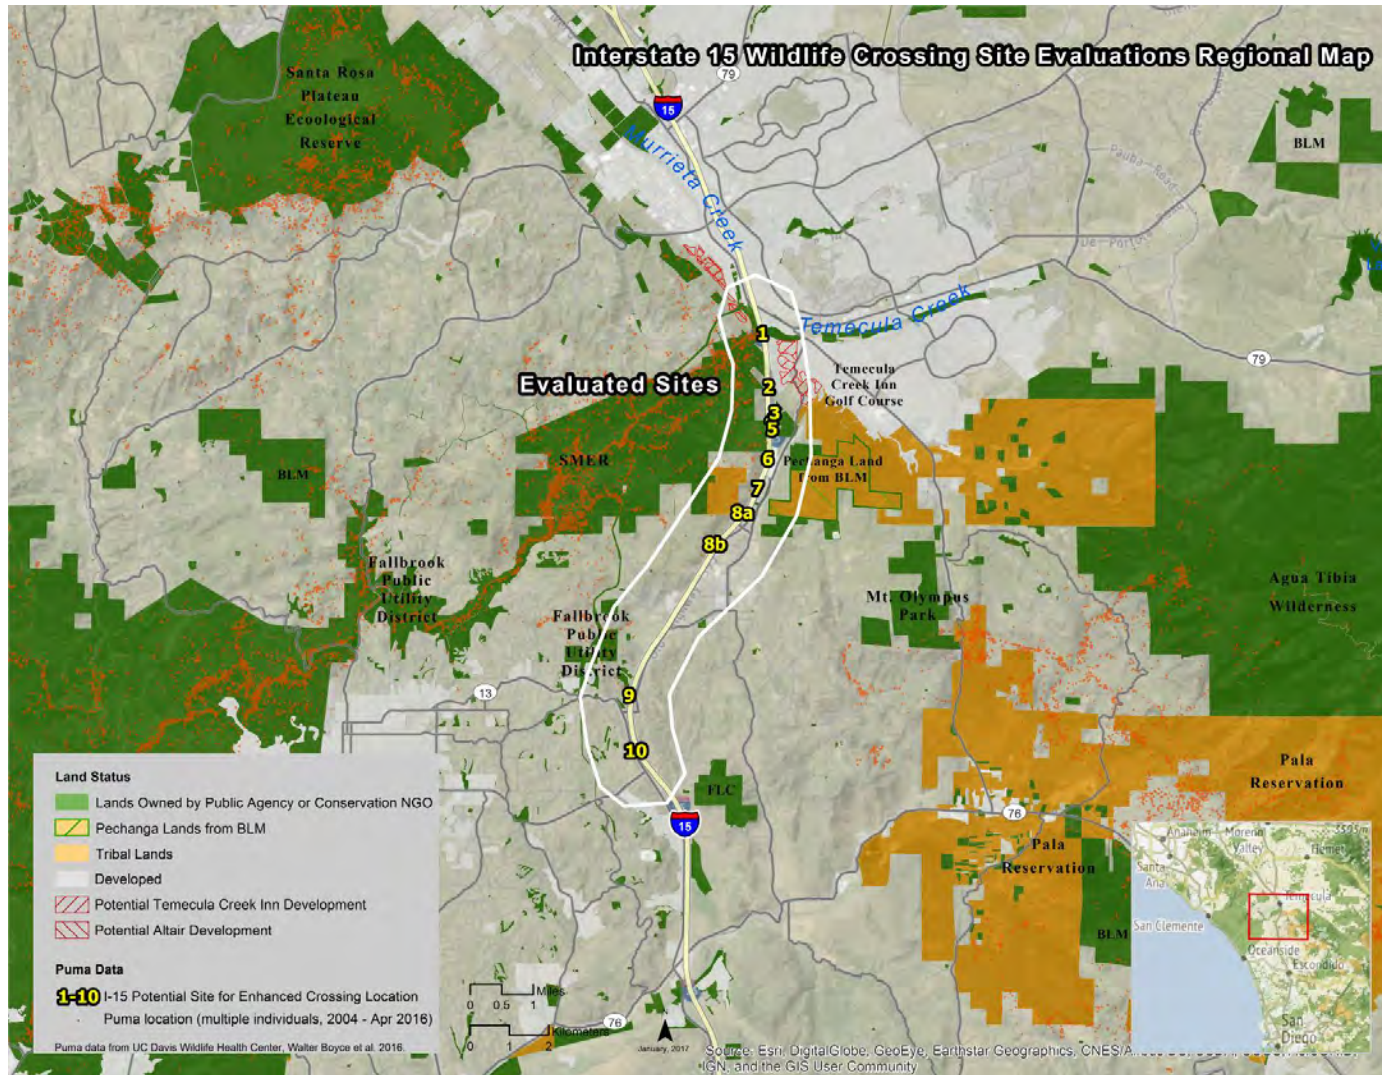

**Figure 1.** Regional map of the Santa Ana to Palomar Mountains Linkage and Santa Monica to Sierra Madre Linkage and other priority linkages in Southern California

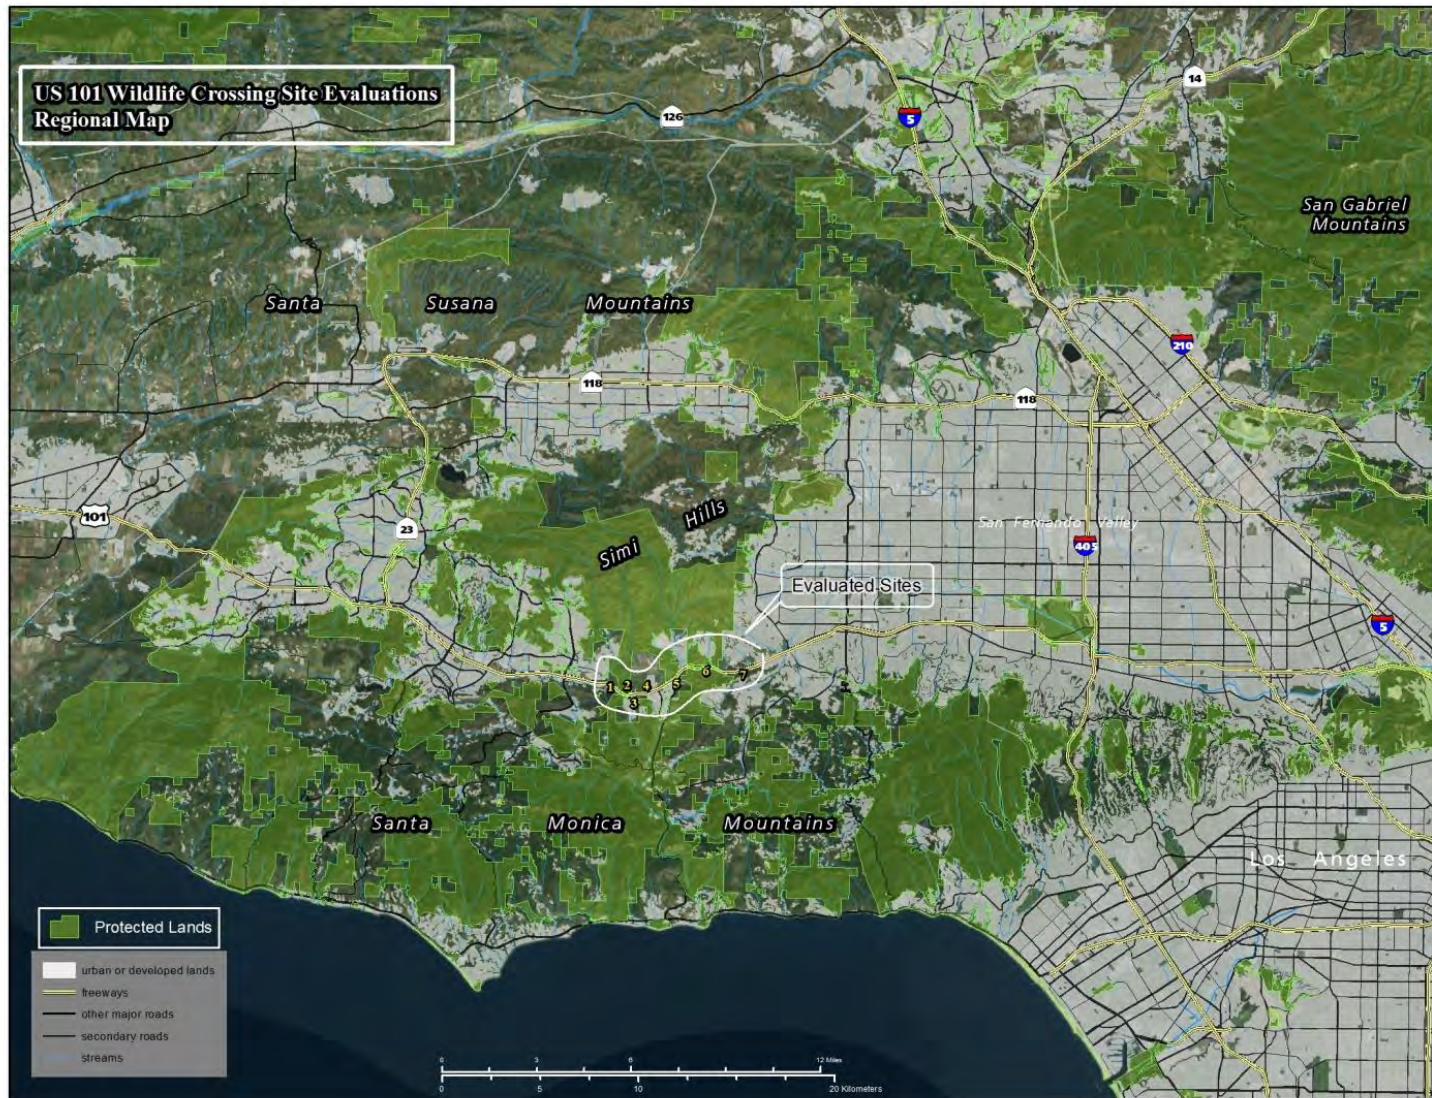

Figure 2. Location map of Santa Ana to Palomar Mountains Linkage, including the area along I-15 evaluated for wildlife crossings.

**Figure 3.** Location map of Santa Monica Mountains to Sierra Madre Mountains Linkage, including the area along 101 evaluated for wildlife crossings, and the intervening natural areas of the Simi Hills and Santa Susana Mountains.

**Project Objective:** The overall objective of this effort was to provide critical information to stakeholders involved in the development of new or improved wildlife crossing structures across the I-15 and 101 Freeways. Stakeholders that are expected to use this information include conservation agencies and organizations (governmental and non-governmental), highway agencies, local jurisdictions involved with land use decisions, wildlife agencies, and others in the region in their efforts to increase connectivity for wildlife.

Given the likelihood that these freeways negatively impact or block free exchange of genes for many wildlife species (documented for the 101 and I-15 Freeways for mountain lions, and for the 101 Freeway for bobcats, coyotes [Riley et al. 2006], and smaller vertebrates [Delaney et al. 2010]) and full use of available habitat by other wild species, assessment of potential crossing locations included the goal of providing potential movement pathways for large and medium-sized carnivores, mule deer, reptiles, amphibians, small mammals, and fish.

In relation to mountain lions specifically, the aim of crossing structure modification or new construction is to enhance the likelihood that juvenile mountain lions can move out of larger populations to the east of the Santa Ana Mountains and to the north of the Santa Monica Mountains, into the coastal mountain ranges. Without this in-migration of dispersing animals, including territory establishment and breeding, genetic diversity in these populations will continue to decline. Out-migration of animals from the Santa Ana Mountains and Santa Monica Mountains would also assure that overall genetic exchange between these populations was adequate for the health of both populations. In the Santa Monica Mountains, there have been repeated instances of close inbreeding between fathers and daughters, as well as extensive mortality from intraspecific fighting (Riley et al. 2014), both of which could likely be reduced by increasing migration out of the Santa Monicas.

This report presents background on both linkages, methods on how wildlife crossing points for each freeway were evaluated and scored through an expert review process and landscape evaluation, and summary results for each crossing point that was evaluated.

## 2. METHODS

The general areas of evaluation for the potential placement of wildlife crossing infrastructure for the I-15 and 101 Freeways were based on the local landscape configuration and detailed linkage assessments completed by South Coast Wildlands (Penrod et al. 2006, South Coast Wildlands 2008), and were further informed by wildlife movement studies and modelling efforts (Gibbons 2008, Tracey and Crooks 2011, Zeller et al 2015, Zeller et al. 2017a, Zeller et al. 2017b, Huber unpublished data).

Specific sites that were evaluated for the placement of wildlife crossing infrastructure along both freeways were identified using several parameters that indicate likely or at least potential use by wildlife if adequate crossing structures were present.

Parameters utilized for initial identification of potential crossing points for evaluation were:

1. Current presence of suitable habitat or pathways that could be restored to wild habitat on both sides of the potential crossing;
2. Evidence from GPS or radio tracking, camera traps, or other methods, of close approaches of mountain lions or other carnivores (e.g., bobcats and coyotes) to the freeway at that location;

3. Indication in movement or corridor models that mountain lions and other wildlife are likely to approach or cross the roadway at that point;
4. Documented crossing by mountain lions or other wildlife at that location previously (either through existing structures or at grade);
5. Occurrence of mountain lion mortalities from roadkill at that location.

Scoring of each location for ranking purposes was accomplished by use of two methods, with equal weight in final rankings assigned to each method.

## Method 1: Expert Opinion

The following connectivity experts were assembled in January 2015 for a three-day workshop aimed at discussing, evaluating, and ranking locations and designs for infrastructure to improve connectivity (undercrossings, overcrossings, fencing, etc.) for the I-15 and 101 Freeways.

- Dr. Paul Beier, with Northern Arizona University, is a professor of wildlife biology who is widely recognized as one of the nation's leading experts on habitat connectivity and the design of wildlife corridors. He has studied the movements of mountain lions in southern California, has published numerous journal articles on designing, conserving, and managing functional corridors in urbanizing areas, and is the founder of CorridorDesign.org.
- Dr. Anthony Clevenger is a senior research scientist at the Western Transportation Institute, Montana State University who has been studying road effects on wildlife populations in Banff and the surrounding national and provincial parks in the Canadian Rocky Mountains since 1996. During his 20+ years of research, Dr. Clevenger's interests have been broad and ecologically based, but have been weighted towards the ecological effects of roads and the conservation of small remnant populations of carnivores.
- Dr. Patricia Cramer is a Research Assistant Professor at Utah State University. Her research focuses on transportation ecology, wildlife connectivity, and carnivore and ungulate movement. She is nationally renowned advocate for wildlife crossings, and has conducted extensive evaluation of wildlife crossing structures throughout North America and developed recommendations for their construction.
- Julia Kintsch is an ecologist specializing in conservation planning, road ecology, large landscape conservation, and collaborative problem-solving. She is recognized across North America as an expert in wildlife crossing siting and design, offering a unique understanding of the features that influence successful passage for species ranging from salamanders to deer to the elusive Canada lynx. Following an active career working for non-profit organizations such as the Nature Conservancy, Southern Rockies Ecosystem Project, and Freedom to Roam, she launched ECO-resolutions LLC in 2008.
- Dr. Patrick Huber is a Project Scientist with the Information Center for the Environment at the University of California, Davis. He earned a Ph.D. in geography at UC Davis and wrote his dissertation on spatial scale and conservation planning. His work focuses on conservation planning, landscape connectivity, and reserve design primarily in California.
- Kathy Zeller earned a PhD in Environmental Conservation at the University of Massachusetts. Her research is focused on designing wildlife corridors, modeled across a resistance-to-movement surface where the landscape is quantified in terms of the difficulty different landscape features pose to a moving organism. Her work includes methodological comparisons

for estimating resistance to movement and modeling corridors, using data from mountain lions in southern California and black bears in northern Idaho.

- Kelsey Stricker earned her Master's degree studying road impacts on wildlife along I-15 by utilizing remote camera arrays. She lives in the area and is the lead biologist for the Pechanga Tribe, a major landowner in the vicinity of the Santa Ana to Palomar Mountains Linkage.

The panel of experts was provided with available information relating to both linkage areas (aerial photos, maps, adjacent land conservation status, existing locations of culverts and bridges, data on crossing point use, modeling results, wildlife movement data) and participated in day-long field tours of each linkage area to evaluate various sites for the potential placement of connectivity structures. Field tours were then followed on the third day by an all-day workshop to discuss and rank sites and options for connectivity structures for each linkage. At this workshop, the experts were joined by transportation planners, wildlife agency representatives, and various local connectivity experts who have been involved in past assessments of wildlife connectivity status and options at these locations.

During the all-day workshop, the invited experts were asked to rank the crossing point locations, and in many cases expressed their opinions relating to the likely best types of structures that could be utilized at those locations. These expert opinions are noted in the report, however determining the most feasible or best type of structure that could be utilized at any crossing point was beyond the level of engineering expertise that was present at the workshop. Thus, this report is primarily focused on relating the ranking of crossing point locations and the type of structure, with specific structure feasibility assessments to occur in the future.

Rankings were converted into a point system that assigned a point score of 3 to each expert's first choice, a score of 2 to their second choice, and a score of 1 to their third choice. For the Santa Ana to Palomar Mountains I-15 Linkage crossing point assessments, some experts ranked more than one crossing point identically. In that case, both crossing points were given the same point score. Expert scores were then rescaled to a maximum score of 5 before combination with the Landscape scores (also scaled to 5).

## **Method 2: Assessment of Landscape Characteristics and Wildlife Use**

In this method, points were assigned to each wildlife crossing location based on important characteristics that were scored categorically (Table 1). Possible points for each characteristic ranged from 0-1 based on the strength of that characteristic at the site. In some instances, fractional scores were given to reflect partial satisfaction of the listed condition (e.g., for Landscape pattern - broad scale, if connectivity was present in 3 of 4 directions, this would generate a score of 0.75). The maximum number of points attainable by any individual site was 5. Rankings from each method were then added together for a composite total score (maximum score of 10) which were used to determine overall rankings.

Table 1. Attributes used for Landscape scoring of crossing points in both linkage areas.

Attribute	Score Guide
<b>1. Evidence of mountain lion use</b>	
Confirmed crossing or roadkill, or close approach both sides	1
Approach within 100 meters (close approach) - either side	0.66
Approach within 500 meters (medium approach) - either side	0.33
No known approaches	0
<b>2. Landscape pattern - broad scale</b> <i>What is the overall landscape connectivity like, i.e., can animals effectively reach the vicinity of the crossing point?</i>	
Both sides have good connectivity	1
One side has good connectivity	0.50
Neither side has good connectivity	0
<b>3. Landscape pattern - fine scale</b> <i>Is the landscape in the immediate vicinity of the crossing conducive to wildlife movement - all the way to the crossing structure or freeway edge itself?</i>	
Both sides conducive to animals getting to and through the crossing	1
One side conducive to animals getting to and through the crossing	0.50
Neither side conducive	0
<b>4. Land securement - broad scale</b> <i>Is land generally continuously protected in larger blocks within 1 km of site?</i>	
Both sides protected	1
One side protected	0.50
Neither side protected	0
<b>5. Land securement - fine scale</b> <i>Is land protected leading to the crossing point from larger blocks of habitat, and at the crossing?</i>	
Both sides protected	1
One side protected	0.50
Neither side protected	0

### 3. RESULTS

Results are presented separately for each linkage. Background information on each linkage is followed by assessments of each crossing point, briefly in this section and then in more detail in the Appendices (Appendix A for Santa Ana to Palomar Mountains Interstate 15 Linkage, and Appendix B for Santa Monica to Sierra Madre Mountains 101 Freeway Linkage). Assessments for each crossing point include a summary of existing conditions related to habitat, conservation status, documented wildlife use, threats, and existing crossing structures. Assessments are then followed by a summary of the overall results based on the combination of the Expert and Landscape scores.

Note: Statements in this report regarding the potential for constructing various types of structures at each site are based on previous publications and discussions with wildlife agency personnel, other stakeholders and experts, and, in the case of the 101 Freeway crossings, preliminary engineering studies. To the authors' knowledge, no detailed engineering studies have been conducted relating to the I-15 sites to ascertain viability or costs of any options mentioned.

There are some general characteristics of successful wildlife crossings (Clevenger and Huijser, 2011; Vickers unpublished data) that have helped to inform the recommendations in this report:

1. Undercrossings that are intended to accommodate mule deer movement are generally larger than those required for most other wild species. Frequently crossings intended or with the potential for wildlife use may be judged on their "openness," which refers to the size of the opening relative to the length of the crossing, and specifically by the "openness ratio", arrived at by multiplying width times height in meters, and dividing by length in meters  $[(\text{Height} \times \text{Width}) / \text{Length}]$ . For ungulates in general, and mule deer specifically, the shorter and wider the structure the more likely mule deer are to use it. Although there is certainly variability between sites, between species, and even within species, previous research has indicated that an openness ratio of 0.6 m or greater is preferred; however, landscape character, adaptations to the highway, width relative to height, and other factors may be more important (Kitsch and Cramer 2011). This generally requires a bridge-type structure to carry the highway above the crossing, or a large arch culvert. Mule deer have been documented using arch-type culverts with lower openness ratios (0.25 – 0.3m) in situations where the terrain favors extensive deer use of the approaches to the structure (Vickers unpublished data), thus terrain modification near the crossing end points might allow for a somewhat smaller structure. In a study of 15 freeway crossings in the Santa Monica Mountains area (Ng et al. 2004), the two crossings with significant deer use were wide bridges with openness ratios of 5.2 (15 crossings) and 4.1 (9 crossings); one tunnel with a ratio of 0.37 but good natural vegetation on both sides had two crossings.

Some proposals for enhancing connectivity have proposed a 4m round "jack and bore" culvert as the solution for the need for new crossings. For the 101 Freeway, tunnel length would likely be close to 100m, resulting in an openness ratio of 0.13m for a 4m diameter opening, less than 1/4 of the recommended value, making it not suitable for mule deer. Tunnel length for I-15 would vary depending on the site.

2. As in almost all effective wildlife crossing structures, animals must be able to see through the structure to the opposite end and the habitat cover at both ends needs to promote wildlife movement by the full range of species expected to use the structure. Arch culverts also allow for

the placement of internal structural components such as rocks, shelves, or water features that can effectively promote the movement of small rodents, reptiles, amphibians, etc. through the structure.

3. Mountain lions and other wildlife have been documented using round culvert structures that are smaller (~4 meters in diameter) than that required by mule deer (Clevenger and Waltho 2005, Kintsch and Cramer 2011, W. Vickers unpublished data). Thus, discussions of undercrossing designs and costs need to take these two different parameters into account, and the determination should be made early in the process whether connectivity for mule deer and other smaller species with more specific needs should be assured for any new or modified crossing structure to be judged successful.
4. In general, overcrossings for wildlife have several characteristics that are expected to enhance their use by a wider range of species than culverts. They are typically wide (50m or more), contain vegetation and natural substrates, have vegetation structure that accommodates the movement tendencies of multiple species, have structural elements that block sound and light from the roadway below, and incorporate modifications to the landscape and vegetation on the approaches that assist in funneling wildlife to the structure entrances.
5. In addition, high fencing (preferably 3- to 3.7-meter (10 – 12 ft.) high chain-link, buried to prevent animals digging underneath, and with barbed-wire outriggers) should be installed for long distances (up to a mile or more) in both directions along both sides of the roadway to funnel wildlife to any new or improved crossing structure (Huijser et al. 2016). This design is expected to minimize the likelihood of mountain lions, mule deer, and most of the smaller carnivores entering the roadway. Fencing of different designs and as low as 2.4 meter (8 ft.), such as "webwire" fencing without outriggers or burial, would be expected to restrict mule deer entrance to the highway but not mountain lions, smaller carnivores, or other wildlife.

## **Santa Ana to Palomar Mountains Linkage: Assessments of Interstate 15 Crossing Points**

The Santa Ana to Palomar Mountains Linkage connects the Santa Ana Mountains and adjoining coastal lowlands with the Palomar Mountains and other inland portions of the Peninsular ranges primarily in San Diego County. The Santa Ana Mountains include over 120,000 hectares of protected chaparral, coastal sage scrub, grasslands, vernal pools, and oak and riparian woodlands. Lands that are protected as wildlife habitat are owned or managed by various public agencies including the National Forest Service, Department of Defense, California State Parks, the Counties of Orange, Riverside, and San Diego, San Diego State University, California Department of Fish and Wildlife, and a variety of water districts, non-profit entities, and others. The linkage has been studied by wildlife biologists for over 25 years and is widely recognized as critical for maintaining biodiversity in the Santa Ana Mountains, as it is the last option for securing connectivity between this coastal range and larger intact natural lands to the east (Figure 2). The linkage is necessary to maintain ecological processes and genetic diversity in the Santa Ana Mountains as they become more degraded and fragmented by development.

In practical terms, urban, rural, and agricultural development have limited the potential I-15 crossing area to an approximately 10-kilometer-long (6-mile) stretch of I-15 south of Temecula where wildlands and agricultural lands are present on both sides of the freeway (Figure 2; Luke et al 2004). The only

exception to this generalization is that, further south, the bridge over the San Luis Rey River provides safe passage for wildlife under I-15, but for mountain lions, an east to west crossing at that location requires that they follow the San Luis Rey River west through the cities of Fallbrook, Bonsall, San Luis Rey, Oceanside, and developed portions of Marine Base Camp Pendleton before reaching wild areas of the Santa Ana Mountains to the north of Oceanside. Thus, this pathway is not one that is expected to support regular movement of mountain lions in and out of the Santa Ana Mountains.

Urban and rural development remain a threat to what remains of the linkage, and I-15 and associated development, as well as secondary roads, have formed an apparent partial or complete barrier to east-west movement for wildlife and plants. One secondary road of concern is Rainbow Canyon Rd (Old Hwy 395), which runs parallel to the I-15 Freeway and is a lesser but likely significant barrier to wildlife movement that needs to be addressed as part of linkage planning.

Two extensive mountain lion studies have been conducted in the region, both of which included multiple radio-collared and GPS-collared animals circulating in the Santa Ana to Palomar Mountains Linkage (Beier and Barrett 1993, Vickers et al. 2015). Mountain lion GPS points from the Vickers et al. (2015) study are depicted in Figure 2. In the Beier and Barrett study period, only two mountain lions were documented to have crossed I-15 (both west to east). In the Vickers, et al. (2015) study, only one GPS-collared animal was documented to have crossed the freeway (west to east. Based on that genetic analysis (Ernest et al. 2014), that animal (M86) did reproduce, potentially enhancing the gene pool in the Santa Ana Mountains lion population; however, few of his probable offspring have survived as of late 2016 in the population, and M86 was killed by a vehicle strike (Vickers and Boyce unpublished data). Genetic analyses from 146 sampled pumas indicate that seven pumas crossed I-15 over the last 15 years, including four males from west to east, and three males from east to west (Gustafson et al. 2017). Vickers et al. (2015) demonstrated that survival rates in the Santa Ana Mountains are lower than in most other mountain lion populations throughout the west, compounding the threat posed to the Santa Ana Mountain's population by genetic isolation.

At least five separate modelling efforts have been performed using available data (landscape and vegetation characteristics, existing culvert and bridge locations, and mountain lion movement data) to determine the best locations for wildlife crossing structures in the approximately 10-kilometer section of I-15 south of Temecula (Tracey and Crooks 2001, Gibbons 2008, Zeller et al. 2015, Zeller et al. 2017b, Huber unpublished data). These modelling efforts have indicated that several different locations have potential as sites for new or improved wildlife crossing structures. However, no consensus crossing point locations have emerged from these models, or from discussions between local wildlife agency personnel, county conservation agency personnel, other governmental representatives, and conservationists.

### **Crossing Point Assessments – Santa Ana to Palomar Mountains I-15 Linkage**

A total of eleven potential crossings points along the roughly 10-kilometer (6-mile) segment of I-15 south of Temecula were evaluated as part of this project (Figure 3). Four of the eleven sites (Sites 8a, 8b, 9 and 10) were determined to be too highly constrained by existing development to be considered during the evaluation process. These four sites all received Landscape Scores (Table 3), but none were ranked by the experts as first, second, or third choices, possibly because of the extensive agricultural and human development on both sides of the freeway at those sites. Thus, those sites' scores were lower than any of the first seven sites described, and they are not described in depth in Appendix A, though more detailed maps of these sites are included there.

**Figure 4.** Eleven potential wildlife crossing points (1-8a,8b-10) along a 10-km (6-mile) stretch of I-15 in the Santa Ana to Palomar Mountains. Conserved lands are depicted in dark blue. View depicted is looking from the Palomar Mountains northwest to the Santa Ana Range with the Pacific Ocean to the west in the upper left corner.

Appendix A contains detailed information about each of the evaluated crossing points for the Santa Ana to Palomar Mountains I-15 Linkage, including: 1) a summary of existing conditions related to habitat, conservation status, documented wildlife use, threats, and existing crossing structures, if present, 2) Landscape Scores for the crossing based on available information about landscape structure and wildlife use, and 3) Expert Scores based on the experts' rankings of the location as a crossing.

#### **Brief Crossing Point Site Descriptions and Scoring Results – Santa Ana to Palomar Mountains Interstate 15 Linkage**

**Site 1: Temecula Creek Bridge:** This site is at the northern end of the linkage and consists of two separate span bridges for the north and south-bound traffic lanes of I-15. The bridge crosses over Temecula Creek, and each span is roughly 22 meters wide with a 15-meter separation between spans (60 meters total width). The bridge length is approximately 75 meters and the height is approximately 15 meters. Protected open space is located on either side of the bridge; however, proposed development threatens both the west and east side of this crossing. Residential uses and a civic use are proposed on a 76-hectare site just north of the west side of the bridge. In its current state, Site 1 received a Landscape Score of 4.25 out of 5 and an Experts' Score of 2.78, and ranked as the second highest priority crossing point location.

Note: Sites 2 through 4 all have steep up-slopes on the west side of the highway and downslopes on the east. All culverts noted as pre-existing are steeply sloped on their eastern ends making them unsuitable currently for regular wildlife use. It was beyond the expertise level of the group in this workshop to evaluate engineering factors that would determine whether any type of undercrossing could be constructed at these sites that would be adequately horizontal to allow for wildlife use.

Site 2: This site is the location of an existing 2m diameter culvert that drains from the west side of I-15 to the east. Intact but unprotected chaparral habitat is found on the west side of the freeway, while oak woodland and golf course development are found on the east side of the freeway at the base of the lightly vegetated downslope. Site 2 received a Landscape Score of 2.91 and an Experts' Score of 0.37 and ranked seventh overall.

Site 3: This site currently has a 2m culvert that drains west to east with intact chaparral habitat on both sides of the freeway. The property on the west side of the crossing point is currently being pursued for conservation, while the property on the east side of the culvert has been recently acquired for conservation. Site 3 received a Landscape Score of 3.33 and an Experts' Score of 1.67 and ranked fourth overall.

Site 4: This site has a 1.5m diameter culvert that drains from west to east across I-15. The west side is composed of an oak-lined drainage that is part of the Santa Margarita Ecological Reserve, while the east side of the culvert drains into intact chaparral habitat that was recently acquired for conservation. Site 4 received a Landscape Score of 3.83 and an Experts' Score of 2.59 and ranked third overall.

Site 5: This site is composed of a steep up-slope of varying height (approximately 15 - 30 meters) on both sides of the highway. The west side of the highway is protected habitat that is part of the Santa Margarita Ecological Reserve and supports rock outcrops and chaparral habitat. The east side is intact chaparral habitat that was recently acquired for conservation. Site 5 received a Landscape score of 5.0 and an Experts' score of 4.07 and was ranked as the highest priority location for a crossing structure, with the assumption by the experts that a wildlife bridge was the only type of structure that could be feasibly placed at that location.

Site 6: On the west side of I-15 at this site there are several small gullies with intact but unprotected chaparral, rock outcrops, and small oak trees. The east side includes a lightly vegetated down-slope that extends below the highway edge, and an adjoining open lot containing mixed native and non-native vegetation that is approximately 100 x 120 meters in size and bordered by commercial lots to the north and south and Rainbow Canyon Road to the east. The U.S. Border Patrol has a check station with off-ramp just north of the site where extensive light and human activity are present 24 hours a day. Site 6 received a Landscape Score of 2.33 and an Experts' Score of 0.74 and ranked sixth overall.

Site 7: The west side of I-15 at this location is a steep rocky up-slope adjoining a small canyon with intact chaparral, rock outcrops, and small oak trees. The east side includes a sparsely vegetated down-slope that extends below the highway edge and adjoins an open lot that is approximately 150 x 150 meters in size with scattered small buildings at the edge. This lot is bordered by commercial lots to the north and south and Rainbow Canyon Road to the east. Site 7 received a Landscape Score of 3.25 and an Experts' Score of 0.74 and ranked fifth overall.

Sites 8a, 8b, 9, and 10: These sites are all located along I-15 south of Site 7. All sites received Landscape Scores (Table 3), but none were ranked by the experts as first, second, or third choices because of the

extensive agricultural and human development on both sides of the freeway at these sites. Thus, the scores for these three sites were lower than any of the first seven sites described, and they are not described in depth in Appendix A, though more detailed maps of these sites are included there.

## **Summary of Results – Santa Ana to Palomar Mountains Interstate 15 Linkage**

Site 5 ranked highest in the expert scoring with 6 out of 9 experts selecting it as the highest priority, and a wildlife bridge structure at this site was considered by the experts to be the most functional for the widest array of wildlife and plant species, including mountain lions and deer. Both the location and wildlife bridge concept are consistent with previous studies (Beier and Barrett 1993, Fisher and Crooks 2001, Luke et al. 2004). This site ranked first in the landscape scoring. The exact location where a bridge structure would be placed in the stretch of the freeway encompassed by Site 5 would be dependent on engineering feasibility studies.

All experts ranked Site 1, Temecula Creek Bridge, as one of the top three crossing point locations; however, eight of the nine experts ranked this site as second or third priority, with only one expert ranking it as the highest priority location. Experts pointed to the fact that this site currently has the highest existing potential for wildlife movement, but has significant challenges to its proper function due to road noise and human presence. They felt that road noise and human disturbances could be sufficiently mitigated to increase this location's functionality for species such as mountain lions and deer. Recommended improvements include substantial reduction of sound and light pollution from traffic crossing the bridge, removal of lighting at the pump station on the west side of the bridge, prohibition of human presence under the bridge and in the creek bed at night, prohibition of further human development and nighttime activity on the Temecula Creek golf course and near the confluence of Temecula and Murrieta creeks and the Santa Margarita River on the west side of the bridge. In addition, experts agreed that increased native vegetative cover should be established on the golf course to promote the use of the site by deer and other wildlife. Even if the proposed residential development moves forward, the experts felt that this crossing could still function for medium-sized carnivores, smaller wildlife and plants, but its function for mountain lions and mule deer would be further degraded.

Site 4 ranked third overall in the cumulative Landscape and Experts' score; however, like Site 5, making this crossing site functional would necessitate construction of a new structure. The experts were equally divided on whether the crossing structure for this location should be an overpass or an underpass.

Site 3, previously suggested by some county staff and wildlife agency personnel as a possible location for an underpass to accommodate mountain lions and medium-sized carnivores, ranked fourth overall, and was a second or third priority for four of the nine experts.

Sites 2, 6, and 7 ranked similarly low in the expert scoring, each only receiving one vote as a first, second or third priority, though site 7 ranked fifth overall due to the occurrence of two puma roadkills at that location, confirming as at some other sites that pumas would potentially use a crossing if constructed at that location.

Sites 8a, 8b, 9, and 10 did not receive any support from the experts, although 8a and 8b both had puma roadkill occur very near their locations. Due to the lack of support from the experts, the cumulative score for each of these crossing points were very low.

## Discussion – Santa Ana to Palomar Mountains Interstate 15 Linkage

Overall, when combined, the Expert and Landscape scores for the Santa Ana to Palomar Mountains I-15 Linkage support Site 5 as the highest priority location for the placement of a ***new wildlife crossing structure***.

However, Site 1, Temecula Creek Bridge, received the second highest Landscape Score ***in its current state*** based on existing landscape structure and evidence of use by many species including those requiring water for connectivity, and it placed second in overall scoring. It was also recognized as the only site of the 11 evaluated that currently functions for any significant wildlife movement, and that function is threatened by a development proposal recently approved by the City of Temecula. It was also the site that the experts felt had the most economic viability with regards to near term improvement.

Sites 4 and 3 were the next highest ranked crossing sites, but like Site 5, both ***would require construction of a new crossing structure*** (either over or under crossing) to become viable wildlife crossings. It is notable that sites 3, 4, and 5 all lie within a short (~0.3 mi) section of I-15 and have similar vegetation structure on either side of the freeway, and similar large-scale connectivity potential. Because landscape structure does not favor one over the other enough to rule either of the others out, if funding for a new structure becomes feasible, the ultimate choice between these three may rest most strongly on engineering factors and whether the land is conserved where any new crossing structure would have its end points.

The expert consensus was that ***more than one structure should be constructed or enhanced*** to provide the best potential for improved connectivity for a variety of wildlife species. Relying on only one highway crossing structure to provide adequate connectivity, especially for a wide range of species, between two entire mountain ranges, was regarded by the experts as risky and likely to fail. Thus, ***retention and enhancement of function of the Temecula Bridge is indicated even if a new wildlife structure may someday be built at Site 3, 4, or 5.***

Additional measures recommended by the experts for any new or improved wildlife crossing structures include: 1) wildlife fencing along both sides of I-15 to help funnel wildlife to the crossing structures (Huijser et al. 2016), 2) habitat modification of dense chaparral slopes on either side of the roadway, such as the construction of wildlife trails, to facilitate wildlife movement through the habitat to a new or improved structure, and 3) construction of an additional wildlife crossing structure across Rainbow Canyon Road, a busy secondary road to the east of I-15.

The crossing point rankings and the recommendation for more than one crossing structure are consistent with the findings of local experts who have evaluated crossing options over the last 25 years. In the last five years, local agencies and experts have prioritized a wildlife undercrossing structure at Site 3, and a wildlife overpass at Site 5. Although a wildlife overpass is viewed by local experts as the best option to serve the widest variety of species, local government agencies have generally expressed greater interest in an undercrossing due to a lower perceived expense. However, relative expense levels have not yet been determined via engineering studies, and we urge that such studies be done in order that informed decisions may be made on this question.

## Santa Monica to Sierra Madre Mountains Linkage: Assessments of Crossing Points for the 101 Freeway

Santa Monica Mountains National Recreation Area (SMMNRA) is the largest urban national park in the country. Its 150,000 acres of mountains and coastline in Los Angeles and Ventura counties are a network of local, state, and federal parks interspersed with private lands and communities. SMMNRA is part of a globally rare Mediterranean ecosystem that is exceptionally biodiverse, with more than 450 animal species and 84 distinct plant alliances.

The Santa Monica Mountains, which run east-west to the north of Malibu, to the west of the Los Angeles Basin, and to the south of the San Fernando and Conejo Valleys, are substantially cut off from other large natural areas to the north by the 101 Freeway. This freeway is 8-10 lanes and receives very heavy traffic: it is one of the busiest freeways in the world, and in fact the 101-405 Freeway interchange (about 19 kilometers, or 12 miles to the East of the study area) is the second most trafficked in the entire country. As a national park in the Los Angeles area, at Santa Monica Mountains National Recreation Area the National Park Service has always been interested in and concerned about the effects of urbanization and habitat fragmentation on natural resources, including wildlife populations, particularly for wide-ranging species such as mammalian carnivores.

For more than two decades, the park, along with other partner agencies in the region such as the Santa Monica Mountains Conservancy and California State Parks, has been concerned about habitat connectivity between the Santa Monica Mountains and other remaining natural areas in the region. These and other agencies and groups have worked hard and spent millions of dollars in land acquisition money to strategically acquire and conserve land near the 101 Freeway, especially in the Liberty Canyon area in Agoura Hills. It was easy to see from the beginning of these efforts, and it is easy to see on any current map of the region, that the Agoura Hills-Calabasas grade area, specifically from Palo Comado Canyon Rd. to Mureau Rd., is one of the last areas where wildlife connectivity would be possible across the 101 Freeway (Figure 3). This area is one of the few remaining places along the Freeway where there is natural habitat adjacent to it on both sides. Planners did not consider the connectivity needs of wildlife when it was built in this area in 1949, or in the ensuing decades, and thus there is urban development along the 101 Freeway throughout the San Fernando and Conejo Valleys. The one other place in the Santa Monica Mountains where there is remaining natural habitat on both sides of the road is in the Conejo Grade area, just east of Camarillo. This area is less desirable for a wildlife crossing primarily because north of the Freeway, connectivity to other large natural areas is seriously compromised by roads and development. This area is also at the far western end of the Santa Monica Mountains, making it less accessible to as many animals as areas in the middle of the Mountains. However, two sub-adult mountain lions did cross the 101 Freeway in the Conejo Grade area in 2015 (National Park Service, unpublished data). Multiple crossings and connectivity in multiple areas are both generally desirable, so creating a safe wildlife crossing in this area in the future would be optimal.

The consensus maps developed as part of the South Coast Wildlands Linkage Design show the 101 Freeway crossing near the Agoura Hills-Calabasas grade area as the best location for providing connectivity for multiple species (Penrod et al. 2006). Starting in 2011, multiple agencies in the region formed the Linkage Implementation Alliance (LIA) to develop and coordinate efforts to turn the linkage maps into conservation reality through land acquisition, easements, education, etc. This group continues to meet quarterly.

In 1996, the park began studies of mammalian carnivores, specifically bobcats and coyotes and later (in 2002) mountain lions as well, to better understand wildlife movement in the area and the effects of the major barrier of the 101 Freeway. These studies have found that while carnivores can and sometimes do use developed areas, they largely use remaining natural areas, subsist on natural foods, and are subject to regular mortality from anthropogenic sources such as vehicles and toxicants (Riley et al. 2003, Riley et al. 2007, Riley et al. 2010, Gehrt and Riley 2010, Beier et al. 2010). The 101 Freeway was found to be a major barrier to movement for all three species, and in fact was also found to be a barrier to gene flow, such that significant genetic differentiation was present across it (Riley et al. 2006, Riley et al. 2014, Serieys et al. 2015). For mountain lions, the barrier effects of 101, along with other freeways in the region such as 405 and 5, are particularly severe. Genetic diversity for Santa Monica mountain lions is very low (Riley et al. 2014), lower than has been measured anywhere else in the west and like that in the isolated Santa Ana Mountains population (Ernest et al. 2014). The barrier effects of the freeway are also likely contributing to close inbreeding between relatives (e.g., fathers and daughters) and potentially to increased mortality from intraspecific strife (adult males killing subadult males and females, and even an adult female) because of the severely restricted dispersal of subadults out of the Santa Monicas (Riley et al. 2014). A recent population viability model incorporating both demographic and genetic factors predicted a continued steep decline in genetic diversity, leading to likely quick extinction once inbreeding depression compounds the effects of the already small population (Benson et al. 2016). The model found that even modest increases in immigration greatly ameliorated both demographic and genetic problems. Finally, research on smaller, less mobile species has also documented the genetic effects of roads and urban development. Specifically, significant genetic differentiation related to habitat fragmentation was found for three different lizard species, western fence lizards, side-blotched lizards, and western skinks, as well as for a common chaparral bird, wrentits (Delaney et al. 2010).

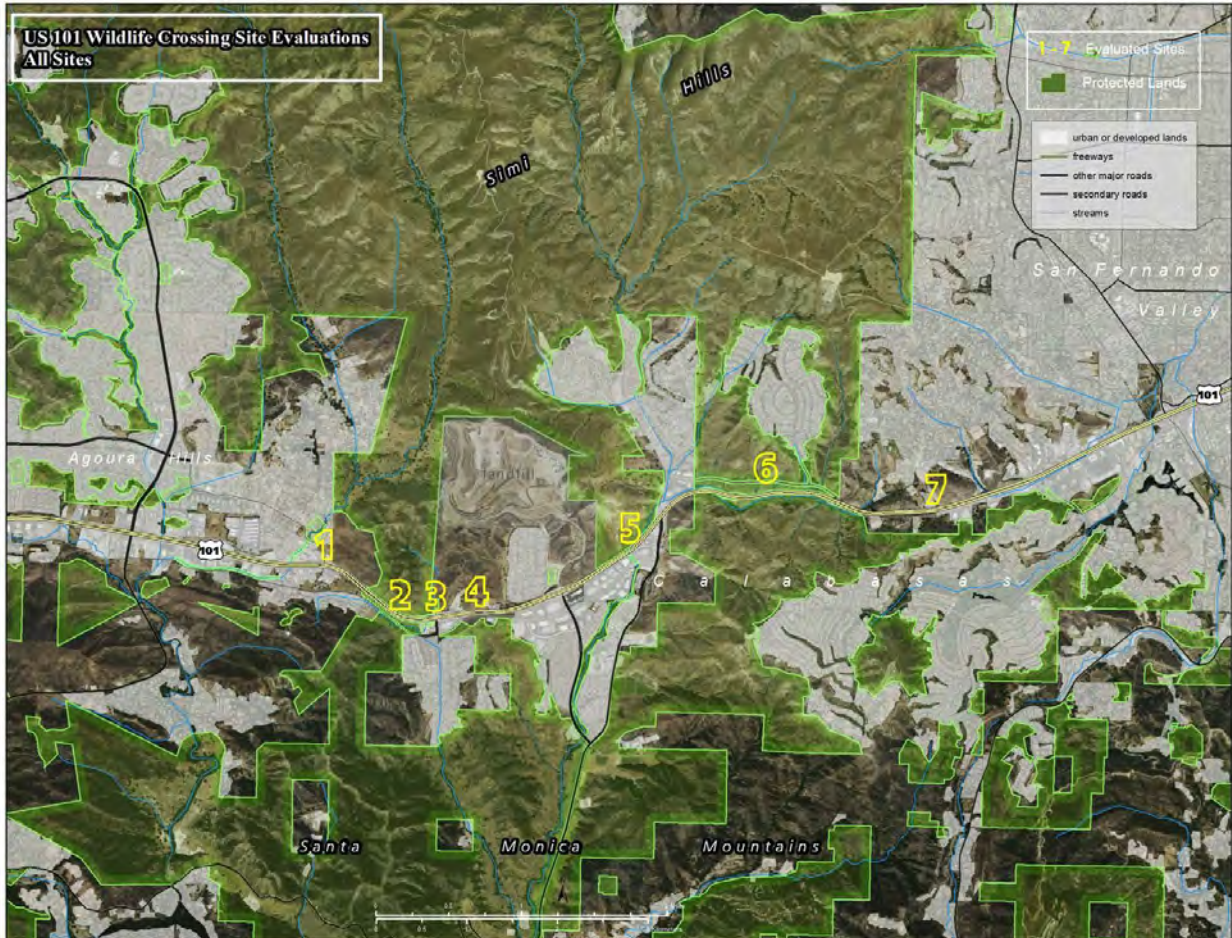

Overall, the mandate of the National Park Service, and the goal of the other open space agencies in the region, is to preserve the natural populations and communities present in the Santa Monica Mountains and the surrounding region as much as possible. The 101 Freeway, and the massive interruption in connectivity that it represents, is a significant impediment to this goal. Connectivity between natural areas is critical for all components of the natural communities, especially for wide-ranging species such as mountain lions or mule deer, but for all species of plants and animals as well. Over the long-term, we cannot hope to have naturally functioning ecosystems without increasing the effective connections between the Santa Monica Mountains and other natural areas to the north. Therefore, it has been a high priority to establish more connectivity across the 101 freeway for wild populations, particularly for wide-ranging animal species. Multiple agencies in the region, including the National Park Service, Caltrans, SMMC/MRCA, California State Parks, and others have been working towards this goal for more than two decades.

Specifically, for this workshop, the goal was to bring in experts who had experience with wildlife connectivity and road challenges around the country and the world, and to obtain their input on our situation here with the 101 Freeway and connecting the Santa Monicas to other protected areas to the north. In this report, the goal was also to integrate landscape information and current wildlife knowledge with the expert opinion to provide the fullest picture of the challenges and potential solutions.

### **Crossing Point Assessments – Santa Monica to Sierra Madre Mountains 101 Freeway Linkage**

A total of seven potential wildlife crossing points along a 9.5-kilometer (5.9-mile) stretch of the 101 Freeway in the Agoura Hills-Calabasas area were evaluated as part of this analysis (Figure 5). A brief description of each of these potential crossing points is presented below.

**Figure 5.** Seven potential wildlife crossing points along a 9.5 km (5.9 mile) stretch of the 101 Freeway in the Agoura Hills-Calabasas area of the Santa Monica to Sierra Madre Mountains Linkage.

Appendix B provides more detailed information about each crossing location, including: 1) a summary of existing conditions related to habitat, conservation status, documented wildlife use, threats, and existing crossing structures, if present; 2) Landscape Scores for the location based on existing data related to landscape conservation status and wildlife use, particularly for mountain lions, and 3) Expert Scores based on their rankings of the crossing locations.

## **Brief Crossing Point Site Descriptions and Scoring Results – Santa Monica to Sierra Madre Mountains 101 Freeway Linkage**

Site 1: Palo Comado Canyon Road Bridge. This farthest west site is a bridge for a two-lane paved road that receives moderate vehicle use, including entering and exiting freeway traffic. The bridge is immediately adjacent to residential development on both sides, although at the broader scale there is protected open space in three of four directions. The site received a Landscape score of 1.25 (6th) and a 0 from the experts, for a total score of 1.25 out of 10 (sixth overall).

Site 2: West Liberty Canyon. This site is just west of Liberty Canyon. It has natural vegetation on both sides, connects to protected open space both immediately adjacent to and farther away from the crossing location, and has extensive known use by wildlife including mountain lions and other carnivores. This was by far the best site, based on both Landscape scores (5) and Expert evaluation (5): it received a 10 out of 10 overall, while no other site had a landscape score above 3.33 or an overall score above 5.

Site 3: Liberty Canyon Road. This is the road underpass where Liberty Canyon Road passes under the freeway. It is well connected to open space on the north side, and broadly to the south, with known wildlife use. However, there is commercial development immediately adjacent on the south side, and the underpass itself is unvegetated and open with regular traffic entering and exiting the freeway. There was some underpass use by wildlife in a study from 1999-2000, but recent monitoring has found very little, despite extensive use of nearby areas by all species, including mountain lions. The overall score was 3.70, fourth out of seven.

Site 4: Agoura Road Pass. This site is east of Liberty Canyon, where there are hills rising above the freeway on both sides which could assist with overpass construction, and a mountain lion was killed on the freeway here. However, the land is not protected immediately to the north or south, and the broader connectivity is poor to the south. This site received a Landscape score of 3 (4th of 7), but was given no priority by the experts, for an overall score of 3.

Site 5: Las Virgenes Creek. This site is where Las Virgenes Creek goes under the freeway. It is a nice wide, natural underpass, with some documented use by wildlife including deer. Although it is well connected to natural and protected areas to the north, to the south the creek passes through intensive residential and commercial development for a long stretch before it connects with natural protected lands. This was the third highest ranked site for the experts, second in Landscape Score, and third overall (4.76 out of 10).

Site 6: Mureau Road Tunnels. This site includes multiple culverts for water passage in the vicinity of Mureau Rd (north of the freeway). The site is well connected and protected immediately adjacent to the crossing points, but at a broader scale there is development in some directions on both sides. There is also generally standing water on the south side of the culverts, decreasing their effectiveness. The experts felt this site had some potential (ranking second, with 1.95 out of 5), and it was second in Landscape Score at 3.08, ranking second overall (4.98 out of 10).

Site 7: Mureau Road Bridge. This is the farthest east site, another road bridge over the freeway where Mureau Road crosses it. It is one lane each way with a sidewalk on the east side and regular traffic between Hidden Hills and Agoura Hills to the north and Calabasas to the south. It is not well-connected

on either side at the fine or the broad scale, although there is some land protection to the southwest. This was the lowest ranked site by every measure, with a 0.75 out of 10 overall score.

### **Summary of Results – Santa Monica to Sierra Madre Mountains 101 Freeway Linkage**

Overall, the results of the crossing point assessment for the 101 Freeway were very clear in terms of the best location for a new crossing structure, with the same conclusion coming from both the Expert and the Landscape Score assessments: West Liberty Canyon is the best location for a new wildlife crossing structure. As noted in the site descriptions and as is clear from Tables 4 and 5, on both sides this site has protected, natural habitat both adjacent to the freeway and farther away, and it has had known use nearby by multiple wildlife species including mountain lions and other carnivores. This site scored 5 out of 5 on the Landscape Score assessment, and was the unanimous top choice among the seven sites for the experts.

The Mureau Road culverts, Las Virgenes Creek, and Liberty Canyon Road all scored between 3.7 and 4.98 overall, reflecting some potential, but all were far behind West Liberty Canyon because of various problems. Liberty Canyon Road is an active road with traffic coming on and off the freeway, and it is completely open and unvegetated underneath the bridge. It also has development immediately adjacent to the road on the south side, both to the southeast and southwest. Recent monitoring with remote cameras has documented no confirmed crossings by wildlife in two years (through April 2017), despite detections of many species, including mountain lions, immediately adjacent to it (National Park Service, unpublished data). Las Virgenes Creek has a natural, vegetated crossing under the freeway and good direct connections to open space immediately on the north side, but to the south there is a long stretch of thin riparian vegetation through intense urban development (Fig. 5). The Mureau Road Culverts are across a major secondary road, Mureau Road, from large areas of open space, and many of them are small, dark, and have bends, so the other side is not visible. Of the two tunnels that do have line of sight all the way across, one has a large pool of standing water on the south side which would seriously impede use from either direction. All of these locations could have some value as redundant sites, especially with improvements (see below), but again, all are far inferior to the West Liberty Canyon site.

## **Discussion - Santa Monica to Sierra Madre Mountains 101 Freeway Linkage**

In terms of what kind of structure would be best, the consensus of the experts was that an overpass, over both 101 and Agoura Rd., at the West Liberty Canyon site would be the best solution for the most number of taxa. The experts agreed that an overpass just over the Freeway, which based on the site characteristics would need to end right next to Agoura Rd, would not be desirable because it would endanger animals coming off the structure, they would not be delivered across the road to nearby natural habitat, and it would be a bad precedent and perception both for this and future projects. Given the quality of the site, the next most effective solution would be a tunnel also at the Liberty Canyon West Site, although the tunnel also would not convey animals across Agoura Rd, south of 101. A tunnel, regardless of size, would also not be as effective for smaller species such as small mammals, reptiles, and amphibians. Both an overpass and a large tunnel were considered to likely be functional for all the medium and large mammals considered, including mountain lions and deer, although a tunnel large enough for deer under a freeway that wide (10 lanes of pavement) would pose serious engineering and traffic challenges, and therefore come at great monetary and social and political cost.

In the long run, multiple crossing structures should be available for a wide range of species to effectively cross the 101 Freeway between the Santa Monica Mountains and areas to the north. In terms of other sites, the existing Las Virgenes Creek underpass was thought to be functional for some species, including deer, smaller vertebrates, and aquatic species such as amphibians, since it has permanent water. However, though the area north of the freeway is natural and protected, connectivity south of the freeway is limited by the thin vegetated corridor that is surrounded by development for several hundred meters. In the past, the presence of invasive aquatic species, specifically crayfish, made this crossing less ideal for native aquatic species, although recent extensive efforts to remove crayfish in Las Virgenes Creek have reduced this concern. The second-best site in terms of expert opinion and total score was the Mureau Road Tunnels. This site is well connected to protected natural habitat near the Freeway, has some connectivity farther away, and has existing tunnels that could be improved. Although these tunnels are long and relatively small, they could be valuable for carnivores, and could serve to augment an overpass at West Liberty Canyon. A disadvantage here is that Mureau Road separates the crossing area from the open space to the north, so animals would have to cross four lanes of pavement and a median. This would be a significant barrier for many smaller species, and a potential mortality source for larger ones. Experts agreed that wildlife fencing should also be constructed in association with any new or improved structures to help funnel wildlife to the crossings (Huijser et al. 2016).

## **4. OVERALL CONCLUSIONS**

Both the Santa Ana to Palomar Mountains and the Santa Monica to Sierra Madre Mountains Linkages in southern California have been a focus of regional wildlife research and conservation planning efforts for over 25 years. These two linkages are widely recognized as critical for maintaining biodiversity in the two largest coastal southern California mountain ranges, and both these linkages represent the last local opportunity for securing connectivity with larger intact natural lands.

For both linkages, the expert consensus was that, to maximize connectivity for multiple wildlife species, a diversity of crossing structures should be enhanced or constructed. While wildlife overpasses would likely serve the broadest suite of species, experts also pointed to the opportunities provided by enhancing existing creek crossings. Temecula Creek in the Santa Ana Mountains and Las Virgenes Creek in the Santa Monica Mountains might provide the best and most economical option for improving

connectivity for smaller mammals, amphibians, and fish. These are the only potential aquatic crossings for either the I-15 or 101 Freeways; however, both Temecula and Las Virgenes Creeks have urban edge issues of noise, exotic species, light, and human activity that would require mitigation and long-term management.

In addition to wildlife fencing to funnel wildlife to the crossing structures, some form of habitat modification would benefit both linkages. For the I-15 linkage, which has dense chaparral on both sides of the freeway, it was recommended that wildlife trails be constructed through the chaparral to attract carnivores and deer to the crossing structures. For the 101 Freeway, the restoration of coastal sage scrub in areas currently dominated by non-native grassland would provide needed cover for wildlife approaching the crossing, such as on the north side at the West Liberty Canyon site.

Participants also stressed that secondary roads that run parallel to both freeways – such as Rainbow Canyon Road in the I-15 Linkage and Agoura Road in the 101 Freeway Linkage - can be problematic for wildlife and that both linkages need to incorporate crossing structures for these secondary roads.

The authors recognize that assuring adequate connectivity for wildlife in these two areas will require significant public investment and political will, particularly because of significant costs associated with crossing structure construction and land protection. We hope that the results of this workshop will help guide all parties to a consensus opinion relating to crossing improvements, which can then allow progress towards improving wildlife connectivity at both critical locations.

## 5. ACKNOWLEDGEMENTS

The authors would like to thank all who participated in the workshop and who provided feedback during the preparation of this report. Specifically, we would like to thank The National Park Service, The Nature Conservancy, and Vicki Long for providing financial support for the workshop.

# Mitigating Roadway Impacts to Migratory Mule Deer—A Case Study With Underpasses and Continuous Fencing

HALL SAWYER,<sup>1</sup> *Western EcoSystems Technology, Incorporated, 200 S 2nd Street, Suite B, Laramie, WY 82070, USA*

CHAD LEBEAU, *Western EcoSystems Technology, Incorporated, 200 S 2nd Street, Suite B, Laramie, WY 82070, USA*

THOMAS HART, *Wyoming Department of Transportation, 5300 Bishop Boulevard, Cheyenne, WY 82009, USA*

**ABSTRACT** Wildlife–vehicle collisions pose a major safety concern to motorists and can be a significant source of mortality for wildlife. Additionally, roadways can impede movements and reduce habitat connectivity. For migratory ungulates, these problems can be exacerbated when roadways bisect migration routes, as is the case in Southwest Wyoming, USA, where a 21-km section of U.S. Highway 30 overlaps with a critical winter range and migration route used by thousands of mule deer (*Odocoileus hemionus*). In an effort to reduce deer–vehicle collisions (DVC) and maintain migratory connectivity, the Wyoming Department of Transportation installed 7 concrete box-culvert underpasses with continuous game-proof fencing between each crossing structure. To evaluate the effectiveness of this mitigation project, we used remote cameras to quantify the number of mule deer that used the underpasses, estimate passage rates through time, and compare rates of DVCs before and after underpass construction. Through 3 years of monitoring (which encompassed autumn migration [2008, 2009, and 2010], winter use, and spring migration [2009, 2010, and 2011] for 3 migration cycles), we documented 49,146 mule deer move through the underpasses. Passage rates of deer approaching underpasses steadily increased from 54% in Year 1 to 92% in Year 3. Peak movements during the autumn migration occurred in mid-December, while peak spring movements were in mid-March and early May. Underpass and fence installation effectively reduced DVCs by 81%. Had fence gates remained closed and cattle guards clear of snow, DVCs could be eliminated altogether. Our results suggest that underpasses, combined with game-proof fencing, can improve highway safety for motorists while providing safe and effective movement corridors for large populations of migratory mule deer. © 2012 The Wildlife Society.

**KEY WORDS** connectivity, fencing, highways, migration, mitigation, mule deer, *Odocoileus hemionus*, underpass, wildlife–vehicle collisions (WVC), Wyoming.

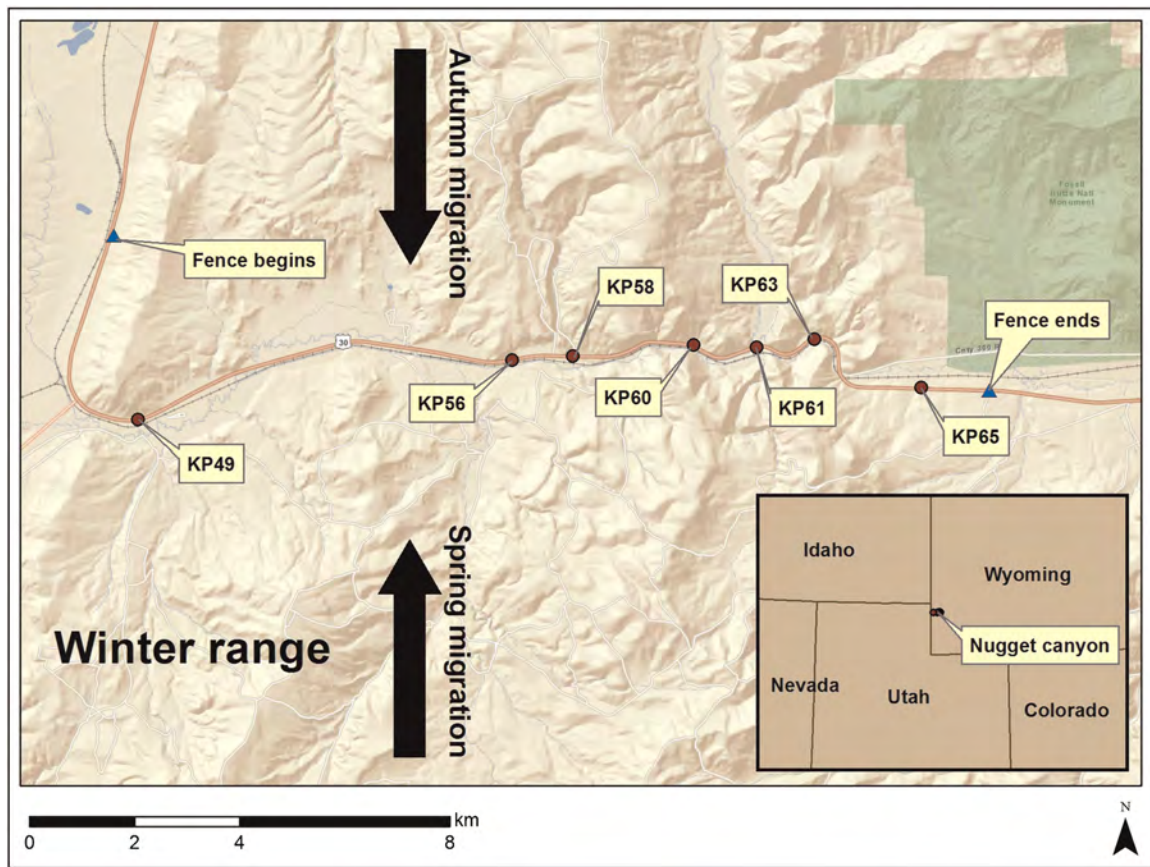

Wildlife–vehicle collisions (WVC) are a serious safety concern for motorists and can be a significant source of mortality for affected wildlife (Romin and Bissonette 1996, Putman 1997, Forman et al. 2003, Langbein et al. 2011). Additionally, roadways can restrict animal movements and increase fragmentation (Forman and Alexander 1998, Trombulak and Frissell 2000). For ungulate populations, potential impacts can be especially problematic when roads intersect with migration routes (e.g., Berger 2004, Sawyer et al. 2005). A case in point is U.S. Highway 30 in western Wyoming, USA. This 2-lane rural highway extends 21 km through crucial winter range and a migration route used by thousands of mule deer (Fig. 1). Deer–vehicle collisions (DVC) have historically been high along this roadway, with an average of 130 deer killed/year between 1989 and

2001 (Plumb et al. 2003). Despite a variety of mitigation measures implemented through the 1990s aimed at slowing traffic and warning motorists of potential collisions with wildlife (e.g., signs, reflectors, flashing lights), dozens of DVCs continued to occur each year in this segment of highway (Reeve and Anderson 1993, Gordon et al. 2004). The high rates of DVCs created safety concerns for motorists and, as traffic volumes increased by 42% between 1990 and 2000, managers were also concerned with maintaining habitat connectivity across the highway for migratory mule deer. In an effort to move deer underneath the highway and reduce DVCs, the Wyoming Department of Transportation installed a concrete box culvert at the western edge of the highway segment in 2001 (Fig. 1). To facilitate mule deer use of the underpass, a 2.4-m-high fence extended approximately 5.5 km on either side of the underpass. Although several hundred deer used the underpass in subsequent years (Gordon and Anderson 2003), remaining portions of the 21-km roadway continued to have high rates of DVCs, and it was apparent that additional crossing structures were needed. Accordingly, 6 new underpasses

**Figure 1.** Location of game-proof fencing and 7 mule deer underpasses constructed along U.S. Highway 30 in Southwest Wyoming, USA.

and 10 km of fence were constructed in the summer of 2008.

Although previous studies have documented how many animals move through a particular underpass (Foster and Humphrey 1995, Ng et al. 2004, Kleist et al. 2007, McCollister and Van Manen 2010), none have focused on large migratory populations where animals can migrate at grade-level during one year, while the next year they cannot. Ungulates show strong fidelity to their migration routes (Berger et al. 2006, Sawyer et al. 2009, Sawyer and Kauffman 2011) and how they respond to fencing and underpasses is generally unknown. Our goal was to evaluate whether underpasses and associated fencing effectively reduced roadway impacts to this migratory deer population. First, we quantified the number of mule deer that used the underpasses. Second, we identified the seasonal and daily temporal patterns of deer movements through underpasses. Third, we estimated the passage rates of deer through underpasses to evaluate habituation through time. Finally, we evaluated DVCs before underpass construction (1990–2000), after construction of 1 underpass (2002–2007), and after construction of 6 additional underpasses (2009–2011). A clear understanding of whether underpasses and fencing can mitigate roadway impacts (i.e., DVCs, habitat connectivity) to migratory mule deer will improve the ability of wildlife and transportation agencies to sustain migratory ungulate populations and improve public safety on roadways.

## STUDY AREA

Our study site was a 21-km section of U.S. Highway 30 situated in Southwest Wyoming, in an area locally known as Nugget Canyon (Fig. 1). The canyon was characterized by steep sagebrush (*Artemisia tridentata*) canyons and open hill-sides. Elevations along the 2-lane roadway ranged from 1,890 m to 1,950 m, but the edges of the canyon reached elevations of 2,320 m. The Nugget Canyon area provided critical winter range to thousands of mule deer that migrated north each year to summer in the Wyoming Range. Because U.S. Highway 30 bisected this winter range, animals that wintered on the south side of Nugget Canyon must cross U.S. Highway 30 to complete their seasonal migrations. To reduce the number of DVCs, the Wyoming Department of Transportation installed 11 km of game-proof fence and 1 concrete box-culvert underpass (KP49) in 2001 (Fig. 1). In 2008, the fence was extended another 10 km, and an additional 6 underpasses (KP56, KP58, KP60, KP61, KP63, and KP65) were installed (Fig. 1). Underpass dimensions were approximately 6 m (width) × 18 m (length) × 3.0–3.5 m (ht), with an openness ratio of 1.10 (Fig. 2). We note that the openness ratio (opening width × ht/length of crossing) was calculated in metric units (Foster and Humphrey 1995). The height varied by as much as 0.5 m because of the amount of dirt fill used at each site. We refer readers to Reeve and Anderson (1993) and Gordon

et al. (2004) for detailed history of roadway mitigation efforts in Nugget Canyon, Wyoming.

## METHODS

We installed 3 digital infrared Reconyx<sup>®</sup> (Holmen, WI) cameras in each of the 7 underpasses, including one at the entrance, one in the middle, and one at the exit. This camera configuration allowed us to count the number of deer that approached and passed through each underpass from either direction. Underpasses were equipped with cameras from 1 October through 31 May for 3 years. The study period encompassed autumn migration (2008, 2009, and 2010), winter use, and spring migration (2009, 2010, and 2011) for 3 migration cycles. We defined the autumn migration as 1 October through 31 December and spring migration as 1 March through 31 May. The winter period was January and February. We note that cameras were not installed the first year until 16 December, so only the later part of the autumn migration was documented that year. We refer to years 1, 2, and 3 as monitoring seasons 2008–2009, 2009–2010, and 2010–2011, respectively. We used digital photos to count the number of deer and other wildlife that used each underpass. We examined seasonal temporal patterns by calculating the number of deer that passed through each underpass each day. We examined the daily temporal

patterns by calculating the number of deer that moved through underpasses each hour of the day, during a 10-day sampling period that corresponded with the peak level of use during spring and autumn migrations.

When faced with a novel disturbance such as an underpass, ungulates may take some time to habituate before using it (e.g., Gagnon et al. 2011). We evaluated the passage rate success by calculating the proportion of animal approaches that resulted in successful crossings (Dodd et al. 2007). We defined an approach as any event in which animals moved to within 50 m of the underpass entrance (Gagnon et al. 2007b). The passage rate was then calculated by dividing the number of animals that successfully passed through the underpass by the number of animals that approached. This metric was intended to quantify the effectiveness of each underpass and help evaluate whether passage rate success improved over time (e.g., Xia et al. 2007, Gagnon et al. 2011). We calculated passage rates during the 10-day peak migration period of each season (autumn 2008 [17–26 Dec], autumn 2009 [08–17 Dec], autumn 2011 [21–30 Nov], spring 2009 [23 Apr–02 May], spring 2010 [17–26 Apr], spring 2011 [01–10 May]).

We used DVC data collected by the Wyoming Department of Transportation to assess how underpass and fence construction reduced DVCs. We compared the number of DVCs during 3 time periods: 1) 1 January 1990–1 October 2001, (141 months) prior to construction of the first underpass, 2) 1 October 2001–1 October 2008, (82 months) following construction of the first underpass, and 3) 1 October 2008–1 May 2011, (31 months) following construction of 6 additional underpasses. To make comparisons between the 3 periods that differed in temporal length, we standardized the number of DVCs by the number of months in each period.

## RESULTS

### Underpass Use by Mule Deer

We documented 49,146 mule deer that moved through the 7 underpasses between December 2008 and May 2011 (Table 1), including 12,483 during the 2008–2009 monitoring season, 13,403 during 2009–2010, and 23,260 during the 2010–2011 monitoring season. Overall, most deer movement occurred at the KP49 (47%;  $n = 22,924$ ) and KP58 (28%;  $n = 14,012$ ) underpasses (Table 1; Fig. 3). However, use at the other 5 underpasses steadily increased through the 3 years of study and accounted for the remaining 12%, 28%, and 34% of deer use during the 2008–2009, 2009–2010, and 2010–2011 monitoring seasons, respectively. Most underpass activity occurred during spring (37%;  $n = 18,194$ ) and autumn (46%;  $n = 22,569$ ) migrations, but deer crossings (17%;  $n = 8,383$ ) also occurred on a regular basis throughout the winter period (Table 1).

Deer use varied between underpasses, with most use occurring at KP49 and KP58 (Fig. 3). Additionally, the amount of deer use varied between spring and autumn migrations at several of the underpasses (Fig. 3). For example, the proportion of deer use was higher at underpass KP49 during the

**Table 1.** Number of mule deer that moved through underpasses during the autumn migration (Oct–Dec), the winter period (Jan–Feb), and the spring migration (Mar–May), December 2008 through May 2011, Nugget Canyon, Wyoming, USA.

Underpass	2008–2009	2009–2010	2010–2011	Total
Autumn migration				
KP49	1,552	3,308	5,553	10,413
KP56	83	274	855	1,212
KP58	638	885	4,242	5,765
KP60	149	1,062	1,529	2,740

Total	12,483	13,403	23,260	49,146

autumn compared with the spring, whereas deer use at underpass KP58 was higher during the spring compared with autumn. With the exception of KP49 and KP58, the proportion of deer use generally increased throughout the study period (Fig. 3).

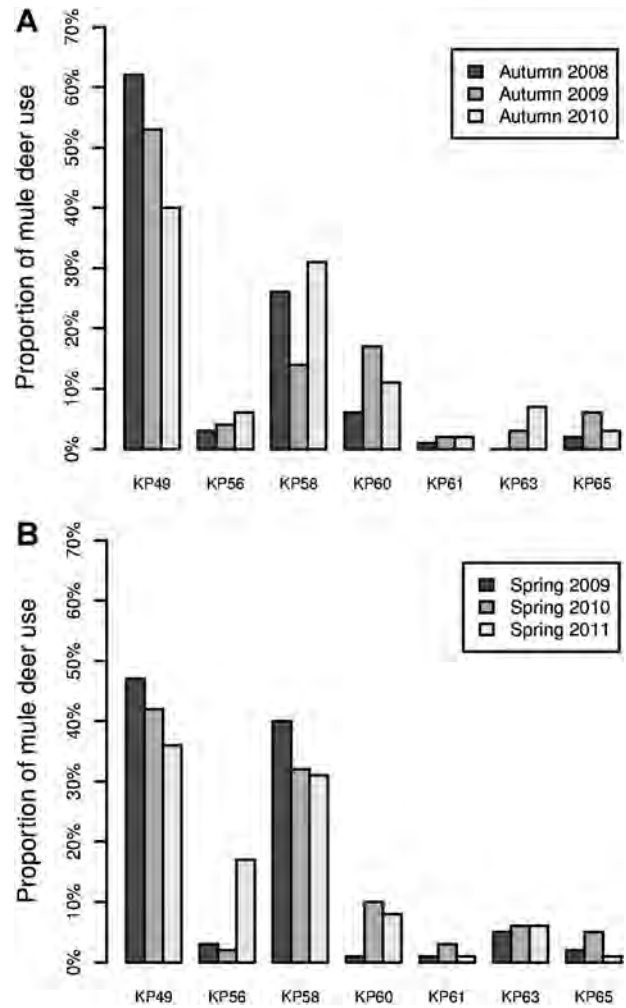

The timing of peak movements during the autumn migrations occurred in mid-December, with a maximum of 284 animals/day (Fig. 4). Spring migrations were characterized by multiple peaks of deer movement that generally occurred in mid-March and early May, with a maximum of 223 animals/day (Fig. 4). On a daily basis, peak levels of underpass use occurred in the mornings (0600–0800 hours) and evenings (1800–2000 hours; Fig. 5). Morning use was more prominent during the spring, whereas evening use was more common in the autumn.

### Passage Rates

Passage rates averaged 54% among all 7 structures during the first year of study and increased to 72% during the second year and 92% in the third year (Fig. 6). The oldest underpass (KP49) had a relatively high success rate to begin with, presumably because it had been in place already for 7 years. Passage rates observed at the 6 new underpasses steadily increased through the 3-year study period, further suggesting that it may take mule deer up to 3 years to habituate to underpasses before using them without hesitation.

### Mule Deer–Vehicle Collisions

Prior to underpass construction, the average number of DVCs in the 21-km study area was 9.75/month.

**Figure 3.** Proportional level of mule deer use at each underpass during spring and autumn migrations, December 2008 through May 2011, Nugget Canyon, Wyoming, USA.

Following construction of the first underpass in 2001, the average number of DVCs declined by 12% to 8.58/month. After construction of 6 additional underpasses and fencing in 2008, the average number of DVCs was further reduced to

**Figure 4.** Mean number of mule deer moving south to north (spring migration) and north to south (autumn migration) underneath U.S. Highway 30, Nugget Canyon, Wyoming, USA.

**Figure 5.** Number and time of day that mule deer moved through underpasses during the spring and autumn migrations, December 2008 through May 2011, Nugget Canyon, Wyoming, USA.

1.82/month. Overall, the construction of 7 underpasses and associated fencing reduced mule DVCs by 81%.

### Underpass Use by Other Wildlife

In addition to mule deer, we recorded 1,953 elk (*Cervus elaphus*), 201 pronghorn (*Antilocapra americana*), 13 coyotes (*Canis latrans*), 77 bobcats (*Lynx rufus*), 9 badgers (*Taxidea taxus*), 13 moose (*Alces alces*), 3 raccoon (*Procyon lotor*), and 1 cougar (*Puma concolor*) as they moved through the underpasses.

## DISCUSSION

Reducing DVCs is needed across wide regions of North America to improve highway safety and minimize deer mortality (Romin and Bissonette 1996, Putman 1997, Forman et al. 2003, Langbein et al. 2011). We found underpass and fence construction reduced DVCs by 81% in a 21-km stretch of U.S. Highway 30, where thousands of animals must cross the highway to complete their seasonal migrations. Previous studies have shown that game-proof fencing used in conjunction with underpasses can effectively move animals underneath roadways and reduce WVCs (Romin and

**Figure 6.** Average passage rates ( $\pm$ SE) of mule deer at each underpass during 3 years of study, December 2008 through May 2011, Nugget Canyon, Wyoming, USA.

Bissonette 1996, Clevenger et al. 2001, McCollister and Van Manen 2010). Our study broadens support of these findings and suggests that this mitigation approach can effectively move thousands of migrating mule deer underneath roadway segments that extend  $>20$  km. Importantly, DVCs did not increase in areas immediately adjacent to the fence ends, where deer were free to move across the highway at grade-level (Sawyer and LeBeau 2011). Rather than shift their migration routes and move around the fencing, deer moved underneath the highway, presumably through the underpass closest to their original migration route. We note that DVCs were not completely eliminated from the project area. Deer occasionally accessed the roadway through cattle guards filled with snow or gates left open by recreational users. Fortunately, both of these problems are correctable and if the fence infrastructure (i.e., cattle guards, gates) is managed properly, especially during the peak movement periods during spring and autumn migrations, then DVCs could be eliminated altogether.

As traffic volumes increase and roadways are widened, it also becomes more difficult to maintain habitat connectivity (Forman et al. 2003). Our study suggests that underpass and fence construction did not affect the permeability of U.S. Highway 30 to migratory mule deer. Rather, underpasses provided mule deer with a safe means to cross the 2-lane highway and maintain connectivity with their distant seasonal ranges. We documented 49,146 mule deer that moved underneath U.S. Highway 30 during a 3-year period and 83% of those animals were in the process of migrating. During peak migration periods,  $>200$  deer/day moved through the underpasses, with most use occurring in morning and evenings. Other studies suggest that underpass and fence construction may actually improve highway permeability because animals are less affected by traffic volume when moving underneath the roadway, compared with crossing at grade-level (Gagnon et al. 2007a, Dodd and Gagnon 2011).

Across the globe, migratory ungulates tend to outnumber their nonmigratory counterparts (Fryxell et al. 1988). Mule deer are no exception (e.g., Garrott et al. 1987, Brown 1992) and typically migrate 15–150 km between their seasonal ranges (Sawyer et al. 2005, Sawyer and Kauffman 2011). Sustaining these herds will require that mule deer safely cross roadways that overlap with established migration routes. Given the strong fidelity that mule deer show to their migration routes (Thomas and Irby 1990, Sawyer et al. 2009), maintaining routes across roadways with high traffic volume will likely require some form of crossing structure (e.g., underpass or overpass). In general, structures with high openness ratios are considered more appealing to wildlife (Foster and Humphrey 1995, Clevenger and Waltho 2000, Gordon and Anderson 2003). Yet, regardless of the openness ratio of a structure, some habituation period for animal use should be expected. For example, Gagnon et al. (2011) recently showed that elk may take up to 4 years to habituate to open-span bridge underpasses. Similarly, we found mean passage rates of mule deer through concrete-box underpasses steadily increased from 54% in Year 1 to 92% in Year 3, suggesting that mule deer habituation may also take several

years. Passage rates are likely influenced by a variety of factors including structure design, traffic levels, and species of animal (Clevenger and Waltho 2000; Gagnon et al. 2007*a, b*). Nonetheless, having some knowledge of the expected habituation period will help refine expectations and public perceptions of mitigation projects, especially in high-profile areas where animal movements are visible from the roadway.

Of the 7 underpasses we monitored, most deer use occurred at KP49 and KP58. Given that each underpass was the same size, it is of interest why those two were used more than others. Certainly, factors such as vegetation, human activity, and topography may influence the effectiveness of underpasses (Clevenger and Waltho 2000, 2005; Ng et al. 2004). Although we did not conduct any formal analysis to evaluate how these factors differ between the 7 underpasses, we suspect that the location of the underpasses relative to established migration routes was the most likely explanation for the differential use. In other words, because underpasses KP49 and KP58 were situated in close proximity to existing migration routes, they received the highest levels of deer use. Although we do not have telemetry data to document where established migration routes occurred before construction, we do know that road segments with the highest levels of DVCs closely corresponded with the locations of KP49 and KP58 (Sawyer and LeBeau 2011), which suggests that higher numbers of deer historically crossed the highway in these areas. It has long been recognized that wildlife-crossing structures should be situated along existing movement corridors or migration routes to increase the effectiveness of the structure (Singer and Doherty 1985, Bissonette and Adair 2008). New methods to identify migration routes and prioritize sites for crossing structures are quickly emerging (e.g., Sawyer et al. 2009, Lewis et al. 2011) and will improve the ability of transportation planners to ensure underpasses are located within existing movement corridors. Collecting migratory data prior to designing a mitigation project can improve the effectiveness of underpasses by ensuring they are sited correctly, and potentially reduce costs by determining the minimum number of underpasses needed. For example, Bissonette and Adair (2008) recommend underpasses be spaced every 1.6 km in areas with high DVCs. The average spacing in Nugget Canyon was 2.7 km, and it is possible that our mitigation project would have been equally successful with even fewer underpasses, provided we had spatially explicit migration data to refine planning and determine the number and location of underpasses.

The benefits of reduced DVCs and migratory connectivity across U.S. Highway 30 were not limited to mule deer. We documented a variety of other ungulates, carnivores, and small mammals that moved through the underpasses. Of particular interest was use by pronghorn, moose, and elk. Use of concrete-box underpasses by all 3 species is considered relatively rare (Forman et al. 2003), but our results suggest these types of underpasses may benefit them as well as mule deer.

Given the ability of underpasses in Nugget Canyon to reduce DVCs and maintain permeability to thousands of animals across U.S. Highway 30, it may be of interest to

consider the economic and logistical challenges for a construction project of this type. The 6 new underpasses and 10 km of fencing constructed in 2008 cost approximately US\$ 4.1 million, with \$2.8 million used for underpasses and \$1.3 million for fencing. Four million dollars is a sizable amount, but when we consider that each DVC has an estimated cost of US\$ 8,388 (Huijser et al. 2008) and the underpasses effectively eliminate 95 DVCs/year, the savings per year is \$796,860. Thus, the 4.1 million could be realized in approximately 5 years. Of additional concern are construction time and traffic delays. Construction of the 6 underpasses in 2008 began in May and was completed in September, outside of the migratory time period. Two underpasses were constructed at a time, such that traffic lights could be placed at each end and a pilot car directed traffic through a 1-lane dirt detour on the side of the road. Each set of 2 underpasses took approximately 50 days to complete. In short, it is possible to complete underpass projects such as Nugget Canyon in one construction season with minimal traffic delays.

## MANAGEMENT IMPLICATIONS

Ideally, mitigation measures aimed at reducing WVCs should also maintain habitat connectivity by encouraging animals to travel underneath or over the roadway via crossing structures. Installation of underpasses and continuous fencing can effectively reduce DVCs and maintain habitat connectivity for migratory mule deer populations that number in the thousands. However, careful maintenance of fence infrastructure (e.g., gates and cattle guards) is needed to ensure that animals stay off the roadway, especially during periods of peak animal movements. Similar to elk (Gagnon et al. 2011), mule deer may take up to 3 years to habituate to underpasses and move through them with no hesitation. For migratory ungulates, underpasses should be located as close to existing migration routes as possible. Collection of migratory data prior to project design can help ensure that the correct number of underpasses is constructed and that they are placed in the best location. Although some ungulates are believed to prefer overpasses (Forman et al. 2003), our results suggest that underpasses may be a viable option for moving a variety of ungulates, including mule deer, elk, moose, and pronghorn, underneath 2-lane highways.

## ACKNOWLEDGMENTS

We thank R. Bingham, J. Eddins, T. Carpenter, J. Hoffman, N. Hymas, M. Zornes, S. Lockwood, and B. Rudd for administrative and logistical support. This study was funded by the Wyoming Department of Transportation. Comments from 2 anonymous reviewers improved the manuscript.

## REVIEW SUMMARY

## CLIMATE CHANGE

# The broad footprint of climate change from genes to biomes to people

Brett R. Scheffers,\* Luc De Meester, Tom C. L. Bridge, Ary A. Hoffmann, John M. Pandolfi, Richard T. Corlett, Stuart H. M. Butchart, Paul Pearce-Kelly, Kit M. Kovacs, David Dudgeon, Michela Pacifici, Carlo Rondinini, Wendy B. Foden, Tara G. Martin, Camilo Mora, David Bickford, James E. M. Watson

**BACKGROUND:** Climate change impacts have now been documented across every ecosystem on Earth, despite an average warming of only ~1°C so far. Here, we describe the full range and scale of climate change effects on global biodiversity that have been observed in natural systems. To do this, we identify a set of core ecological processes (32 in terrestrial and 31 each in marine and freshwater ecosystems) that underpin ecosystem functioning and support services to people. Of the 94 processes

considered, 82% show evidence of impact from climate change in the peer-reviewed literature. Examples of observed impacts from meta-analyses and case studies go beyond well-established shifts in species ranges and changes to phenology and population dynamics to include disruptions that scale from the gene to the ecosystem.

**ADVANCES:** Species are undergoing evolutionary adaptation to temperature extremes,

**Climate change impacts on ecological processes in marine, freshwater, and terrestrial ecosystems.** Impacts can be measured on multiple processes at different levels of biological organization within ecosystems. In total, 82% of 94 ecological processes show evidence of being affected by climate change. Within levels of organization, the percentage of processes impacted varies from 60% for genetics to 100% for species distribution.

and climate change has substantial impacts on species physiology that include changes in tolerances to high temperatures, shifts in sex ratios in species with temperature-dependent sex determination, and increased metabolic costs of living in a warmer world. These physiological adjustments have observable impacts on morphology, with many species in both aquatic and terrestrial systems shrinking in body size because large surface-to-volume ratios are generally favored under warmer conditions. Other morphological changes include reductions in melanism to improve thermoregulation, and altered wing and bill length in birds.

## ON OUR WEBSITE

Read the full article at <http://dx.doi.org/10.1126/science.aaf7671>

Broader-scale responses to climate change include changes in the phenology, abundance, and distribution of species. Temperate plants are budding and flowering earlier in spring and later in autumn. Comparable adjustments have been observed in marine and freshwater fish spawning events and in the timing of seasonal migrations of animals worldwide. Changes in the abundance and age structure of populations have also been observed, with widespread evidence of range expansion in warm-adapted species and range contraction in cold-adapted species. As a by-product of species redistributions, novel community interactions have emerged. Tropical and boreal species are increasingly incorporated into temperate and polar communities, respectively, and when possible, lowland species are increasingly assimilating into mountain communities. Multiplicative impacts from gene to community levels scale up to produce ecological regime shifts, in which one ecosystem state shifts to an alternative state.

**OUTLOOK:** The many observed impacts of climate change at different levels of biological organization point toward an increasingly unpredictable future for humans. Reduced genetic diversity in crops, inconsistent crop yields, decreased productivity in fisheries from reduced body size, and decreased fruit yields from fewer winter chill events threaten food security. Changes in the distribution of disease vectors alongside the emergence of novel pathogens and pests are a direct threat to human health as well as to crops, timber, and livestock resources. Humanity depends on intact, functioning ecosystems for a range of goods and services. Enhanced understanding of the observed impacts of climate change on core ecological processes is an essential first step to adapting to them and mitigating their influence on biodiversity and ecosystem service provision. ■

Most ecological processes now show responses to anthropogenic climate change. In terrestrial, freshwater, and marine ecosystems, species are changing genetically, physiologically, morphologically, and phenologically and are shifting their distributions, which affects food webs and results in new interactions. Disruptions scale from the gene to the ecosystem and have documented consequences for people, including unpredictable fisheries and crop yields, loss of genetic diversity in wild crop varieties, and increasing impacts of pests and diseases. In addition to the more easily observed changes, such as shifts in flowering phenology, we argue that many hidden dynamics, such as genetic changes, are also taking place. Understanding shifts in ecological processes can guide human adaptation strategies. In addition to reducing greenhouse gases, climate action and policy must therefore focus equally on strategies that safeguard biodiversity and ecosystems.

Atmospheric concentrations of greenhouse gases from burning fossil fuels and deforestation are approaching levels that have not been detected in the past 20 million years (1). This has altered the chemical composition of the Earth's atmosphere, oceans, and fresh waters (2). As a result, temperatures

in the upper ocean and on land are now ~1°C higher than in preindustrial times, and temperature, wind, and precipitation regimes have become more variable and extreme (3, 4). These changes are having clear impacts on planetary biophysical processes, including desalinization and acidification of the world's oceans (5) and melting of permafrost, ice sheets, and glaciers (6, 7). Lakes and rivers have increased in temperature, altering seasonal patterns of mixing and flows (8).

Changing climate regimes have been an important driver of natural selection in the past (9) and, as in the past, species are responding to the current human-induced climate event in various ways. Previous reviews have covered many of the more obvious changes in species ranges, phenologies, and population dynamics (10–15) but have usually focused on one ecological system at a time. Here, we discuss the full range and scale of climate change effects on biota, including some of the less obvious disruptions observed in natural systems. We present examples of case studies of observed impacts across terrestrial and aquatic biomes and find evidence that climate change is now affecting most biological and ecological processes on Earth—spanning genetics, organismal physiology and life-history, population distributions and dynamics, community structure, and ecosystem functioning (Fig. 1 and table S1). People depend on intact, functioning ecosystems for a range of goods and services, including those associated with climate adaptation (16). Understanding the observed impacts of current climate change on core ecological processes is therefore an essential first step in humans planning and adapting to changing ecosystem conditions.

Although inherently different, marine, freshwater, and terrestrial realms share a common hierarchy of levels of biological organization, ranging from genes to organisms, populations, species, communities, and ecosystems. Broadly adapting from Bellard *et al.* (17), we screened the literature (supplementary materials) to evaluate evidence that climate change is affecting ecological components across different levels of biological organization, each of which comprises a core set of ecological processes (Fig. 1, fig. S1, and table S1). We identify a set of core ecological processes on Earth (32 in terrestrial and 31 each in marine and freshwater), which together facilitate ecosystem functioning that supports services to people (17). These processes include changes in genetic diversity (genetics), metabolic rates (physiology), body size (morphology), timing of migration (phenology), recruitment (population dynamics), range size (distribution), loss of synchronization (interspecific relationships), and biomass (productivity) (17). Because our main goal is to assess what processes are affected by climate change, we define “impact” on each process as an observed change in that process linked to climate change. We do not differentiate between “positive” (adaptive, buffering, or mitigating) and “negative” (stress or damage) responses because responses may be positive at one level of biological organization (such as genetic adaptation to climate change) but negative at another (such as reduced genetic variation and capacity to deal with other stressors). We then consider the relevance of the affected ecological processes in human systems and illustrate observed impacts to ecosystem services such as food and resource security (fisheries, agriculture, forestry, and livestock production), human health, and hazard reduction.

## Ecological impacts of climate change

### Organisms Genetics

There is now growing evidence that species are undergoing evolutionary adaptation to human-induced climate change. For example, between the 1960s and 2000s the water flea (*Daphnia magna*) evolved to cope with higher thermal extremes in the UK (18), and cornflower (*Centaurea cyanus*) life history traits have recently evolved in response to warmer springs across northern France (19). Other examples include the evolution of earlier migration timing in anadromous pink salmon (*Oncorhynchus gorbuscha*), with decreased frequency of incidence of a genetic marker that encodes for late migration (20). Time-series data that control for physiological acclimatization also show strong evidence for genetic responses to climate change. For example, Bradshaw and Holzapfel showed that genotypic values for the critical day length that induces diapause in the pitcher plant mosquito (*Wyeomyia smithii*) change with latitude, and that the latitudinal relationship has changed over the period from 1972 to 1996 (21). Onset of diapause now occurs later, which is consistent with a longer

**Fig. 1. Climate change impacts on Earth's marine, terrestrial, and freshwater systems.** The presence of observed impacts on the different levels of biological organization and its inner components across the Earth's marine, terrestrial, and freshwater ecosystems. The denominator represents the total number of processes that we considered for each group, and the numerator is the number of these processes with evidence of impact (a complete list of processes is provided in fig. S1 and table S1). In total, 82% of all ( $n = 94$ ) ecological processes that were considered have observed evidence of impact by climate change.

Each process has at least one supporting case study. The asterisk indicates whether the affected process was assessed in a meta-analysis in addition to case studies. Thus, double-asterisk indicates that two processes were assessed in at least one meta-analysis. Confidence that the observed impact can be attributed to climate change was assigned for each level of organization and ranges from very low, low, medium, high, to very high; this assessment is based on tables 18-7, 18-8, and 18-11 in (13). The darkest circle indicates confidence level with the most literature support.

growing season under warmer conditions. Oceanic phytoplankton have adapted to a temperature change of +0.73°C associated with 15 years of climate warming in the Gulf of Cariaco, Venezuela, by adjusting their thermal niche by +0.45°C (22). Although such evidence from small organisms with short generation times is accumulating, we found little documented evidence of evolutionary change from species with longer generation times such as birds, mammals, and trees (14, 23), although adaptation appears to be possible in some long-lived reef corals (24).

Changes in species ranges have altered or created new “hybridization zones” across the planet. For example, in North America, hybrid zones between black-capped (*Poecile atricapillus*) and Carolina chickadees (*P. carolinensis*) are shifting in response to warmer winter temperatures (25), and because the southern flying squirrel (*Glaucomys volans*) has expanded its range northward in eastern North America, it is now hybridizing with the northern flying squirrel (*G. sabrinus*) (26). In North American rivers and streams, hybridization between invasive rainbow trout (*Oncorhynchus mykiss*) and native cutthroat trout (*O. clarkia*) has increased in frequency as the former expand into warming waters (27). Such hybridization events have also been observed in some marine fishes, such as the coastal West Coast dusky cob (*Argyrosomus coronus*), and are expected to increase as species shift their ranges poleward in response to rapidly warming ocean conditions (28).

### Physiology

Many species display temperature-driven trait plasticity in physiological processes such as thermal optima (29). Whereas some responses, such as acclimation to high temperatures, maximize fitness, others can reflect failure to cope with temperature stress and other climate-mediated changes. These responses can occur within a generation or between generations through maternal or epigenetic effects (30).

There is some observational evidence that warming has affected temperature-dependent sex determination (TSD) of species in marine and terrestrial systems. Snake pipefish (*Entelurus aequoreus*) in the northeastern Atlantic have altered their operational sex ratios and reproductive rates as a consequence of warmer sea surface temperatures (31). Most evidence for impacts on TSD in marine systems, however, is derived from experimental studies, which provide strong support for TSD changes in sea turtles and various fish species (32, 33). In terrestrial and freshwater systems, TSD has been implicated in masculinization and feminization, respectively, of lizard and turtle populations (34, 35).

In marine systems, physiological responses to both climate warming and changing ocean conditions are widespread (36, 37). Matching field and laboratory data for the eelpout (*Zoarces viviparus*) show increased metabolic costs associated with warming in the North and Baltic Seas (38). In aquatic systems, warming increases oxy-

gen demand but decreases oxygen content of the water, resulting in substantial metabolic costs (39). Although climate change per se does not cause acidification of the oceans, both arise directly from higher atmospheric carbon dioxide, and experimental evidence has raised concerns regarding negative effects of ocean acidification on calcification, growth, development, and survival of calcifying organisms (12). For example, acidification has led to extensive shell dissolution in populations of the pteropod *Limacina helicina* in northwest North America and in the Southern Ocean off Antarctica (40, 41).

### Morphology

Individuals in some species are becoming smaller with increasing warming because large surface-to-volume ratios are generally favored under warmer conditions (42)—a phenomenon that is linked to standard metabolic principles (43). In the Appalachian Mountains, six species of *Plethodon* woodland salamander have undergone, on average, an 8% reduction in body size over the past 50 years (44). Similarly, three species of passerine birds from the northeast United States show an average 4% decrease in wing length correlated with recent warming (45), and the long-distance migrant bird the red knot (*Calidris canutus*) is now producing smaller offspring with smaller bills, which reduces survival in juveniles because of altered foraging success on underground bivalves (46). In general, decreasing body size with warming is expected, but evidence from cold, high-altitude habitats suggests that increased primary productivity and longer growing seasons from warming have led to increased body size in some mammal species such as American marten (*Martes americana*) and yellow-bellied marmot (*Marmota flaviventris*) (47, 48). In South Australia, leaf width in soapberry (*Dodonaea viscosa*) has decreased compared with the ancestral condition documented under cooler temperatures 127 years ago (49). Other climate change impacts on morphology include color changes in butterflies, dragonflies, and birds (50–53) and pronounced changes in skull shape in the alpine chipmunk (*Tamias alpinus*) (54).

### Population

#### Phenology

For most species, migrations and life-history processes (such as budding and flowering in plants, hatching and fledging in birds, and hibernation in mammals) are closely tied to seasonal and interannual variation in climate, and there is now overwhelming evidence that both have been affected by climate change (10, 37, 55, 56). Across marine, freshwater, and terrestrial ecosystems, spring phenologies have advanced by 2.3 to 5.1 days per decade (10, 57). A combination of climate warming and higher atmospheric CO<sub>2</sub> concentrations has extended the growing period of many plant populations (58). In a large global analysis, which included 21 phenological metrics such as leaf-off and leaf-on dates and growing-season length, plant phenologies were found to have shifted by more than 2 standard deviations

across 54% of Earth’s land area during the past three decades (59).

In marine and freshwater systems, advances in the timing of annual phytoplankton blooms—the basis for many aquatic food webs—have occurred more rapidly than temporal shifts in terrestrial plants (37, 60). Such changes in plankton phenology have been attributed to increases in water temperatures, reduction in the duration of ice cover, and the alteration of the seasonal duration of thermal stability or stratification of the water column.

Shifts in spawning times have been documented for 43 fish species in the northeast Pacific Ocean from 1951 to 2008, with earlier spawning associated with increased sea surface temperature and later spawning associated with delays in seasonal upwelling of nutrients toward the ocean surface (61). Similar impacts on breeding have been observed in terrestrial and marine bird species (62).

Changes in the timing of migration events have been extensively documented, including advances in spring arrival dates of long-distance migratory bird species in Europe, North America, and Australia (63–65). Similarly, long-term data on many amphibians and mammals have shown advancements in spring and delays in autumn migration (66–68) and altered peak calling periods of male amphibians (67–69). In the largest meta-analysis to date of phenological drivers and trends among species in the southern hemisphere, 82% of terrestrial data sets and 42% of marine data sets demonstrated an advance in phenology associated with rising temperature (70).

#### Abundance and population dynamics

Acute temperature stress can have severe negative effects on population dynamics such as abundance, recruitment, age structure, and sex ratios. Meta-analyses across thousands of species report that ~80% of communities across terrestrial, freshwater, and marine ecosystems exhibited a response in abundance that was in accordance with climate change predictions (10, 70). In a meta-analysis of marine species, 52% of warm-adapted species increased in abundance, whereas 52% of cold-adapted species decreased (71). Temperature spikes may cause mass mortality of key ecosystem engineers in both temperate and tropical oceans. Excessive heat kills canopy-forming macroalgae in temperate marine systems (72) and causes bleaching and mass mortality of corals in the tropics (73). Reductions in sea ice extent have caused declines in abundances of ice-affiliated species in the Arctic [for example, ivory gulls (*Pagophila eburnea*), ringed seals (*Pusa hispida*), and polar bears (*Ursus maritimus*) (74)] whereas in some cases, such as on Beaufort Island in the southern Ross Sea, the loss of ice from receding glaciers resulted in increased abundances of Adélie penguins (*Pygoscelis adeliae*) (75). In the United States, the bull trout (*Salvelinus confluentus*) has lost >10% of its spawning grounds in central Idaho over the past 13 years because of increased water temperatures (76), while the brown trout (*Salmo*

*trutta*) has lost habitat in the Swiss Alps (77). In western Canada, reduced survival of adult migrating Fraser River sockeye salmon (*Oncorhynchus nerka*) has been observed with increased water temperatures (78), and in eastern Canadian lakes, golden-brown algae dramatically increased in abundance as water temperature increased 1.5°C during the latter part of the 20th century (79). Some of the best evidence for climate-change impacts on the abundance of terrestrial species comes from analyses of bird population trends derived from systematic monitoring schemes in Europe, with warm-adapted species having increased in abundance on average since the 1980s and cold-adapted species having declined (80).

Climate change can increase the abundance of temperature-sensitive disease vectors, with subsequent effects on disease outbreaks. In the African Serengeti, there is some evidence that a combination of extreme weather, high abundances of ticks carrying *Babesia*-piroplasm, and suppressed immunity to canine distemper virus led to widespread mortality of lions (*Panthera leo*) (81). In marine systems, field evidence shows that corals are increasingly susceptible to white band disease at higher temperatures, leading to declines in two of the most important reef-building acroporid (branching) corals in the western Atlantic (82).

### Species Distribution

One of the most rapid responses observed for marine, freshwater, and terrestrial species is a shift in their distributions to track optimal habitat conditions (71, 83, 84). Across land and aquatic ecosystems, species have expanded their leading (cold limit) edge by 19.7 km per decade, with marine species expanding by 72 km per decade compared with 6 km per decade in terrestrial species (37). The distributions of many marine taxa have shifted at higher velocities than those of terrestrial taxa (37) because areas with rapid changes in climate extend across broader regions of the ocean than on land, and connectivity in marine environments tends to be high (85). To illustrate this point, corals around Japan have shifted their range by up to 14 km per year over the past 80 years (86), and in waters off the southeast coast of Australia, intertidal invertebrate species have shifted their geographic distributions polewards at an average rate of 29 km per decade (87). Where connectivity allows for dispersal, some freshwater fishes are capable of shifting at rates comparable with those of marine and terrestrial taxa (88), but mean shifts by river fishes in some regions have been insufficient to compensate for measured temperature rises (89).

There has been a consistent overall trend for tropical, warm-adapted species to expand their ranges into environments previously dominated by temperate cold-tolerant species (“tropicalization”) (90). A similar phenomenon has been documented in the Arctic, where boreal fish communities have responded to warming in the Barents Sea by shifting northward, resulting in a

high turnover in Arctic fish communities (“borealization”) (91). Similarly, on land, increased minimum temperatures have driven rapid changes in the range size (as well as distribution) of Swedish birds, with northern species retracting and southern species expanding northward (92).

In addition to latitudinal changes, many observed shifts in species distributions have occurred across elevation gradients. In the mountains of New Guinea, birds have shifted their distributions upslope by 95 to 152 m from 1965 to 2013 (93). A similar upslope shift was observed in recent decades in mountainous stream-dwelling fish in France (89), North American plants (94), and Bornean insects (95). An analogous response has been the shift to deeper, colder waters among some marine fishes (91).

In some cases, species have shown no response or even downhill shifts in their distributions (96) or increased frequency of range disjunction rather than poleward or upward range shifts (97). Savage and Vellend (98) found upward range shifts in North American plant species and an overall trend toward biotic homogenization from 1970 to 2010, but their study also documents considerable time lags between warming and plant responses (99, 100). Delayed community responses to increasing temperature may be in part due to the buffering effects of microhabitats (101, 102) and possibly moisture, which is a critical, but less often studied, driver in the redistribution of species (103). For example, Crimmins *et al.* observed downhill movements for North American plants under climate change over an 80-year period, which they attribute to changes in water balance rather than temperature (104).

### Community Interspecific relationships

As a by-product of the redistribution of species in response to changing climate, existing interactions among species are being disrupted, and new interactions are emerging (105, 106). These novel biotic interactions can exacerbate the impacts of abiotic climate change (107, 108). Woody plants are invading arctic and alpine herb-dominated communities in response to rapid warming in recent decades, leading to secondary shifts in distribution of other plants and animals (92). In the Sierra Nevada Mountains of California, Tingley and Beissinger found high levels of avian community turnover during the past 100 years at the lowest and highest elevations (109), and in Greece, Sgardeli *et al.* found similar patterns of temperature-driven turnover in butterfly communities (110). There are surprisingly few studies of observed impacts of climate change on competitive interactions (108). In one example from Sweden, Wittwer *et al.* found that among four bird species occupying the same ecological guild, resident birds were able to adapt to warmer temperatures and out-compete the sole long-distance migrant, *Ficedula hypoleuca* (111).

New interactions among species can also lead to trophic disruptions such as overgrazing. In western Australia, for example, overgrazing of

subtropical reefs by the poleward spread of tropical browsing fish has suppressed recovery of seaweeds after temperature-induced mortality (112). These types of trophic disruptions are escalating, with range shifts by tropical herbivorous fishes increasing herbivory rates in subtropical and temperate coastal ecosystems where seaweeds are the dominant habitat-forming taxa (90).

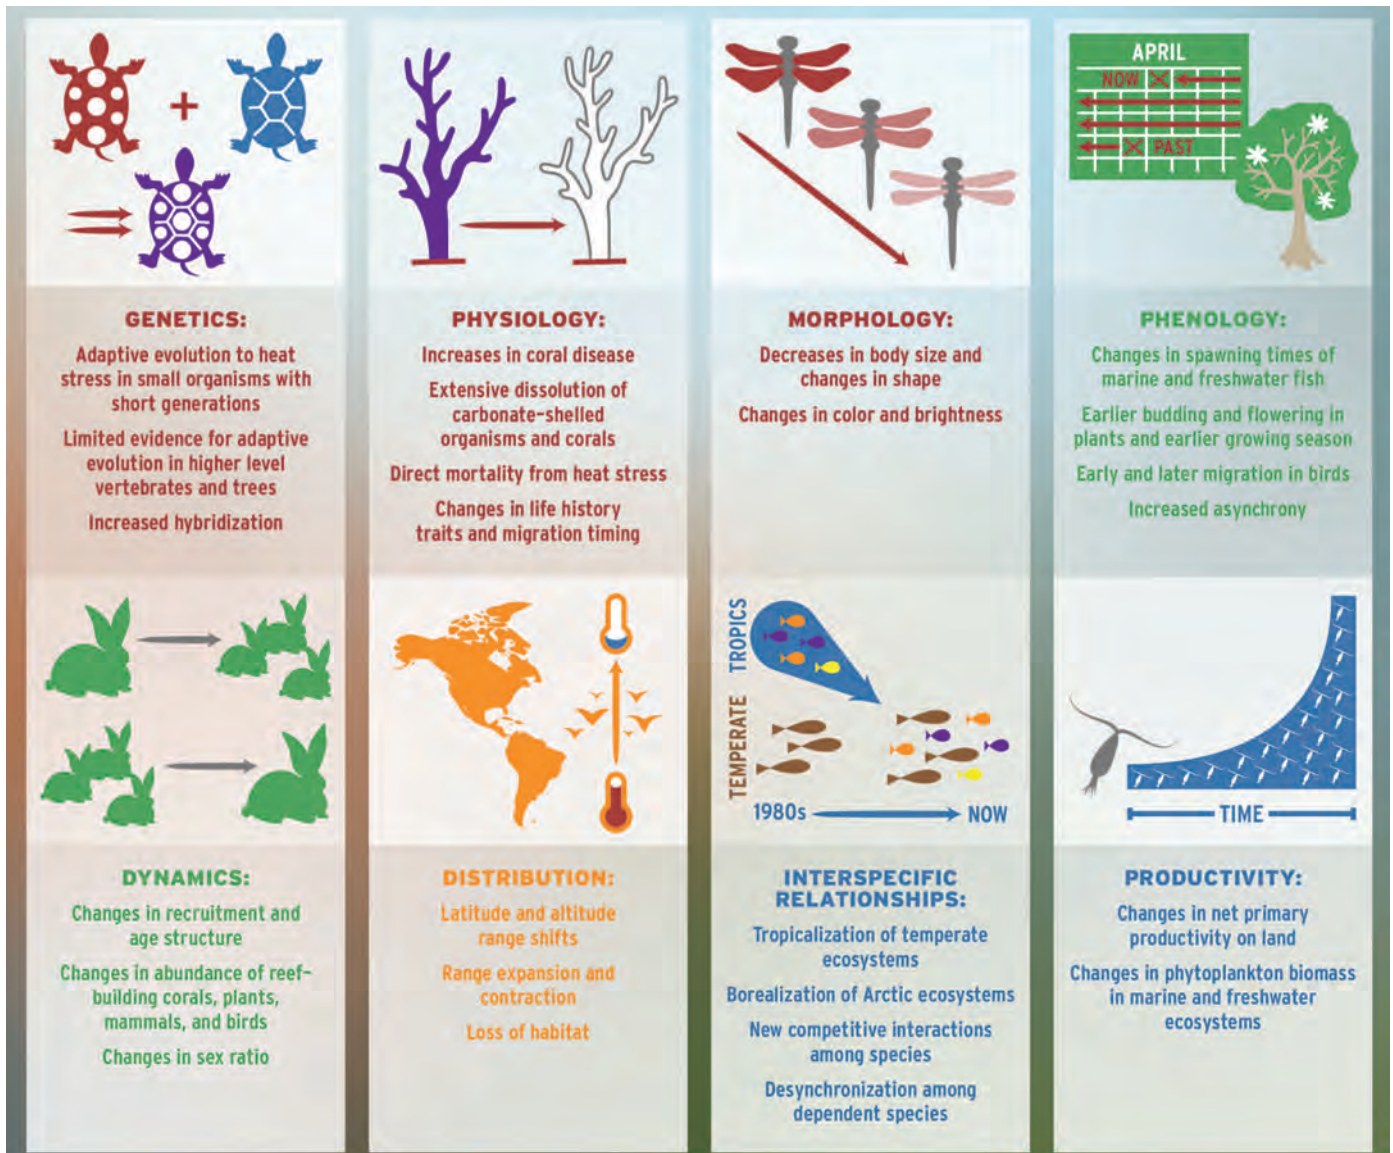

Phenological mismatches have been observed between butterflies and their annual host plants, with the plants dying before the insect larvae were ready to enter diapause (113). Similarly, an analysis of 27 years of predator-prey data from the UK showed asynchronous shifts between the tawny owl (*Strix aluco*) and its principle prey, the field vole (*Microtus agrestis*), which led to reduced owl fledging success (114). In Lake Washington, United States, spring diatom blooms advanced by over 20 days since 1962, resulting in predator-prey mismatches with their main grazer, the water flea (*Daphnia pulex*), and population declines in the latter (60). In Canadian Arctic lakes, asynchronous shifts in diatom blooms resulted in generalist water fleas being replaced by more specialist species (115). At higher trophic levels, warming has affected the fry and the juvenile life-history stages of lake char (*Salvelinus umbla*) via direct impacts on their zooplankton and vendace (*Coregonus alba*) food sources (116).

### Productivity

Changes in productivity are one of the most critical impacts of climate change across aquatic and terrestrial ecosystems (117, 118). In marine systems, climate-mediated changes in chlorophyll-*a* concentrations as a proxy of phytoplankton biomass have been highly variable (119). Depending on location, these include both dramatic increases and decreases in abundance as well as changes in phenology and distribution of phytoplankton over the past several decades. In a global study of phytoplankton since 1899, an ~1% decline in global median phytoplankton per year was strongly correlated with increases in sea surface temperature (120), whereas in the Antarctic Peninsula, phytoplankton increased by 66% in southern subregions and decreased by 12% in northern subregions over a 30-year period. These conflicting observations in the Antarctic are in part linked to changes in sea surface temperature but also changes in ice cover, cloudiness, and windiness, which effect water-column mixing (121).

In deep tropical freshwater lakes dominated by internal nutrient loading through regular mixing, warmer surface waters confer greater thermal stability, with reduced mixing and return of nutrients to the photic zone, substantially decreasing primary productivity (122), phytoplankton growth (123), and fish abundance (122). In contrast, eutrophication effects are exacerbated by higher temperatures in shallow lakes, resulting in increased productivity and phytoplankton and toxic cyanobacteria blooms (124).

**Fig. 2. Climate impacts on ecological processes.** Examples of ecological components and processes affected by climate changes across marine, freshwater, and terrestrial ecosystems (fig. S1 and table S1).

Globally, terrestrial plant growth has increased with increasing temperatures and CO<sub>2</sub> levels. This may in part explain the on average 6% increase in net primary productivity (NPP) from 1982 to 1999 (125), although these changes in NPP may also be related to natural variation in El Niño–La Niña cycles (126). However, responses are highly variable, and some terrestrial systems are not experiencing increased productivity owing to either extreme temperatures or lack of water. Severe short-term droughts in climatically stable rainforest environments are unusual but in recent years have increased in frequency. These events have led to changes in forest canopy structure in Amazonia (127) and decreases in above-ground woody and leaf biomass in the Congo basin (128). Across large expanses of the Amazon, there has been an overall reduction in above-

ground biomass owing to increased climate variability over the past three decades (129).

#### Impacts across ecosystems

All three biotic realms (terrestrial, freshwater, and marine) are being affected by climate change, and the evidence summarized here reveals that these impacts span the biological hierarchy from genes to communities. Of the 94 processes considered, we found that 82% have evidence of impact by climate change, and this has occurred with just 1°C of average warming globally (Fig. 1). Impacts range from genetic and physiological changes to responses in population abundance and distribution (Fig. 2).

The fact that evidence is missing for some processes is more likely to reflect data deficiencies than the absence of any response to climate

change. We only considered field-based case studies that report changes in the processes through time. For many components, such as genetics (23) and physiology (29), there is strong evidence from experiments on a wide range of species that individuals and populations can and likely will respond to climate change. Thus, even though we found compelling evidence of widespread responses across the biological hierarchy, we still consider our discussion of impacted processes to be conservative. To illustrate this point, Box 1 shows the range of observed responses in the water flea *Daphnia*, which spans the entire hierarchy of biological organization.

#### Ecosystem state shifts

As ecological systems continue to accumulate stress through compromised ecological processes

**Box 1. A complete hierarchy of climate change impact in one model system: the water flea *Daphnia*.**

Combining time-series data with experimental approaches can lend insights to the breadth of climate change impacts. For water fleas of the genus *Daphnia*, for instance, there is evidence for responses to temperature at all levels of biological organization. *Daphnia* are important grazers in lakes and ponds (180). They adapt to temperature increase through genetic changes in thermal tolerance (18), body size, and life history traits (181, 182). In the laboratory, *Daphnia* exhibit phenotypic plasticity in physiology to changing temperatures [for example, hemoglobin quality and quantity (183) or metabolic activity (184)], behavior [such as swimming activity (184)], life history traits (185), and body size (182). *Daphnia* adjust their phenology (186) and abundance (187) in response to increases in temperature, which results in mismatches with phytoplankton dynamics (60). Warmer, drier weather over two decades can lead to expanded distributions and increased colonization capacity (188). Temperature influences interactions of *Daphnia* with predators (189) and parasites (190), and adaptation to increased temperature influences competitive strength (185). In the absence of fish, high abundances of *Daphnia* in +4°C heated mesocosms exert strong top-down control on phytoplankton (191).

either directly from climate change or interactively with other forced disturbances (discussion is provided in the supplementary materials), diminished resilience may lead to ecological regime shifts—in which one ecosystem state shifts to an alternative and potentially undesirable stable state. For example, some reefs are transitioning from coral- to algal-dominated states as a consequence of mass coral mortality (130),

whereas kelp forests are turning into rocky barrens in temperate seas (90, 131, 132). In lakes, climate change has increased the risk of regime shifts from clear-water to turbid states and increased the occurrence of cyanobacteria blooms (124). If sufficient community-based processes are affected at regional scales, wholesale biome shifts can occur such as has been observed in Alaska, where tundra is transitioning to boreal conditions (133). These are clear signs of large-scale ecosystem change and disruption, in which disequilibrium rapidly pushes the system into a new state (134).

**Using ecology to better understand climate change impacts on human well-being**

*Threats to production*

The impacts of climate change on marine fisheries have major consequences for human societies because these currently provide ~17% of the global protein for people (135). There is, however, no current consensus on the costs and benefits of the ongoing global redistribution of fisheries because trends are highly variable. In the Arctic, commercially important fish, such as Atlantic cod (*Gadus morhua*) and walleye pollock (*Theragra chalcogramma*), have increased in biomass primarily because of increases in plankton production from reduced sea ice (136, 137), whereas changes in fish biomass in the Southern Ocean are less clear (138). In Switzerland, which has experienced twice the average global temperature increase, trout catches have been halved over two decades because of rising temperatures in Alpine streams (77).

Changes in total marine productivity are not just attributed to abundance shifts but also morphological shifts. Indeed, some fish species appear to be shrinking, but attributing this solely to ocean warming is difficult because size-dependent responses can be triggered by commercial fishing as well as long-term climate change (139). However, long-term trend analyses show convincingly that eight commercial fish species in the North Sea underwent simultaneous reductions in body size over a 40-year period because of ocean warming, resulting in 23% lower yields (140). Reduced body size in fish is also being recorded in lakes and rivers throughout Europe and has been linked to increased temperature and climate-induced shifts in nutrient inputs (141, 142).

Impacts on plant genetics and physiology are influencing human agricultural systems. For example, yields in rice, maize, and coffee have declined in response to the combined effects of rising temperatures and increasing precipitation variability over past decades (143–145). Genetics is being used to counteract decreasing yields in some key crops such as wheat [for which, globally, yields have declined by 6% since the early 1980s (146)] through crossing domesticated crops with wild relatives to maintain the evolutionary potential of varieties (147). Yet, some important wild strains are also showing signs of impact from climate change. Nevo *et al.* documented high levels of genetic changes in the

progenitors of cultivated wheat and barley in Israel over the past 28 years (148). These wild cereals exhibited landscape-level changes in flowering time and a loss of genetic diversity in response to increasing temperatures.

Losing genetic resources in nature may undermine future development of novel crop varieties (149) and compromise key strategies that humans use to adapt to climate change. One such strategy is to use assisted gene flow, the managed movement of individuals or gametes between populations to mitigate local maladaptation in the short and long term (150). Where genetic introgression—the movement of genetic material from one species into the genome of another—can occur from unexploited natural populations to managed or exploited populations that are poorly adapted to warmer or drier conditions, adaptive changes may be facilitated (147), as in white spruce (*Picea glauca*), a tree commonly harvested for timber (151). Human-assisted evolution may also be a key strategy in maintaining reef-dependent fisheries by accelerating and enhancing the stress tolerance of corals (152).

Phenological changes due to milder winters are influencing crop and fruit production (153). Climate change has reduced winter chill events in temperate agricultural areas (154), which can desynchronize male and female flowers and trigger delayed pollination, delayed foliation, and reduced fruit yield and quality. To counter this, tree crop industries have developed adaptation measures such as low-chill cultivars with dormancy-breaking chemicals. For example, the “UFBest” peach requires four times fewer chill days than cultivars from more temperate climates (155). Advances in the timing of budding, flowering, and fruiting of plant species has induced earlier harvesting periods in some countries [such as Japan (156)].

Pollination is a key process linked to yields for a large number of crops. The short-lived, highly mobile insect species that provide pollination services to numerous crops have responded rapidly to changing climates by shifting their ranges throughout North America and Europe (157). Additionally, over the past 120 years, many plant-pollinator networks have been lost with overall decline in pollination services, which is attributed to a combination of habitat loss, pollution, and climate warming (158). Yet, observed changes in the phenology, abundance, and distribution of common pollinators have not been directly linked to declines in yields of animal-pollinated crops. This is likely due to limited data that directly link pollination services to crop yield over time and may, in part, reflect resilience provided by the diversity of insect species that pollinate many crops (159, 160). More specialized pollination systems are expected to be more vulnerable to climate change. Humans have adapted to the declines in native pollinators by transporting domesticated pollinators to crop locations.

*Pest and disease threats*

Climate-induced ecosystem-level changes, such as forest die-offs, have an obvious impact on

**Table 1. Climate change consequences for humans.** Affected ecological processes have direct consequences in food systems and human health.

	Organism	Population	Species	Community
	Genetics, physiology, morphology	Phenology, dynamics	Distribution	Interspecific relationships, productivity
<b>Resource security</b>	Rapid genetic adaptation to climate change in timber species	Increased herbivory on crops and timber by pests	Overall distribution shifts in marine and freshwater fisheries	Decline in plant-pollinator networks and pollination services
	Decreased crop yields in hot climates and increases in cool climates	Decreased genetic diversity and altered flowering time in wild cereals and novel crop varieties	Reduced range size or changes in pollinator abundance	Novel pests and invasive species
	Increased weed-crop competition and parasite-livestock interactions	Reduced fruit yields from fewer winter chill events		
	Decreased yield in fisheries from reduced body size	Reduced productivity in commercial fisheries		
<b>Human health</b>	Decline in reef calcifiers threatens coastal communities; loss of protection from storm surges and loss of food/protein sources	Increased costs and risk to subsistence communities from loss of sea ice and permafrost	Expanding and/or new distributions of disease vectors	Increased human-wildlife conflicts
	Rapid adaptation of disease vectors to new climatic conditions		Redistribution of arable land	Novel disease vectors

people, with a reduction in timber supplies and carbon sequestration, and changes in water quality and watershed volume (161–163). Several native insect species from North America, with no prior records of severe infestation, have recently emerged as severe pathogens of forest resources because of changes in population dynamics. These include the Aspen leaf miner (*Phyllocnistis populiella*), the leafblotch miner (*Micrurapteryx salicifoliella*), and the Janet's looper (*Nepytia janetae*), which have decimated millions of hectares of aspen, willows, and spruce-fir forests since the early 1990s (164). Known pests such as mountain and southern pine beetles (*Dendroctonus frontalis* and *D. ponderosae*, respectively) and spruce beetles (*D. rufipennis*) have recently expanded their distribution and infestation intensity on commercially important pine and spruce trees (161, 164). These outbreaks may increase in the future because hundreds of plant pest and pathogen species have shifted their distributions 2 to 3.5 km year<sup>-1</sup> poleward since the 1960s (165).

An emerging threat to human health under climate change is vector-borne disease (166). Vectors that have shifted their ranges and abundance can be found in marine, freshwater, and terrestrial systems. For example, in marine systems, unprecedented warming in the Baltic Sea led to emergence of *Vibrio* infections in Northern Europe (167, 168), a geographic locality that had limited prior occurrence of this water-borne bacterial pathogen. Mosquitoes (e.g., *Aedes japonicus*, *A. aegypti*, *A. albopictus*) are extending their distribution into areas that are much warmer than their original habitats. As a result of eco-

logical adaptation, mosquitoes have become more competent vectors for spreading diseases such as chikungunya, dengue, and possibly the emerging Zika virus (169). Last, in terrestrial systems Levi *et al.* found that the nymph stage of the Lyme disease-carrying blacklegged tick (*Ixodes scapularis*) exhibited an overall advancement in nymph and larvae phenology since 1994, shifting the timing of greatest risk for pathogen transfer to humans to earlier in the year (170).

#### Losing intact ecosystems and their function

Changes in ecological processes might compromise the functionality of ecosystems. This is an important consideration because healthy systems (both terrestrial and marine) sequester substantial amounts of carbon (171), regulate local climate regimes (172), and reduce risks associated with climate-related hazards such as floods, sea-level rise, and cyclones (173). In island and coastal communities, coral reefs can reduce wave energy by an average of 97% (174), and coastal ecosystems such as mangroves and tidal marshes buffer storms (175), while on land intact native forests are important in reducing the frequency and severity of floods (176). In many cases, maintaining functioning systems offers more sustainable, cost-effective, and ecologically sound alternatives than conventional engineering solutions (16).

#### Science and action in a warmer world

The United Nations Framework Convention on Climate Change (UNFCCC) and the recent COP21 agreement in Paris presently offer the best

opportunity for decisive action to reduce the current trajectory of climate change. This latter agreement set global warming targets of 1.5 to 2°C above preindustrial levels in order to avoid “dangerous climate change,” yet the current 1°C average increase has already had broad and worrying impacts on natural systems, with accumulating consequences for people (Table 1). Minimizing the impacts of climate change on core ecological processes must now be a key policy priority for all nations, given the adoption of the UN Sustainable Development Goals aiming to increase human well-being. This will require continued funding of basic science focused on understanding how ecological processes are interacting with climate change, and of programs aimed at supporting ecosystem-based adaptations that enhance natural defences against climate hazards for people and nature and ensure ongoing provision of natural goods and services (177).

We must also recognize the role that intact natural ecosystems, particularly large areas, play in overcoming the challenges that climate change presents, not only as important repositories for carbon but also because of their ability to buffer and regulate local climate regimes and help human populations adapt to climate change (16, 173). These systems are also critical for maintaining global biodiversity because the connectivity provided by large, contiguous areas spanning environmental gradients—such as altitude, depth, or salinity—will maximize the potential for gene flow and genetic adaptation while also allowing species to track shifting climate spatially (178).

The overriding priority of the UNFCCC is to set in motion a sustained global reduction in greenhouse gas emissions. This must be achieved alongside an improvement in our understanding of key ecological processes that form the foundation of biological and human systems, and in tandem with efforts to conserve the natural habitats in which such ecological processes operate.

It is now up to national governments to make good on the promises they made in Paris through regular tightening of emission targets, and also to recognize the importance of healthy ecosystems in times of unprecedented change (179). Time is running out for a globally synchronized response to climate change that integrates adequate protection of biodiversity and ecosystem services.

Editor's Summary

**Accumulating impacts**

Anthropogenic climate change is now in full swing, our global average temperature already having increased by 1°C from preindustrial levels. Many studies have documented individual impacts of the changing climate that are particular to species or regions, but individual impacts are accumulating and being amplified more broadly. Scheffers *et al.* review the set of impacts that have been observed across genes, species, and ecosystems to reveal a world already undergoing substantial change. Understanding the causes, consequences, and potential mitigation of these changes will be essential as we move forward into a warming world.

**Abstract** Anticoagulant rodenticides (ARs) are increasingly recognized as a threat to nontarget wildlife. High exposure to ARs has been documented globally in nontarget predatory species and linked to the high prevalence of an ectoparasitic disease, notoedric mange. In southern California, mange associated with AR exposure has been the proximate cause of a bobcat (*Lynx rufus*) population decline. We measured AR exposure in bobcats from two areas in southern California, examining seasonal, demographic and spatial risk factors across landscapes including natural and urbanized areas. The long-term study included

bobcats sampled over a 16-year period (1997–2012) and a wide geographic area. We sampled blood ( $N = 206$ ) and liver ( $N = 172$ ) to examine exposure ante- and post-mortem. We detected high exposure prevalence (89 %, liver; 39 %, blood) and for individuals with paired liver and blood data ( $N = 64$ ), 92 % were exposed. Moreover, the animals with the most complete sampling were exposed most frequently to three or more compounds. Toxicant exposure was associated with commercial, residential, and agricultural development. Bobcats of both sexes and age classes were found to be at high risk of exposure, and we documented fetal transfer of multiple ARs. We found a strong association between certain levels of exposure (ppm), and between multiple AR exposure events, and notoedric mange. AR exposure was prevalent throughout both regions sampled and throughout the 16-year time period in the long-term study. ARs pose a substantial threat to bobcats, and likely other mammalian and avian predators, living at the urban-wildland interface.

## Introduction

Anticoagulant rodenticides (ARs) are toxicants increasingly recognized as a threat to nontarget wildlife (Erickson and Urban 2004; US EPA 2008; Elmeros et al. 2011; Gabriel et al. 2012; California Department of Pesticide Regulation 2013). As vitamin K antagonists, ARs interrupt the production of vitamin K-dependent blood clotting proteins, leading to the depletion of these proteins over a period of days inducing mortality by hemorrhage (Erickson

and Urban 2004). Comprised of two classes of compounds, ARs are the primary chemical method used worldwide for the control of rats and mice (Stone et al. 1999; Eason et al. 2002). First-generation ARs, including warfarin, diphacinone, and chlorophacinone, are more readily metabolized, have a shorter half-life in hepatic tissue (2 weeks to several months) (Eason et al. 2002), and must be consumed in multiple feedings to reach a lethal dose (Erickson and Urban 2004). Second-generation ARs include brodifacoum, bromadiolone, and difethialone, and were developed to target rodents with genetic resistance to warfarin (Hadler and Buckle 1992). Second-generation ARs have prolonged action and increased potency (Petterino and Paolo 2001), with hepatic half-lives ranging 6–12 months, and may persist in liver tissue for more than a year in some species (Eason et al. 2002). Both classes of compounds have delayed onset of action, and death from AR consumption can occur up to 10 days after ingestion (Cox and Smith 1992). Individual rodents may continue to accumulate the compounds over a period of days, increasing their attractiveness to predators as they become weakened by the toxicant, and are easier to capture (Cox and Smith 1992; Berny et al. 1997; Berny 2007). For predators that consume prey targeted with ARs, both acute and chronic secondary exposure to the toxicants can occur (Erickson and Urban 2004; Riley et al. 2007; Elmeros et al. 2011; Gabriel et al. 2012).

Exposure of nontarget wildlife to ARs has been documented for numerous predatory mammal and bird species (McDonald et al. 1998; Stone et al. 1999; Riley et al. 2003, 2007; McMillin et al. 2008; Walker et al. 2008; Elmeros et al. 2011). Detection rates for ARs can exceed 80–90 % in wildlife and are directly responsible for mortalities in many species including coyotes (*Canis latrans*, Riley et al. 2003), San Joaquin kit foxes (*Vulpes macrotis mutica*, McMillin et al. 2008), California fishers (*Martes pennanti*, Gabriel et al. 2012), mountain lions (*Puma concolor*; Riley et al. 2007), red kites (*Milvus milvus*, Berny and Gaillet 2008), barn owls (*Tyto alba*), barred owls (*Strix varia*) and great horned owls (*Bubo virginianus*) (Stone et al. 2003; Albert et al. 2009). Factors that lead to secondary exposure of nontarget species are complex (Eason et al. 2002; Shore et al. 2006) because exposure is related to the persistence of compounds, levels of usage, how and where the compounds are applied, and trophic ecology (Eason et al. 2002; Shore 2003; Erickson and Urban 2004; Shore et al. 2006). The accurate assessment of AR exposure in wildlife is difficult because studies often rely on post-mortem sampling of liver tissue from carcasses found opportunistically. This may lead to a bias towards detection of those compounds with the longest persistence in hepatic tissue and at lethal dosages, and an underestimation of the number of animals that are exposed to ARs.

In southern California, more than a decade of research by U.S. National Park Service biologists in and around Santa Monica Mountains National Recreation Area (SMMNRA), a national park bordering Los Angeles, has documented widespread AR exposure in multiple carnivore species. AR exposure was the second leading cause of mortality during a 9-year coyote study in which 83 % of individuals tested were exposed (Riley et al. 2003; Gehrt and Riley 2010). Approximately 90 % of mountain lions and bobcats (*Lynx rufus*) in the study area were also exposed (Riley et al. 2007; Beier et al. 2010). Using telemetry data on bobcats and mountain lions, AR toxicant load, or the concentration of AR residues detected, was positively associated with use of developed areas (Riley et al. 2007, 2010; Beier et al. 2010) suggesting that developed areas are a major source of AR contamination.

Although high rates of exposure were documented for bobcats in SMMNRA, death as a result of AR exposure was reported only once (Riley et al. 2010). However, secondary AR exposure at  $\geq 0.05$  ppm was significantly associated with death due to severe notoedric mange (*Notoedres cati*), an ectoparasitic disease (Riley et al. 2007). Further, a precipitous population decline and genetic bottleneck in bobcats occurred as a result of the mange outbreak from 2002 to 2006 (Riley et al. 2007; Serieys et al. 2014). Notoedric mange was previously reported only in isolated cases in free-ranging felids (Pence et al. 1982; Maehr et al. 1995; Pence et al. 1995), however, the disease may be increasing in bobcats across California (Serieys et al. 2013; Stephenson et al. 2013). To date, all bobcats with mange that have been tested were positive for ARs ( $N = 19$ , Riley et al. 2007;  $N = 11$ , Serieys et al. 2013). These correlative findings suggest that chronic, sublethal exposure to ARs may influence immune function in bobcats, increasing their susceptibility to mange infestation and decreasing anti-mite immune response (Riley et al. 2007; Serieys et al. 2013).

We investigated risk factors for exposure to ARs in bobcats from two areas in southern California: in the SMMNRA area northwest of Los Angeles, and in Orange County to the southeast. We used blood and liver to detect exposure to ARs across varied landscapes that included fragmented urban and protected natural areas. Liver samples were collected postmortem to evaluate exposure history of individuals. Blood samples were collected primarily during animal capture to evaluate recent exposure. We used multiple measures of AR exposure including prevalence of exposure to any AR, prevalence of exposure to specific ARs, the number of different compounds detected, and compound residue concentrations (toxicant load). We evaluated AR exposure from 1997 to 2012 as part of the long-term study at SMMNRA, and from 2006 to 2010 in Orange County. We assessed risk factors for exposure

including sex, age, season, and landscape characteristics, specifically proximity to residential, commercial, and other developed areas. Using a much larger number of samples collected over a longer period of time and from a greater geographic area than a previous study (Riley et al. 2007), we examined the potential association between ARs and notoedric mange by evaluating the association between mange and a range of residue concentrations and the number of compounds detected.

## Methods

### Study area and sample collection

Sampling primarily occurred in two areas (Fig. 1). In Los Angeles and Ventura Counties, samples were collected by NPS and University of California, Los Angeles (UCLA) biologists from 1997 to 2012 during an ongoing NPS bobcat ecology study in SMMNRA (Riley et al. 2003, 2006, 2007, 2010; Serieys et al. 2013; Serieys et al. 2014). The eastern boundary of SMMNRA is less than 10 km from downtown Los Angeles and the park encompasses both large regions of continuous protected habitat with minimal urban development, including state and national park lands, and highly fragmented areas with intense urban development. In the Orange County study area (OCSA), bobcats were sampled from 2006 to 2010 by the U.S. Geological Survey (USGS) across a network of public nature reserves within landscapes experiencing rapid urbanization and near the more protected Santa Ana Mountains (Lyren et al. 2006, 2008; Poessel et al. 2014). The Santa Ana Mountains straddle Riverside, Orange, and San Diego Counties but most of the samples (93 %) were collected in Orange County. Anthropogenic development across both study areas includes residential, commercial, and agricultural development, as well as many “altered open” areas such as golf courses and landscaped parks (Table 1). Samples were also opportunistically collected in two additional areas north and south of our study areas in San Barbara ( $N = 3$ ) and San Diego Counties ( $N = 8$ ) when animals died in wildlife rehabilitation facilities or were reported dead by residents.

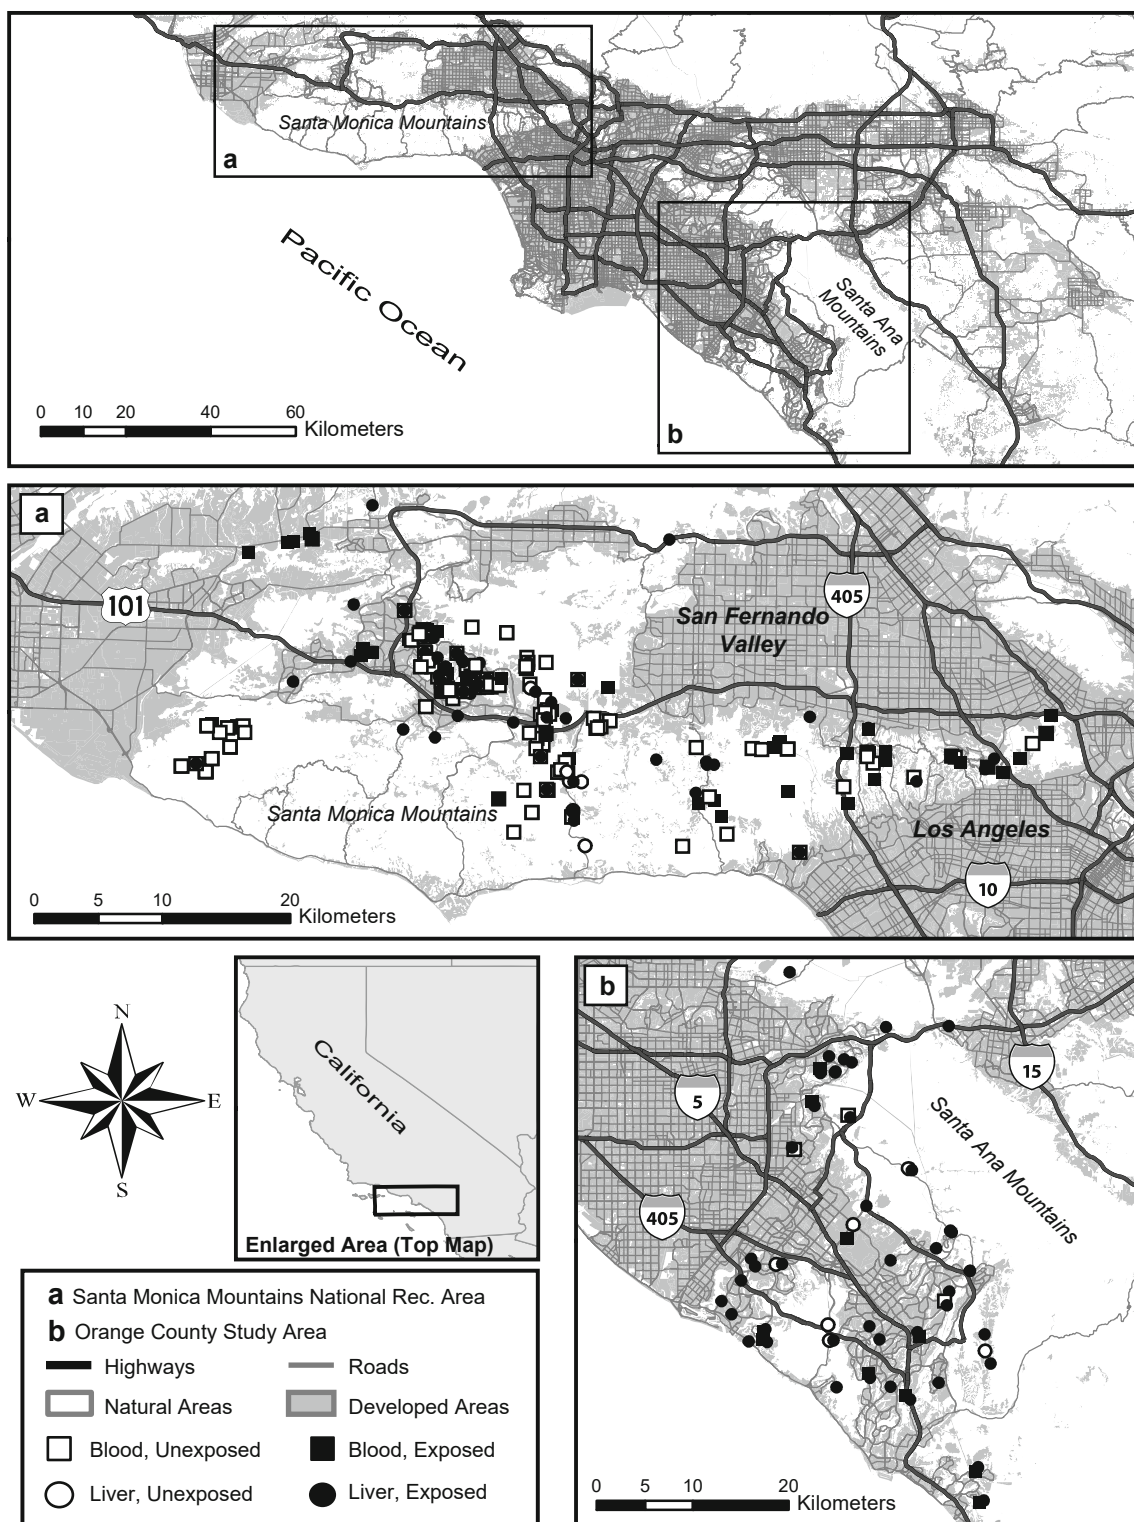

Bobcats were captured and handled as previously described (Riley et al. 2003, 2006, 2007; Serieys et al. 2013) with approval by the Office of Animal Research Oversight of UCLA (Protocol ARC#2007-167-12) and by the Colorado State University Animal Care and Use Committee (Protocol #11-2453A). Scientific collecting permits were authorized by the California Department of Fish and Wildlife (SC-9791). From 2000 to 2009, the majority of trapping efforts occurred from mid-October to mid-February, and thus collected during the non-breeding, wet

season (November 1–April 30). Individuals were chemically immobilized with a mixture of ketamine HCl (10 mg/kg) and xylazine HCl (1 mg/kg) or ketamine HCl (5 mg/kg) and medetomidine HCl (0.1 mg/kg). We recorded age class, sex, weight, and morphological measurements (i.e., chest circumference, body length, tail length, ear length, head circumference, etc.). Individuals were classified as juveniles (<2 years) or adults (>2 years) based on body size, weight, tooth wear and eruption, and reproductive status (Riley et al. 2003, 2006). A subset of individuals were also radio-collared as part of the NPS and USGS studies (Riley et al. 2003, 2006, 2007; Poessel et al. 2014). To obtain serum samples, blood was centrifuged within 24 h of collection and serum was collected. All samples, including liver (see below), were transported from the site of collection to storage facilities on ice packs.

In both study areas, we obtained liver samples during necropsies from opportunistically found carcasses (e.g. road-kill) or from animals that died in rehabilitation centers (Table 2). In SMMNRA, when possible liver samples were also collected from radio-collared animals that died. For 20 individuals, blood and liver were simultaneously obtained postmortem (Table 2). The cause of mortality, collection date, sex, age class, and location found were recorded. All animals were visually inspected for clinical signs of notoedric mange that included severe dermatitis, alopecia, and lichenification of the skin. If clinical mange was observed, skin scrapings in the affected areas were performed to identify mite species as previously described (Riley et al. 2007; Serieys et al. 2013; Stephenson et al. 2013). To measure specific age, an upper canine tooth was extracted during necropsy to determine age in years based on cementum annuli (Matson’s Laboratory LLC, Missoula, MT) (Crowe 1972). Capture and mortality locations were recorded using GPS devices. Blood, serum and liver were stored at  $-20$  or  $-80$  °C until tested. Anticoagulant rodenticide compounds are stable (Waddell et al. 2013) and so the length of time under refrigeration should not have affected the results.

### Anticoagulant assessment

We assessed the presence and amount of warfarin, coumachlor, bromadiolone, brodifacoum, diphacinone, chlorophacinone, and difethialone in 2 g of liver tissue, 1 g of serum, or 2 g of whole blood by high performance liquid chromatography (HPLC) and liquid chromatography-mass spectrometry (LC–MS/MS) (Riley et al. 2007; Ruder et al. 2011; Waddell et al. 2013). Samples were first screened for the presence of each AR by LC–MS/MS. Positive AR samples were then quantitated by HPLC using either UV diode array detection (diphacinone, chlorophacinone and difethialone) or fluorescence detection (warfarin, coumachlor, bromadiolone, and

**Fig. 1** Map of the study areas. **a** Santa Monica Mountains National Recreation Area (SMMNRA) and **b** Orange County Study Area (OCSA). Sampling locations and exposure results are shown. Blood

sampling locations are represented with *squares* while liver sampling locations are represented with *circles*

brodifacoum). Limits of quantitation for these anticoagulants in liver tissue were 0.01 ppm for brodifacoum, 0.05 ppm for bromadiolone, warfarin, and coumachlor, and 0.25 ppm for

chlorophacinone, diphacinone, and difethialone. Thirty-nine of 172 liver results were from Riley et al. (2007) (Table 2) and here we performed anticoagulant assessments using the same

**Table 1** Classification of predictor land use variables used for analysis of dependent AR exposure measures

Broad classification	Specific land use tested in models	Percent of study areas			Percent of buffer zones		
		SMMNRA	OCSA	Mean	SMMNRA	OCSA	Mean
Agriculture	Crops, pastures orchards and vineyards	3.39	3.00	3.20	2.18	1.62	2.07

The percentage of each land use within a single polygon drawn around all bobcat buffer zones for each study area and the mean across both study areas is shown. Additionally, the mean value of each land use type across bobcat buffer zones for each study area and across all composite bobcat buffer zones is shown. The sum of land-use variables for each study area do not equal 100 % because some land-use types (e.g. open water, roads, railroads), comprising a mean of 0.55 % of the study areas, were not included in analyses

approach. In blood, limits of quantitation were 1 ppb for each compound with method detection limits ranging from 0.28 to 0.45 ppb. ARs that were determined to be positive by LC–MS/MS, but were below the limit of quantitation by HPLC, were defined as above the limit of detection (LOD) or “above LOD.”

Finally, to make comparisons between AR exposure in bobcats, and the amount of toxicants applied where bobcats were sampled, we obtained data on reported use in Los Angeles, Orange, and Ventura Counties (measured in pounds) as posted in the California Department of Pesticide Regulation online database from 1997 to 2012 (<http://www.cdpr.ca.gov/docs/pur/purmain.htm>) for the four most commonly detected compounds. Records for Orange County were accessed only for the years for which we had samples from the study area (2006–2010). We averaged the pounds applied across the counties for each sample year (see Fig. 2c, Supplemental Fig. S1c).

#### Land use analysis

To evaluate the land use characteristics of surrounding landscape for all sampled bobcats, we created circular buffer zones with each capture or mortality location as the center. Each buffer zone was equal to the area of an

average home range (95 % minimum convex polygon) for animals that have been radio-tracked in each study area (males: 5.2 km<sup>2</sup> SMMNRA; 5.6 km<sup>2</sup> OCSA; females: 2.3 km<sup>2</sup>, SMMNRA; 3.2 km<sup>2</sup> OCSA) (Riley et al. 2010). Animals that were sampled in Santa Barbara and San Diego Counties were excluded from land use analysis because exact sampling locations were unavailable. We used the 2005 land use dataset provided by Southern California Association of Governments (SCAG, <http://gisdata.scag.ca.gov/Pages/Home.aspx>) with bobcat buffer zones in ArcGIS 10.1 (ESRI, Redlands, CA) to quantify land use types for each bobcat. Seventy-six land use types were included in bobcat buffer zones. These land use types were grouped into five general classes including: (1) agriculture; (2) commercial and industrial; (3) residential; (4) altered open areas such as landscaped parks, golf courses, and cemeteries; and (5) undeveloped natural areas (Table 1). We merged the 76 SCAG land use variables into 13 groups that were broadly characterized into five classes of land uses based on similarity and relevance to this study (Table 1, Supplemental Tables S1–S3). Using the five general classes of land use and the 13 specific variables, we used a total of 17 spatial predictor variables for analyses (Table 1). We quantified percent cover of each predictor variable in each buffer zone. To estimate percentage of

**Table 2** Sample size and information

Sample type	Sample information	Total number
All	Total number of blood and liver samples	378 (individuals, $N = 304$ )

<sup>b</sup> Anticoagulant data from three individuals were not used in analyses (fetuses,  $N = 2$ ; neonate,  $N = 1$ )

each land use type within study areas, we created a single minimum convex polygon surrounding all buffer zones for each study area, and then calculated the percentage of each of the 17 land use variables within each study area's polygon (Table 1).

#### Data analysis

Descriptive statistics are presented as the mean, standard deviation, median, and range because all data were not normally distributed. Anticoagulant prevalence and 95 % confidence intervals for males, females, adults, and juveniles for wet (November 1–April 30) and dry (May 1–October 31) seasons were calculated separately for blood and liver samples. For prevalence calculations based on blood of recaptured animals, only the data from the most recent capture event was used. For spatial analyses using buffer zone data, we used only recaptures and post-mortem sampling that occurred a minimum of 4 months apart because ARs in blood are expected to decay by this time from an initial exposure (Eason et al. 2002; Erickson and Urban 2004; Vandenbroucke et al. 2008). Consequently, these successive samples of individuals are effectively independent measures of an exposure event, avoiding inflated values caused by multiple recaptures. For a subset of animals ( $N = 64$ ), we had both liver and blood results

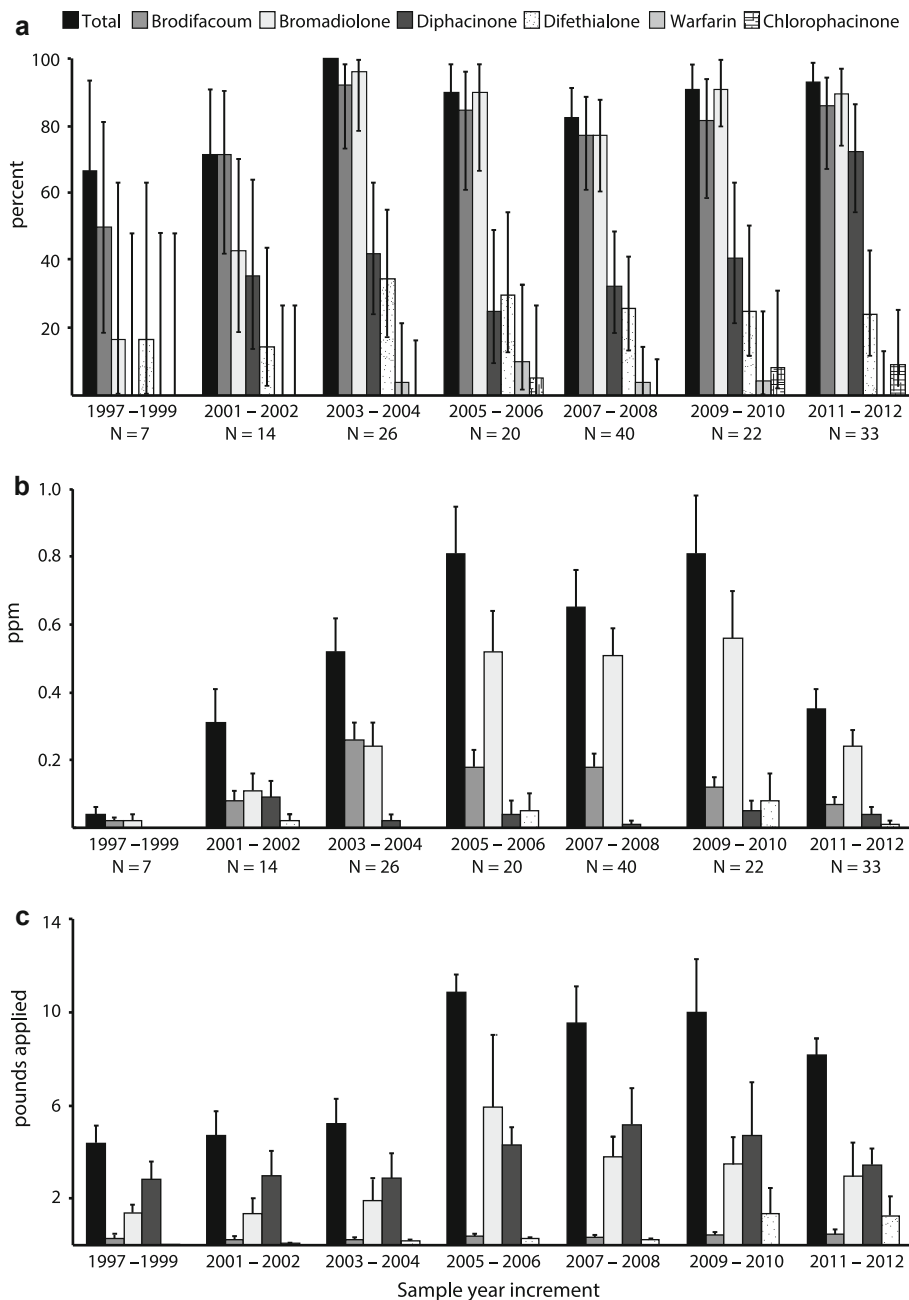

(Table 2). For this group, we combined the AR residue data for both tissue types to calculate the anticoagulant exposure overall, and 95 % confidence intervals as well as range, mean and median number of compounds detected per individual.

We used 11 different measures of AR exposure for liver samples, and one measure for blood samples (Supplemental Table S4). For liver samples, we evaluated total exposure as presence or absence of any compound as well as individual exposure to each of the four most commonly observed individual compounds (brodifacoum, bromadiolone, diphacinone, and difethialone). We also measured the amount of AR exposure as the total residue concentration in parts per million (ppm) of all compounds detected ("total residues"), as well as separately for each of the four most commonly detected individual compounds. Finally, we used the total number of compounds detected (0–7). Using blood results, we evaluated total exposure only because the majority of detections for ARs in blood were diphacinone, and the total concentration of ARs was quantifiable for less than 10 % of samples tested (24 % of positive samples).

We evaluated risk factors for AR exposure using three types of generalized linear models (GLM). For presence/absence, we used a logistic regression to evaluate risk factors for total exposure measured using blood and liver,

**Fig. 2** AR data across 2–3 year time increments. **a** Exposure prevalence overall and by compound per 2–3 year increment. *Error bars* represent 95 % confidence intervals. **b** Concentrations detected per 2–3 year increments. *Error bars* represent standard errors. Warfarin, chlorophacinone, and coumachlor were rarely detected, and if so, were detected at above LOD levels (with the exception of chlorophacinone from 2006 to 2006 when 0.03 ppm was detected). Although lower concentrations of compounds were detected in 2011–2012, the difference, in comparisons with sample years from 2003 to 2010 was not significant. **c** Reported pounds of each compound applied per year increment in the three primary study area counties. *Error bars* represent standard errors. Los Angeles and Ventura Counties are represented across all years and Orange County data was included from 2006 to 2010

and separately, for exposure to brodifacoum, bromadiolone, diphacinone, and difethialone based on liver samples. We used a log-linear GLM to evaluate risk factors for the amount of exposure, both overall using total residues, and using residue concentrations for each of the four most commonly detected compounds in liver tissue. Two of 169 individuals from OCSA had outlier residue concentrations of greater than two standard deviations above the mean, one for difethialone and the other individual for bromadiolone. These individuals were excluded from concentration analyses for these specific compounds and for total residue analyses because preliminary analyses indicated that they

dominated model results. We used a Poisson regression to evaluate risk factors for exposure to multiple compounds (0–7) for liver exposure data.

For each model type, we first performed univariate analyses to identify potential predictors, or risk factors, of exposure (Supplemental Table S4). We tested land use categories within each individual buffer zone, study area (SMMNRA, OCSA), sex (male, female), age class (adults  $\geq 2$ ; juveniles  $< 2$  years), age (in years), and season (wet, dry). For each age dataset, we performed separate analyses to avoid potential confounding effects. To evaluate the change in detection rates over time, animals were grouped

into 2–3 year increments depending on the number of animals sampled yearly such that in all time increments,  $N \geq 7$  ( $N = 23$ ; Fig. 2). Only four liver samples were collected during 1997–1999, so this time increment was excluded from temporal analyses.

Next, we performed multivariate GLMs to examine the influence of particular predictor variables on AR exposure while controlling for all other significant variables. Variables in the multivariate GLMs were selected by backward stepwise selection using Akaike's Information Criterion (AIC) for model selection. We report the strongest models with  $\Delta\text{AIC}$  values  $\leq 2$  (Burnham and Anderson 2002). We report  $\beta$ , the standard error of  $\beta$ , and 95 % confidence intervals for  $\beta$ . A positive  $\beta$  indicates a positive association between the predictor and the exposure outcome, while a negative  $\beta$  indicates a negative association.

We also used logistic regression to examine anticoagulant exposure measures as predictors for notoedric mange. Our predictor variables for these analyses included the 11 anticoagulant exposure measures and the 17 land use predictors. Analyses were performed as above with univariate models followed by multivariate analyses. We also examined the association between notoedric mange and anticoagulant exposure using Fisher's exact tests to evaluate the number of compounds detected ( $\geq 2$ ,  $\geq 3$ , and  $\geq 4$ ) and the threshold value of total residues  $\geq 0.05$  ppm suggested by Riley et al. (2007). To further examine the potential relationship between mange and different levels of AR residues, we plotted the proportion of animals exposed to a range of anticoagulant residue concentrations, for animals with and without mange (Fig. 3). For animals with mange, we observed an increase in the proportion exposed to a residue range of 0.25–0.49 ppm. Consequently, we also used a Fisher's exact test to evaluate the association between mange and total residues  $\geq 0.25$  ppm. Next, we used a Kolmogorov–Smirnov test to evaluate the difference in the distribution of residue concentrations in bobcats that died with mange compared with those that died without mange. Finally, we used a Wilcoxon-rank sum test to evaluate the difference in median residue concentrations between the two groups.

Because commonly used methods of correction for multiple tests have been described as overly conservative with a higher probability of generating Type II errors in comparison with Type I errors (Moran 2003), we did not correct for multiple tests. Thus, all statistical tests were considered significant when  $\alpha \leq 0.05$ , but some of these may represent false positives. All statistical analyses were performed in the program R (R Development Core Team 2011).

When data were unavailable for sex (liver,  $N = 18$ ; blood,  $N = 2$ ), age class (liver,  $N = 25$ ; blood,  $N = 3$ ), year sampled (liver,  $N = 7$ ), season sampled (liver,

**Fig. 3** The proportion of bobcats that died with and without severe mange when exposed to a range of total anticoagulant residues (ppm). The proportion of mange cases, compared with bobcats without mange, increases in the range of 0.25–0.49 ppm, and thus we investigated the relationship between mange and total residues  $\geq 0.25$  ppm. The limits of detection vary by compound. For brodifacoum and bromadiolone, the detection limits were 0.05 ppm, whereas the detection limits of chlorphacinone, diphacinone, and difethialone are 0.25 ppm

$N = 7$ ), or mange status ( $N = 13$ ), AR results for those individuals were excluded from prevalence estimates and statistical analyses requiring these data. We also excluded exposure results from statistical analyses for livers from two fetuses (one from each study area), and a liver from a 1 day-old kitten because their exposure was likely not independent from that of their mother.

## Results

### Prevalence of exposure

Eighty-eight percent of liver samples had 1–5 AR compounds (Table 3; mean = 2.32, median = 2.00). The range of total residues detected in liver was 0.00–5.81 ppm (mean = 0.59, SD = 0.80, median = 0.40). The compounds most frequently detected were second-generation bromadiolone, brodifacoum, and difethialone, and first-generation diphacinone. Mean values for the four most commonly detected compounds were: brodifacoum, 0.14 ppm (SD = 0.20); bromadiolone, 0.38 ppm (SD = 0.55); difethialone, 0.04 ppm (SD = 0.31); diphacinone, 0.03 ppm (SD = 0.12). Brodifacoum and bromadiolone were the two most frequently detected ARs in liver samples (Fig. 4) and were detected approximately twice as frequently as difethialone or diphacinone. Warfarin and

**Table 3** Proportion (Prop.) and 95 % confidence intervals of anticoagulant exposure across the study areas

Variable	Group	Liver			Blood		
		N	Prop.	95 % CI	N	Prop.	95 % CI
Sex	All	169	0.88	0.82–0.92	195	0.39	0.32–0.46
	Female	77	0.88	0.78–0.94	86	0.38	0.28–0.50
	Male	74	0.89	0.79–0.95	107	0.40	0.31–0.50
Age class	Adult	107	0.91	0.83–0.95	127	0.40	0.32–0.49
	Juvenile	37	0.86	0.70–0.95	65	0.37	0.26–0.50
Season	Wet	96	0.90	0.81–0.95	139	0.32	0.25–0.41
	Dry	66	0.89	0.81–0.94	56	0.55	0.42–0.68

Prevalence is partitioned by sample type, sex, age class, and season. When information on sex, age class, or season collected was not available, those data were not included in the proportion estimates, and so data partitioned by sex, age class, and season may not sum to the total number of blood or liver samples

**Fig. 4** Detection prevalence of each anticoagulant compound in the liver, blood, and for a subset of individuals, paired blood and liver tissue results are provided

chlorophacinone were rarely detected and coumachlor was not detected in liver samples. Seventy-seven percent of all bobcats and 87 % of those exposed showed the presence of  $\geq 2$  compounds in the liver.

In contrast, 39 % of blood samples tested positive for ARs (Table 3), most frequently to one compound (76 % of positives), but ranging from 0 to 4 compounds (mean = 0.53 compounds, median = 0.00). The total residues detected in blood ranged from 0 to 0.16 ppm (mean = 0.002, SD = 0.01, median = 0.00). Diphacinone, the most commonly detected compound in blood, was detected more than three times as frequently as brodifacoum or bromadiolone (Fig. 4). For animals with both blood and liver samples ( $N = 64$ ), 92 % were exposed, most frequently to three or more compounds (median = 3.00, mean = 2.61, range 1–5).

Percent exposure was similar across sexes and age classes using liver or blood samples (Table 3). Sixty-six individuals were aged by cementum annuli (age range: 0–12 years). Fourteen individuals had age class data estimated during capture, and cementum annuli data collected postmortem. We used these paired data to test the accuracy of our age class estimations during captures and found we

assigned correct age classes to 12 of 14 individuals. We did not detect a significant association between age and AR exposure measures.

Exposure did not vary by season when tested using liver samples (Table 3). In contrast, based on blood results, animals were significantly more likely to be exposed during the dry season [Odds ratio (OR) = 2.58] compared with the wet season (Tables 3, 4). Overall we detected 72 % more exposure in blood during the dry season than during the wet season with 32 % exposure detected during the wet season, and 55 % exposure detected during the dry season.

We examined exposure prevalence over time in liver samples and found exposure to exceed 67 % for all years, indicating high exposure prevalence throughout the study (Fig. 2a). Exposure rates varied for each of six compounds across sampling increments (Fig. 2a). Overall exposure was highest during 2003–2004 and 2011–2012. There was significantly less exposure overall and to bromadiolone in 2001–2002 compared with other years (Table 5; Fig. 2a). Diphacinone exposure was significantly greater in 2003–2004 and 2011–2012 compared with other time increments (Table 5; Fig. 2a). However, both total and

**Table 4** Results of Fisher's exact tests for parameters that were significant during univariate GLM analyses

Sample type	Parameter	Comparison	Odds ratio	95 % confidence interval	<i>P</i>

Only results from statistically significant univariate analyses are shown

bromadiolone residue concentrations detected were greatest between 2005 and 2010, although the variation in residue concentrations across time was not significant (Fig. 2b). These years included samples from OCSA, where significantly greater bromadiolone residues were detected (Table 6; Fig. 5). Although the residue concentrations we detected in 2011–2012 were lower for all compounds the differences in overall exposure and residue

concentrations were not significant. The apparent decrease in residue concentrations is the result of having OCSA samples, where bromadiolone residues were significantly higher for the years 2006–2010 (see below and Supplemental Fig. S1b). Further, the decrease in total and bromadiolone residues mirrors the County reports we compiled of the amount of rodenticide (in pounds) applied (Fig. 2c, Supplemental Fig. S1c). In blood samples, we did

Only results from statistically significant univariate analyses are shown

not detect a trend of exposure prevalence across sampling years.

Two fetal bobcats were exposed to anticoagulant compounds. One animal was exposed to two compounds (brodifacoum and diphacinone) and the other was exposed to five compounds (brodifacoum, bromadiolone, diphacinone, difethialone, and chlorophacinone). For both fetuses, all compounds detected were above LOD but not quantifiable. The mother of the fetus with five compounds was also tested for exposure and had quantifiable levels of brodifacoum (0.32 ppm), bromadiolone (0.58 ppm) and was positive for difethialone, diphacinone, and chlorophacinone.

#### Spatial correlates of exposure

Exposure prevalence measured using liver tissue did not significantly differ between SMMNRA (89, 95 % CI 81–94;  $N = 104$ ) and OCSA (84, 95 % CI 71–92;  $N = 55$ ) (Fig. 5). The mean total residues were significantly greater in OCSA (Fig. 5; Table 6) even with two outliers removed (OCSA, 0.84 ppm; SMMNRA, 0.40 ppm). Brodifacoum and bromadiolone were each detected at significantly greater concentrations in liver tissue collected in OCSA (0.21 and 0.63 ppm) compared with SMMNRA (0.12 and 0.22 ppm) (Table 6).

**Fig. 5** *Left* Percent total exposure and exposure to individual compounds in SMMNRA (S) and OCSA (O). Bars represent 95 % confidence intervals. *Right* Total residue concentration and residue concentrations for each compound. Bars represent standard errors

Landscape variables were important predictors of exposure in both blood and liver samples (Tables 5, 6). Percent natural area in each individual buffer zone was negatively associated with multiple measures of exposure in blood and liver (Table 5). Golf courses and total altered open area were positively associated with exposure in blood (Table 5) and with total residues and the concentrations of bromadiolone and brodifacoum in liver (Table 6).

In terms of the non-residential urban and agricultural areas, all three more specific agricultural categories (Table 1, Supplementary Table S2) and total agricultural area were positively associated with exposure in blood (Table 5). However, brodifacoum exposure was negatively associated with the category comprised of open, active agriculture (crops, pastures, orchards, and vineyards; Table 5), and given that second-generation ARs are restricted for use indoors and within 100 m from human structures, this negative association is not surprising. Commercial and industrial areas were positively associated with bromadiolone and diphacinone concentrations in liver samples (Table 6). Water storage and transfer facilities and total commercial and industrial areas were positively associated with exposure in blood samples (Table 5). Office and retail area was positively associated with brodifacoum concentration in liver samples (Table 6).

Residential areas, by far the most common type of development in these study areas (22 %, SMMNRA and 23 %, OCSA), were frequently positively associated with AR values observed in both blood and liver samples (Tables 5, 6). In particular, single-family high-density residential area was among the most frequent land use type to have positive associations with anticoagulant exposure, and was significant for 8 of 11 anticoagulant exposure models tested

(Tables 5, 6). In terms of broader measures, single-family high-density residential area was positively associated with overall exposure in blood and liver and the total number of compounds and total residues in liver samples. For specific compounds, single-family high-density residential was also positively associated with brodifacoum and diphacinone exposure and brodifacoum and bromadiolone concentrations in liver. Total residential area was also frequently important in univariate models. In terms of exposure, total residential area was associated with exposure in blood and liver and exposure to brodifacoum and diphacinone in liver. Total number of compounds, total residues, and liver concentrations of brodifacoum and bromadiolone were also positively associated with total residential area.

Multivariate models were significant for five measures of ARs in bobcats (Table 7). In terms of exposure, year and total residential area were important for diphacinone, and for total exposure, percent natural area (the reciprocal of percent development) was significant, along with season. For the amount of ARs detected in liver tissue, the best-fit model included golf courses, single-family high-density residential, and OCSA as the most important risk factors. For brodifacoum concentration detected in liver tissue, office and retail, single-family high-density residential, and total altered open space were the three most important predictors of residue load. Finally, mixed commercial and industrial, golf courses, single-family high-density residential, and OCSA were the most important predictors of total bromadiolone concentration in liver tissue.

#### Anticoagulants and notoedric mange

The median total residues for bobcats with mange was 0.52 ppm (mean = 0.65, SE = 0.06), while for bobcats that died without mange, the median total residues was 0.24 ppm (mean = 0.53, SE = 0.09), a significant difference ( $W = 2141.00$ ,  $P = 0.005$ ). The distribution of residue concentrations within the two groups also differed significantly ( $D = 0.28$ ,  $P = 0.004$ ). The median number of compounds observed was 3 (mean = 3.00) in bobcats with mange and 2 (mean = 2.00) for bobcats without mange. Sixty-four percent of bobcats without mange tested positive for  $\geq 2$  compounds, while 93 % of bobcats with mange tested positive for  $\geq 2$  compounds.

Severe mange was positively associated with anticoagulant exposure, brodifacoum exposure, difethialone exposure, brodifacoum concentration, and the total number of compounds detected. In terms of land use, mange was positively associated with total residential area, but this was the only significant land use predictor (Table 6). The mean total residential area in mange bobcat buffer zones was 32.2 % (SD = 18.61, median = 29.39) compared with a mean of 23.3 % for bobcats without mange

**Table 7** Results of the best-supported statistically significant multivariate model analyses for anticoagulant exposure and mange

Outcome	Best-supported model	Predictor variables	$\beta$	$\beta$ SE	$\beta$ 95 % CI	<i>P</i>
Total exposure (blood)	Season + natural	Dry season	0.71	0.35	0.02–1.40	0.043
		Natural	−3.29	0.68	−4.62 to −1.95	<0.001
Diphacinone exposure	Total residential + year	Total residential	2.57	1.12	0.37–4.77	0.022
		2001–2002	−1.62	0.82	−3.23 to −0.02	0.048
		2003–2004	−1.42	0.69	−2.77 to −0.62	0.040
		2005–2006	−2.11	0.80	−3.68 to −0.55	0.008

		Golf courses	5.69	0.93	3.87–7.51	<0.001
		Single-family high-density residential	1.24	0.42	0.42–2.06	0.004
		OCSA	0.90	0.25	0.42–1.38	<0.001
Mange	Difethialone exposure + brodifacoum exposure	Brodifacoum exposure	1.54	0.53	0.49–2.58	0.004
		Difethialone exposure	0.93	0.40	0.14–1.72	0.021

(SD = 19.60, median = 19.05). In the multivariate model, after controlling for multiple AR parameters and land use, brodifacoum and difethialone exposure remained significant predictors of severe mange while land use was not (Table 6). We found a strongly significant association between mange and total residues  $\geq 0.05$  ppm and total residues  $\geq 0.25$  ppm (Fig. 3; Table 4). Bobcats that were exposed to  $\geq 0.05$  ppm were 4.0 times (95 % CI 1.67–10.48) more likely to die with severe notoedric mange than without, while those exposed to  $\geq 0.25$  ppm were 3.2 times (95 % CI 1.51–6.84) more likely to die with severe mange. Additionally, we observed a strong association between exposure to  $\geq 2$  compounds and severe mange (Table 4). Specifically, bobcats were 7.3 times (95 % CI 2.55–25.70) more likely to die with severe mange than without if they were exposed to 2 or more AR compounds. There were also significant associations between mange and exposure to  $\geq 3$  and  $\geq 4$  compounds (Table 4).

#### Anticoagulants and mortality

Anticoagulant exposure detected in blood was significantly more frequent in samples collected postmortem compared

with samples collected antemortem (Tables 4, 6). In 75 % of blood samples collected postmortem ( $N = 20$ ), we detected at least one AR compound. When blood samples collected at the time of mortality were excluded from blood AR prevalence estimates, we detected a 34 % exposure prevalence in blood samples collected at the time of animal capture ( $N = 175$ ) compared with 39 % overall ( $N = 195$ ). For blood samples collected at the time of mortality, ARs were detected in 77 % of bobcats that died of notoedric mange ( $N = 13$ ), 100 % of bobcats that died of vehicle collision ( $N = 5$ ), and one bobcat that died of starvation after a wildfire. Three bobcats that died of mange, one from a control action, and another that died of unknown cause did not have detectable ARs in their blood.

#### Discussion

We documented widespread exposure of bobcats to first- and second-generation ARs in two southern California areas. Bobcats are obligate carnivores that consume a wide range of small mammals (Anderson and Lovallo 2003) including mice, rats, and gophers (Fedriani et al. 2000;

Riley et al. 2010) that are frequent targets of pest control activities within SMMNRA (Morzillo and Mertig 2011a, b; Morzillo and Schwartz 2011; Bartos et al. 2012) and elsewhere (Morzillo and Mertig 2011b). Given that bobcats are obligate carnivores, it is very unlikely that they consume rodent baits directly. Thus, bobcat exposure to ARs is predominantly, if not entirely, secondary through prey consumption. Exposure rates and compounds detected varied considerably by sample type, but in individuals having blood and liver data (and therefore most comprehensively sampled), we detected an AR exposure rate of 92 % across the study areas, with animals most frequently exposed to three or more compounds. These findings are among the highest reported prevalence rates for AR exposure in a nontarget predatory species (e.g. Shore 2003; Fournier-Chambrillon et al. 2004; Riley et al. 2007; Walker et al. 2008; Gehrt and Riley 2010; Elmeros et al. 2011; Gabriel et al. 2012; Sánchez-Barbudo et al. 2012). Additionally, the combined liver and blood results indicate that exposure prevalence and exposure to certain compounds, specifically diphacinone, may be underestimated with liver samples alone (Fig. 4). We detected exposure to multiple AR compounds in two fetal bobcats, the first such cases, to our knowledge, reported for any wildlife species in a natural population. These data, including individuals caught multiple times more than 4 months apart, indicate multiple exposure events and suggest the potential for chronic exposure to ARs that can begin during prenatal development.

There are no toxicokinetic studies (the movement of toxic substances within the body) of ARs in wildlife, however, hepatic half-lives for ARs are reported across multiple species to be longer than plasma half-lives, particularly for second-generation ARs (Kamil 1987; Robben et al. 1998; Petterino and Paolo 2001; Vandenbroucke et al. 2008). The toxicokinetics of secondary AR exposure is more complex because the movement of the residues in both the primary and secondary consumer must be considered (Erickson and Urban 2004). Thus, we are limited in our ability to interpret bobcat AR exposure results with respect to dose and time since exposure using either blood or liver sample data. However, because we most frequently detect diphacinone in blood despite its shorter plasma half-life than second-generation ARs (Erickson and Urban 2004), diphacinone may be the compound that bobcats encounter most frequently in SMMNRA.

#### Risk factors for exposure

Exposure detected using liver tissue was high throughout the course of the 16-year study, ranging from 67 to 100 % for each 2- to 3-year time period, indicating high prevalence AR exposure in bobcats since at least 1997. Our samples indicated an increase in overall exposure both in

prevalence and residue concentrations since 2002. We detected significant increases in total AR exposure, bromadiolone exposure, and total number of detected compounds. With the exception of diphacinone, overall exposure prevalence and exposure to individual compounds appears to have been relatively constant from 2003 to 2012. Total residues and bromadiolone residues were highest from 2005 to 2010, the time increments for which OCSA samples were available, which appears to reflect the degree of bromadiolone use in Orange County. Diphacinone exposure also increased in frequency from 1997 to 2012, reaching a high in 2011–2012. Despite this increase, the quantity applied in each county as reported to Department of Pesticide Regulation does not appear to have significantly changed over the course of the study (Fig. 2c, Supplemental Fig. S1c). Thus, increased diphacinone exposure may be the result of increased use of the compound in residential areas by homeowners and pest control companies that are not required to report amounts of ARs applied annually. In fact, single-family high-density and total residential area were important predictors of diphacinone exposure. Diphacinone is a first-generation compound and is considered to pose less risk to nontarget wildlife than the more toxic second-generation ARs (Erickson and Urban 2004), although first-generation ARs still pose a risk for toxic effects to wildlife, and secondary exposure can be a direct source of mortality for some species (Littrell 1988; Stone et al. 1999; Riley et al. 2003). Further, the degree to which there are additive or interactive effects between diphacinone and second generation ARs is unknown.

As measured in blood, we detected more than twice as much AR exposure during the dry season compared with the wet season. In southern California, the dry season coincides with peak rodent activity (Meserve 1976), and residents in the region are known to use ARs to target rat, mice, squirrel, and gopher populations (Morzillo and Schwartz 2011; Bartos et al. 2012). Although we detected no seasonal differences in exposure in liver samples, the long hepatic half-lives of second-generation ARs likely obscured our ability to detect seasonal differences. Additionally, because second-generation ARs may persist in small mammal species from 90 to 135 days after removal of poison baits, poisoned small mammals may remain a continuing source of exposure for predatory species long after the end of poisoning programs (Murphy et al. 1998; Sage et al. 2008).

Because an accumulated risk of exposure may occur with bobcat age, and female bobcats have smaller home ranges and are less likely to use urban areas compared with males (Riley et al. 2003, 2010), we expected to detect demographic differences in AR exposure prevalence and residue concentrations. However, neither age nor sex significantly influenced exposure in our study areas. Within

our study areas, the high prevalence of exposure may have diminished our ability to detect demographic differences. Further, the movement patterns and relatively high mobility of some rodent species may lead to AR exposure in even those individuals that avoid the use of urban areas (Riley et al. 2010). For example, wood mice (*Apodemus sylvaticus*) and house mice (*Mus domesticus*) were found exposed to multiple AR compounds in Northern Ireland even though they were sampled in agricultural areas where ARs were not in use (Tosh et al. 2012). Thus, movement of poisoned prey between areas may occur where AR control efforts differ (Tosh et al. 2012). The risk of secondary AR exposure in predatory species, therefore, may not be limited to areas where ARs are in use. As a result, even individuals that use urban areas less, such as female bobcats and not yet dispersed young animals, may still be at high risk of AR exposure.

### Spatial predictors of exposure

The association between AR exposure and specific land use types likely reflects the degree of AR use in those areas. Previous studies have found an association between anthropogenic development and AR exposure in nontarget wildlife. For example, 95 % ( $N = 74$ ) of wildlife carcasses sampled across California from 1994 to 1999 with exposure to ARs were reported to have been collected in areas with significant urban development (Hosea 2000). However, there was no specific information about the type and intensity of urban development where individuals were sampled. Other previous studies in these areas found a positive association between total AR concentrations and the percent of bobcat (Riley et al. 2007) and mountain lion (Beier et al. 2010) radio-telemetry locations in areas affected by anthropogenic development, including areas classified as altered open and areas of more intense urban development (e.g. composite residential, commercial, and industrial areas).

Single-family high-density residential (5–10 housing units/ha) and golf courses were among the most frequent risk factors for various measures of AR exposure, despite comprising a relatively small percentage of the study areas (15.9 and 1.4 %), suggesting their importance as a risk factor for AR exposure and toxicant loads. In a recent study in two southern California areas (SMMNRA, Bakersfield), residents in single-family high-density structures were the most likely to use ARs to control pest populations compared with those in multifamily or single-family low-density structures (Morzillo and Schwartz 2011). Residential AR use was highest in areas in close proximity to open areas, whether natural or altered open, compared with residential areas farther away from open spaces. Golf courses and other altered open spaces in the study areas are

typically surrounded by, or very near to, single-family housing units. Of 21 golf courses in our study areas, 19 are bordered on at least 1 side by single-family high-density residential areas. Because residential AR use may be elevated in areas with altered open space in close proximity (Morzillo and Schwartz 2011), the association between AR exposure and altered open areas may also be the result of increased AR use in the single-family residential areas adjacent to golf courses. In OSCA, where bobcats had greater brodifacoum and bromadiolone residue loads, the mean percent of golf courses in bobcat buffer zones was nearly five times greater than in SMMNRA (0.6 vs. 2.7 %), potentially contributing to increased residue loads in OSCA. Although the residential and altered open types of urban development comprise a relatively small proportion (<25 %) of the study areas, Morzillo and Schwartz (2011) suggested a small degree of AR use in residential areas can lead to increased exposure risk for wildlife. Both bobcats (Riley et al. 2010) and coyotes (Gehrt and Riley 2010) have been observed to routinely utilize residential and altered open areas such as golf courses, increasing their probability of exposure to ARs if the compounds are regularly used there or nearby.

Although percent natural habitat was negatively associated with AR exposure and total residues, four bobcats whose buffer zones comprised 100 % natural habitat were found exposed to ARs. These data indicate that ARs may also affect wildlife living solely within protected park areas. Both of the individuals with bromadiolone residues were radio-collared during ongoing NPS research in SMMNRA, and their documented home ranges did not extend beyond protected park boundaries (Riley et al. NPS unpubl. data). Previous NPS research on coyote utilization of urban areas found that even animals with the lowest urban association died directly from AR toxicosis (Riley et al. 2003). A recent study on fishers (*Martes pennanti*), a remote forest carnivore in protected undeveloped parkland in northern California, found 79 % of fishers exposed to ARs and that four died directly of anticoagulant toxicosis (Gabriel et al. 2012). Gabriel et al. (2012) suggested illegal marijuana cultivation in remote areas could have been the source of ARs. Within SMMNRA, illegal marijuana cultivation also occurs, so this may also contribute to AR exposure for animals that reside entirely in protected park areas.

### Consequences of exposure

Although the prevalence of AR exposure was very high at 92 %, AR exposure alone does not appear to be a significant source of direct mortality for bobcats. At present, there are few cases of AR toxicosis in bobcats documented in the literature. None of the bobcats in OSCA died directly

of anticoagulant toxicity, and in a broader study of poisoning cases of wildlife in California, Hosea (2002) observed clinical signs consistent with anticoagulant toxicosis in two bobcats, one of which was an individual from SMMNRA (Riley et al. 2007). In Marin County, a radio-collared bobcat died of anticoagulant toxicity; chlorophacinone was detected in the liver tissue (Riley 1999). AR exposure was suspected to have caused gastrointestinal bleeding in bobcats that died of severe notoedric mange and were exposed to ARs in several counties in California, though other signs of anticoagulant toxicity were absent (Serieys et al. 2013). Domestic cats are reported to be more tolerant of AR exposure than dog or rodents (Petterino and Paolo 2001; Erickson and Urban 2004). Whether this tolerance is similar for wild felids is unknown, but if so, it may account for the few cases of toxicosis detected. However, felid tolerance to low-grade AR exposure may increase their vulnerability to sublethal toxicosis, or affect their ability to respond to external stimuli such as predators and vehicles (see below).

In SMMRNA, secondary anticoagulant rodenticide exposure was associated with a population decline (Riley et al. 2007) and a genetic bottleneck (Serieys et al. 2014) that occurred due to notoedric mange. Mange and vehicle collisions are the primary sources of mortality for bobcats in our two southern California study areas (Riley et al. 2010). Notoedric mange is now documented in eight counties in northern and southern California. Across all of these areas, animals that died of mange were found to be exposed to ARs whenever tests were conducted (Serieys et al. 2013; Clifford, pers.comm.). Interestingly, 65 % of severe bobcat mange cases observed in our study areas during this 16-year period occurred during the dry season, coincident with increased AR exposure detected in blood samples. Sixty-nine of 70 bobcats that died with severe mange (covering >70 % of their body) were exposed to ARs. We detected a strong association between exposure to  $\geq 2$  compounds and notoedric mange. Detection of multiple compounds in a single individual suggests multiple exposure events since rodenticide baits sold in California are each formulated with a single compound. Thus, we suggest that a single anticoagulant exposure event itself may not increase bobcat susceptibility to mange, but rather repeated exposure events may be an important predictor of potential sublethal effects such as increased susceptibility to mange.

Severe mange in free-ranging wildlife and domestic animals is often associated with decreased immune competence (Pence and Ueckermann 2002). Humans that are immunocompromised are also more likely to suffer severe, crusted forms of mange due to infestation with a related mite, *Sarcoptes scabiei* (Walton et al. 2004; Roberts et al. 2005). The mode by which anticoagulant rodenticide exposure could compromise bobcat immunity is unknown,

although recent studies in humans and laboratory animals have shown therapeutic doses of warfarin to have both immunostimulatory and suppressive effects when administered for  $\leq 30$  days (Kurohara et al. 2008; Belij et al. 2012; Popov et al. 2013). Laboratory experiments have shown that interactive effects between sublethal exposure to anticoagulants and other stressors can induce mortality. For laboratory subjects, sublethal anticoagulant doses produced 40–70 % mortality when combined with other stressors, such as frostbite (Jaques 1959). When stressed by shearing and captivity, sheep (*Ovis aries*) required lower doses of the first-generation AR pindone to die as a result of anticoagulant toxicosis (Robinson et al. 2005). A potential interaction between the toxic effects of chlorophacinone and a bacterial pathogen, tularemia (*Francisella tularensis*) was described in common voles (*Microtus arvalis*, Vidal et al. 2009). Voles that were infected with *F.tularensis* died at lower doses of chlorophacinone than uninfected voles. Tularemia prevalence was also higher in areas treated with chlorophacinone, and the authors suggested that the AR field treatment may have also facilitated the spread of the disease in the affected vole population.

Sublethal AR exposure may also negatively affect individuals directly. In Denmark, Elemeros et al. (2011) found a negative association between anticoagulant exposure and body condition in weasels (*Mustela nivalis*) and stoats (*Mustela erminea*). A reduced escape response has been observed in rats dosed with ARs (Cox and Smith 1992), and if carnivores secondarily exposed to ARs have a similarly reduced response to threats, they may be more vulnerable to vehicle collisions or predation. Elmeros et al. (2011) found that for both stoats and weasels, those that were sampled after being trapped had significantly lower total AR residue concentrations than those sampled after vehicle collisions and predation events. Although we have a limited sample size ( $N = 5$ ), all animals that died of vehicle collisions for which we collected blood post-mortem had detectable AR residues in their blood (compared with 34 % of captured animals). Thus we speculate that recent AR exposure events may increase bobcat vulnerability to vehicle collision but additional data are needed to test this hypothesis.

Bobcats with severe notoedric mange exhibit altered behavior increasing their susceptibility to other primary sources of mortality. For example, although bobcats are primarily nocturnal, especially in urban populations (Riley et al. 2003), we have observed bobcats with severe mange infestation frequently wandering in urban areas during daylight hours (Riley and Serieys unpubl.data). This shifted activity pattern may increase the risk of being struck by vehicles and vulnerability to other sources of mortality.

Though sample sizes are limited, our findings that AR transfers from mother to offspring suggests consequences

for reproduction in bobcats. Contaminant exposure that interferes with the reproductive success of wildlife populations can lead directly to population declines. We tested two bobcat fetuses, one from each study area and both were exposed to multiple AR compounds with one exposed to five compounds. Reproductive consequences associated with AR exposure in other species have included increased miscarriage, fetal toxicosis, fetal congenital deformities, and decreased sperm counts in humans (Ginsberg and Hirsh 1989), dogs (Munday and Thompson 2003), and sheep (Robinson et al. 2005). In humans, prenatal exposure to first-generation coumarin even at low, therapeutic doses has been associated with central nervous system abnormalities (Ginsberg and Hirsh 1989; Wesseling et al. 2001). Brodifacoum toxicosis was documented in neonatal puppies even though the mother was exposed 4 weeks prior to birth (Munday and Thompson 2003). AR exposure may be an important challenge for population viability in urban areas if chemical contamination causes detrimental effects on reproduction.

#### Conservation and management implications

Exposure of nontarget wildlife to ARs is increasingly recognized as a widespread conservation issue (Erickson and Urban 2004; US EPA 2008; California Department of Pesticide Regulation 2013) and numerous species have been exposed, sometimes causing direct mortalities (Scheuhammer 1987; Peakall 1992; Eason et al. 2002; Erickson and Urban 2004; Riley et al. 2007; Gabriel et al. 2012). Species that are exposed include federally listed endangered species such as San Joaquin kit foxes (McMillin et al. 2008), bald eagles (*Haliaeetus leucocephalus*, Stone et al. 2003; Salmon 2010), and the Northern spotted owl (*Strix occidentalis caurina*, Erickson and Urban 2004). Indirect mortalities associated with the poisons may also pose an important threat for wildlife populations, particularly those that are re-colonizing parts of their past range. For example, during a recent study of California fishers, which are candidates for protection under the US Endangered Species Act, a lactating female died of anticoagulant toxicosis, which most likely led indirectly to the death of her litter (Gabriel et al. 2012). For threatened populations, exposure to ARs may influence their reproductive success, lead to sublethal and lethal consequences and increase their vulnerability to other sources of mortality.

Although some U.S. States, such as California, are taking steps to increase regulation of the use and the availability of these poisons to consumers, the adequacy of these is unknown. Under current law, second-generation ARs are restricted to indoor use or within 30 m (100 ft) of buildings. In California, the Department of Pesticide

Regulation has reduced that distance to a 17 m (50 ft) radius from buildings. However, Tosh et al. (2012) found no relationship between distance from buildings and residue concentrations in two species of mice reflecting the high mobility of the small mammals even after ingestion of ARs. They also detected a contaminated wood mouse (*Apodemus sylvaticus*) 110 m from a building where usage occurred and another 160 m from a building where no usage occurred (Tosh et al. 2012). In residential areas within SMMNRA, residents have reported off-label use of ARs, and use of second-generation ARs up to 100 m from buildings (Bartos et al. 2012). We have observed containers of second-generation ARs in natural areas behind homes at greater than 30 m from a building. Residents who use ARs have also reported continued use of the compounds although they were aware of the threat that the compounds posed to nontarget wildlife (Morzillo and Mertig 2011a). If wildlife are especially likely to be exposed to ARs due to use of these compounds in residential areas, then measures that address residential use of ARs may be particularly effective in mitigating ecological risks associated with these compounds.

## ABSTRACT

Landscape connectivity is essential to conserving resilient wildlife populations in the Anthropocene. Maintaining connectivity requires preserving or restoring patches of habitat, accounting for the behavioral factors that determine movement between patches and mitigating threats. We measured natural and anthropogenic features that influence movement and mortality for bobcats (*Lynx rufus*) in a system threatened with complete isolation by urbanization. Our overarching objective was to inform local land acquisition and restoration to maintain two last-chance wildlife corridors. We collected five-minute movement data from 36 bobcats in central California to assess features of road-crossing hotspots and model habitat selection, including functional responses to housing densities and vegetation. We collected opportunistic mortalities and assessed rat poison exposure to evaluate edge effects as acute threats. Bobcats strongly selected for natural vegetation, evident at the level of a single tree or shrub. Individuals selected low-density housing (<5 houses/ha) yet avoided high-density housing development and monoculture agriculture. Narrow (<25 m wide) riparian strips were critical to connectivity. Bobcats successfully crossed the busiest highway in the landscape but frequently died when crossing a less-trafficked road with a high median barrier. Vehicles and disease were dominant sources of mortality, while 94% of bobcats were exposed to rat poisons despite California's 2014 regulations implemented to reduced wildlife exposure. Maintaining landscape connectivity requires conserving key habitats, mitigating the effects of infrastructure, and sustaining populations of highly mobile, healthy individuals. Our findings have driven conservation action through land acquisition. We demonstrate how robust, rapid data collection can facilitate real-world conservation outcomes.

## 1. Introduction

The movement of individuals and their genes across landscapes is vital to population persistence (Fletcher et al., 2016), the adaptability of species to environmental change (Thomas et al., 2004), and ecosystem resilience (Sgrò et al., 2011). Landscape connectivity is a fundamental underpinning of diverse ecological processes including predator-prey interactions, nutrient cycling, and disease dynamics (Fletcher et al., 2016). The global expansion of human populations, however, is drastically changing the ability of organisms to move across landscapes. Seventy-five percent of the planet's terrestrial surface is impacted by numerous anthropogenic activities collectively referred to as the "human footprint" (Sanderson et al., 2002). This footprint has reduced terrestrial mammal vagility by 30–50% (Tucker et al., 2018) and correlates with anthropogenic mortality (Hill et al., 2019). Understanding

factors that influence animal vagility and associated risk is increasingly elemental to biodiversity conservation in the Anthropocene (Fletcher et al., 2016).

Humans transform landscapes and inhibit wildlife movement in two fundamental ways. First, destruction of natural habitat fragments landscapes and reduces connectivity (Foley et al., 2005). Second, humans create infrastructure and linear barriers when building cities, paving roads, erecting fences, or damming rivers. Yet the effects of infrastructure and barriers can be complex and sometimes counterintuitive. Roads, for example, may facilitate movement in areas with low human footprint (Whittington et al., 2011) while in areas with high human footprint, roads can act as a critical impediment to movement (Riley et al., 2014a). Overall, however, roads may act as an important source of mortality (Hill et al., 2019) and suppress animal population abundance (Fahrig and Rytwinski, 2009) irrespective of their effects on

animal movement.

Edge effects around habitat also disrupt population dynamics and persistence (Benson et al., 2016; Fagan et al., 1999; Watling et al., 2011). Thus, the qualities of matrices (i.e., developed portions of the landscape in which habitat patches are embedded) themselves can fundamentally influence ecological connectivity (Watling et al., 2011). For example, dispersal routes obstructed by human infrastructure can increase mortality, especially for subadult individuals, and isolate populations (Riley et al., 2014b; Kramer-Schadt et al., 2004). Isolation erodes genetic variation (Benson et al., 2016), increasing vulnerability to other stressors (Keller and Waller, 2002). Disease dynamics can shift in transformed landscapes while pesticide exposure kills wildlife, may increase disease susceptibility (Riley et al., 2014c), and can cause population declines (Riley et al., 2007). When retaining or restoring connectivity, an appraisal of the acute edge effect threats to populations is essential to implementing robust mitigation measures.

Corridors that facilitate wildlife movement between habitat patches can mitigate barriers caused by fragmentation (Beier, 2018; Beier et al., 2008). Identifying effective corridors is challenging because landscape connectivity is a complex combination of structural features and functional processes, and consequently, corridors based on expert opinion can substantially deviate from animal-defined corridors (LaPoint et al., 2013). Structural connectivity, the presence of habitat linking sub-populations, may be a function of a suite of variables including land cover type, patch size, isolation, mortality risk, and whether linear features facilitate or disrupt movement (Fletcher et al., 2016). Functional connectivity is assessed via the behavioral response of individuals to those landscape features and other factors and movement rates between sub-populations (Carvalho et al., 2016; Kramer-Schadt et al., 2004). Because observing functional movement is difficult due to the need to monitor select individuals at precise times moving long distances, structural connectivity often becomes a proxy for functional movement. Yet, accounting for actual behavior, and in particular varying choice among individuals, provides essential insight into how animals move through the landscape (LaPoint et al., 2013).

Fortunately, we have entered a “golden age” of bio-logging with technological advances that can record extremely fine-grain movement of tagged animals (Wilmers et al., 2015). Using high-resolution data to define movement corridors is more reliable than expert-opinion and cost-based models that ignore unique interactions between animal behaviors and structural features (Abouelezz et al., 2018; LaPoint et al., 2013). Technological advancements improve rapid assessments to inform mitigation and restoration measures via land acquisition and retro-fitting infrastructure to reduce barrier effects (e.g., Serieys and Wilmers, 2019). Additionally, we can pair precise animal locations with high-resolution remote monitoring of extensive landscapes to better match fine-scale movement with fine-scale landscape features down to individual trees.

Here, we use high-resolution movement (5 min) and remote sensing (0.6 m [0.36 m<sup>2</sup> pixels]) data to determine the presence of two “last-chance” wildlife linkages (the only remaining corridors that connect habitat patches) in landscapes threatened by imminent anthropogenic development in central California. We used a landscape-species approach (Sanderson et al., 2002) to identify natural and human-derived features that influence connectivity. Additionally, we wanted to understand factors that reduce functional connectivity by increasing mortality. We chose a mesocarnivore, the bobcat (*Lynx rufus*), because its scale of movement is congruous with the scale of the study areas, while their resource requirements translate into an inherent need to navigate hostile matrices to move among habitat patches (Crooks, 2002). As a mammalian carnivore, bobcats exist at low densities and are thus genetically sensitive to habitat fragmentation and inbreeding (Ruiz-López et al., 2012). Their trophic status leaves them vulnerable to the bioaccumulation of urban pathogens and pesticides (Carver et al., 2016; Serieys et al., 2015). Overall, these ecological traits make them intrinsically vulnerable to extinction associated with habitat degradation

(Cardillo et al., 2005), and excellent proxies for sympatric species (e.g. puma, *Puma concolor*; badger, *Taxidea taxus*; coyote, *Canis latrans*) that have similar extinction risk (Cardillo et al., 2005) and may also contribute to ecosystem processes (Zavaleta et al., 2009) in the study areas.

Our overarching goal was to make management recommendations to local conservation agencies before more extensive habitat loss leads to irreversible population fragmentation and decline. Our specific objectives included: i) intensive monitoring of bobcat movement complemented with movement-explicit step selection functions to identify the relative importance of natural and human-modified landscape features that influence bobcat movement through the last-chance corridors; ii) evaluate the barrier and mortality effects of roads to characterize safe and dangerous road-crossing hotspots so that potentially needed retro-fitting of roads can facilitate connectivity and mitigate threats; and iii) assess the role of vehicles, ubiquitous rat poisons, and an urban-associated disease (notoedric mange, *Notoedres cati*; Serieys et al., 2015) in driving bobcat mortality thereby potentially inhibiting functional connectivity. Given the severity of fragmentation in the region, these high-resolution data are essential to designing mitigation measures to preserve and restore landscape connectivity amidst ongoing development and habitat loss.

## 2. Methods

### 2.1. Study area

We conducted this study within the San Francisco Bay Region and adjacent southern counties (Fig. 1) in the California Floristic Province, the sixth most important biodiverse conservation region within the U.S. (Stein et al., 2000). The region is characterized by a series of mountain ranges with anthropogenic development concentrated in the interlinking valleys.

Our study sites comprised two stretches of fragmented habitat that remain as the only two viable linkages between the Santa Cruz Mountains and the eastern ranges — the Coyote Valley to the east, and the Aromas Hills to the southeast. Local conservation stakeholders describe these areas as the “last-chance” wildlife corridors for Santa Cruz Mountains faunal populations because they constitute the last remaining potential linkages between the Santa Cruz Mountains and adjacent mountain ranges (Fig. 1, Supplemental Fig. S1). Both areas are imminently threatened by intense commercial development. Conservation organizations seek mitigation measures that would preserve remaining natural habitat of greatest importance to wildlife and maintain biological connectivity between the mountain ranges (Serieys and Wilmers, 2019).

Each study area encompasses roughly 30 km<sup>2</sup> (Supplemental Fig. S1). Land uses include orchards, row crops, commercial development, residential neighborhoods, and altered open areas (i.e., golf courses and school yards). Remaining natural areas are a mix of riparian strips, mixed oak and shrub savannah, and serpentine grassland.

### 2.2. Sampling, movement, and mortality data

We used standard cage-trapping techniques to capture bobcats during three trapping sessions between June 2017 and December 2018. In Coyote Valley, dry season trapping occurred June 1–July 30, 2017 while wet season trapping occurred November 10, 2017–February 28, 2018 because one on-the-ground objective in Coyote Valley was to test for potential seasonal differences in bobcat habitat selection. In Aromas Hills, we trapped during one trapping session between June 1, 2018 and December 31, 2018. We used cage traps (Tru-catch traps, Bell Fourche, South Dakota or CamTrip cages, Caging Bobcats, Barstow, California) that were checked a minimum of every 12 h. Individuals were chemically immobilized with a mixture of ketamine HCl (5 mg/kg) and medetomidine HCl (0.1 mg/kg). We recorded age class, sex, weight, and

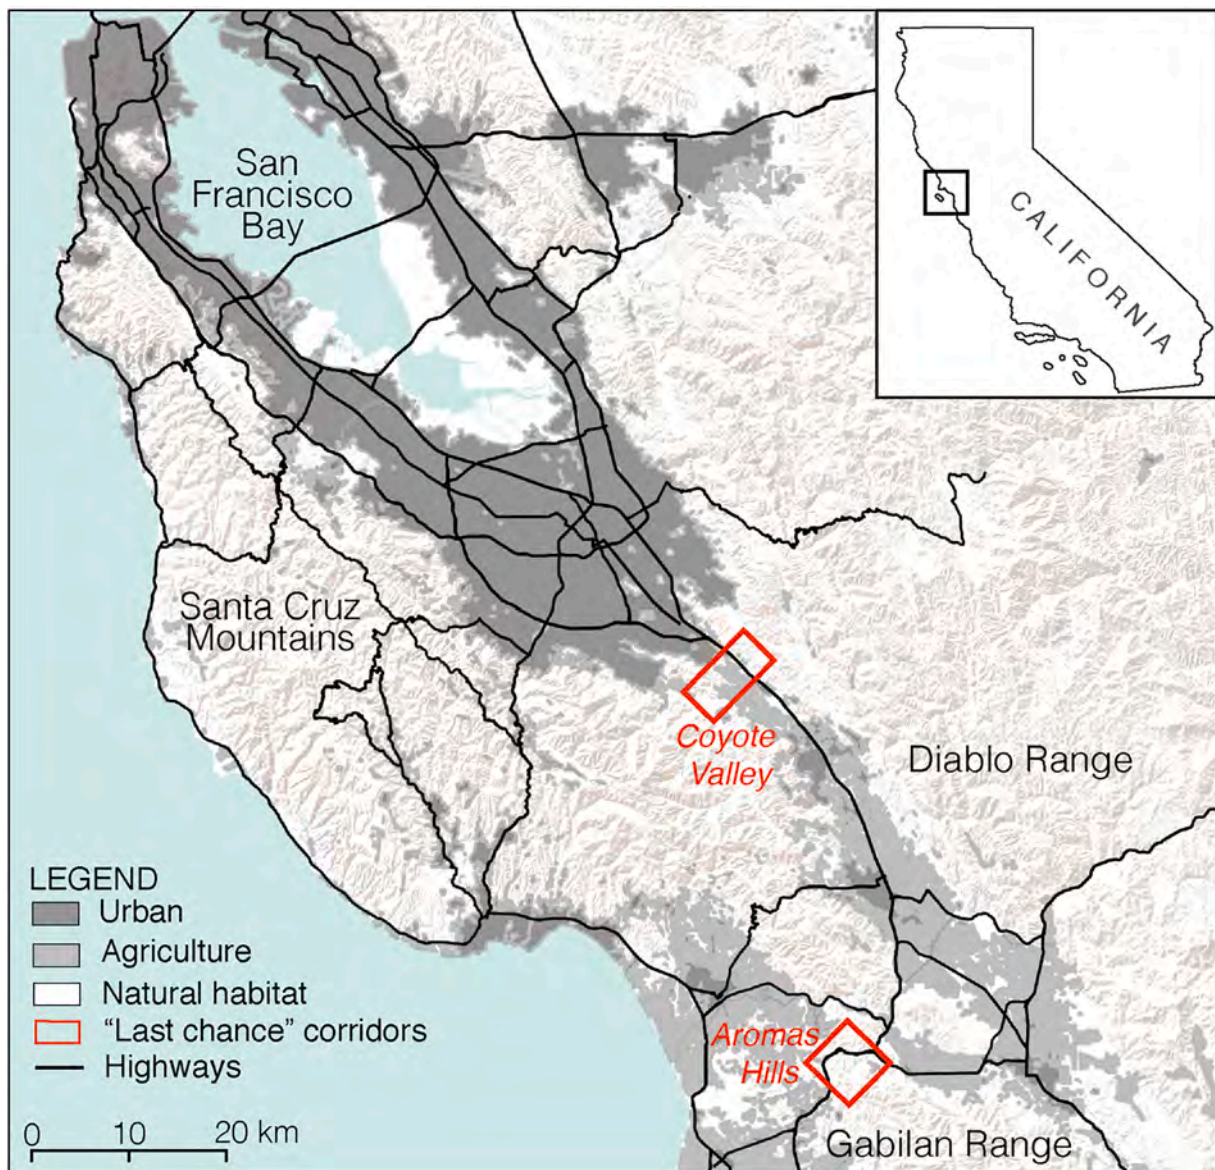

Fig. 1. A map of the Santa Cruz Mountains and neighboring ranges.

morphological measurements. We classified as juveniles (<2 years) or adults ( $\geq 2$  years) based on body size, weight, tooth wear and eruption, and reproductive status (Serieys et al., 2015).

Individuals were collared, and their movements monitored using GPS and triaxial accelerometers (Eobs GmbH; Grünwald, Germany) that sampled locations at 5-min intervals when the animal was moving, and at 3-h intervals when the animal was at rest (Supplemental Methods 1, collar programming file). Collars were set to record data for a minimum of three-months for each individual.

We performed mortality surveys for GPS-collared individuals on a weekly-monthly basis, depending on the ease of locating each individual, particularly given that we were unable to obtain entry access to various regions of the study areas. We opportunistically collected carcasses from untagged bobcats to increase our understanding of factors contributing to mortality in the study areas. We necropsied all carcasses and recorded cause of mortality, collection date and location, sex, age class, and presence of notoedric mange (*Notoedres cati*; Riley et al., 2007).

All animal capture, handling, collaring, and sample collection was approved by the Institutional Animal Care and Use Committee (IACUC) of the authors' institution (Protocol numbers). Scientific collecting

permits were authorized by the California Department of Fish and Wildlife (Aromas, SCP-11968; Coyote Valley, SCP-13565).

### 2.3. Anticoagulant rodenticide exposure

To further assess contributors to mortality, we tested for a standard panel of commercially available anticoagulant rodenticide (AR) compounds (brodifacoum, bromadiolone, difethialone, difenacoum, chlorophacinone, diphacinone, warfarin, and coumachlor) when it was possible to recover the liver of animals that died. The detection of ARs in liver reflects the history of exposure for the individual (Serieys et al., 2015). We assessed the presence and concentrations of each compound using HPLC and LCMS/MS as has been previously described (e.g. Serieys et al., 2015). The threshold of detection required for quantitation by LCMS/MS for our panel of ARs was 0.05 ppm for brodifacoum, chlorophacinone, and diphacinone, and 0.02 ppm for bromadiolone, coumachlor, difethialone, warfarin, and difenacoum. When compounds were detected by HPLC, but at concentrations too low to be quantitated by LCMS/MS, we report the compound as "level of detection" (LOD). For compounds that were LOD, when calculating mean concentrations across individuals, we assigned the smallest non-zero value (0.01) given

our level of detection precision.

#### 2.4. Landscape covariates

We tested the influence of topography (SLOPE), vegetation (TREES, SHRUBS, GRASS, EUCALYPTUS), distance from water (streams, lakes, ponds; WATER), monoculture agriculture (CROPS, ORCHARDS), and anthropogenic landscape features including distance from arterial roads (ROADS) and housing density within a 100-meter radius around each GPS location (HOUSE; see Section 2.6 below for radius selection) on bobcat movement. For additional GIS layer source details, see Supplemental Table S1.

To assess the influence of vegetation on bobcat movement across the study areas, we first conducted a supervised maximum likelihood land cover classification in ArcGIS 10.5 (ESRI, Redlands, CA) from US Department of Agriculture National Agricultural Imagery Program high-resolution (0.6 m [0.36 m<sup>2</sup> pixels]) remotely sensed imagery (USDA 2016) recorded at spectral bands corresponding to blue, green, red, and near-infrared wavelengths. We classified land cover as trees, shrubs, grass, non-vegetation (i.e., urban or rock), and water (Supplemental Table S1). We resampled the land cover raster at 1.2 m resolution to account for errant pixels. We subsequently used the California Department of Conservation agricultural layers for Santa Clara, Monterey, San Benito, and Santa Cruz Counties (California Department of Conservation; [consrv.ca.gov](http://consrv.ca.gov)) to identify monoculture agricultural areas that we classified as either row crops or orchard. Informal quality assessment showed high correspondence between the agricultural layers and row crops and orchards visible in the NAIP imagery. However, informal quality assessment revealed shaded vegetation classified as water; we corrected for this by masking out water bodies using the USGS Natural Hydrography Dataset (NHDH\_CA\_92v200; [usgs.gov](http://usgs.gov)) and reclassifying remaining water pixels (initially classified as water) as TREES. We transformed bobcat locations from WGS84 into the 1983 North American Datum and reprojected them into the Universal Transverse Mercator Zone 10 N coordinate reference system. For each location, we sampled the presence or absence of trees, shrubs, grass, row crops, and orchards such that each category had a binary designation of 0 or 1. To account for GPS error in observed locations, points were classified as trees and shrubs if trees or shrubs were within a 5-meter radius of each location and, if either class was present within the buffer, assumed the true location of the bobcat was within the nearer of the two vegetation classes (though such instances were rare).

We estimated other natural landscape features including the minimum distance from the nearest stream, pond, or reservoir (WATER; USGS Natural Hydrography Dataset [NHDH\_CA\_92v200]; [usgs.gov](http://usgs.gov)) and topographical features, elevation (ELEVATION) and slope (SLOPE), extracted from the USGS 1/9 arc-second Digital Elevation Model ([sciencebase.gov](http://sciencebase.gov)).

We measured four types of disturbed landscapes on bobcat movement—monoculture agriculture, eucalyptus, housing density, and roads. We identified locations within monoculture agricultural areas that included orchards and row crops (ORCHARDS or CROPS, California Department of Conservation; [consrv.ca.gov](http://consrv.ca.gov)). To determine the effect of a dense 4 km<sup>2</sup> eucalyptus grove (in Aromas Hills) on bobcat movement and habitat selection, we used QGIS (QGIS Development Team, 2019) to manually map the eucalyptus grove from the high-resolution NAIP imagery. We tested the effect of housing density within a 100-meter buffer (see ‘Section 2.6. Housing density scale’ below for more details about buffer size determination) surrounding each location (HOUSE, based on Microsoft’s Building Footprints; Open Data Commons Database License). Finally, we calculated the distance of each location from the nearest arterial (primary or secondary) road (ROADS; ESRI Roads [DataMaps10.2]). Primary arterial roads are highways or freeways with high traffic volumes, while secondary arterial roads comprise smaller, less-trafficked roads that feed directly into primary roads (Riley et al., 2014a). Arterial roads in our study included US Route 101 found in both

study areas, as well as six secondary roads of particular interest in the study areas (described further below, Section 2.8).

#### 2.5. Movement-explicit habitat selection

We analyzed movement-explicit habitat selection using step-selection functions (SSFs; Thurfjell et al., 2014) because we wanted to characterize habitat that specifically influenced decision-making while individuals were moving across the landscape. Because the collars collected both 5-min movement, and 3-hour resting locations, we isolated movement locations by removing resting locations. We implemented a standard 1:20 match-case control empirical design by creating strata where each individual’s end ‘used’ location ( $t$ ) was paired with 20 ‘available’ locations (Duchesne et al., 2010; Fortin et al., 2005). We investigated selection in response to topography, vegetation, streams and lakes, monoculture agriculture, distance from arterial roads and housing density.

Habitat selection analyses are sensitive to the spatiotemporal scale at which available habitat is characterized (Boyce, 2006; Wilmers et al., 2015; Thurfjell et al., 2014; Suraci et al., 2019) and fix intervals determine the strength and order of habitat selection (Thurfjell et al., 2014; Suraci et al., 2019). For example, at fine temporal scales (<20 min), movement decisions reflect options within a maximum of several hundred meters (Thurfjell et al., 2014; Suraci et al., 2019). Thus, at fine scales, the selection for natural vegetation within an individual’s immediate vicinity will obscure potential avoidance of risky anthropogenic features on the landscape (e.g. Suraci et al., 2019). A primary objective of this study was to assess the relative influence of both anthropogenic and natural landscape features on movement decision making. Therefore, we subsampled our 5-min movement data to an intermediate (3 h) fix interval following Suraci et al. (2019). At intermediate fix intervals, the relative importance of anthropogenic landscape features is best captured in SSF habitat selection studies in human-dominated landscapes (Suraci et al., 2019).

We simulated ‘available’ locations to match each observed location  $t$  by sampling, with replacement, random vectors originating from the immediately preceding ‘used’ location (i.e., location  $t-1$ ). Random vectors were drawn based on the empirical distribution of turn angles and step lengths between consecutive locations derived from data on all individuals that were the same sex as the focal individual. However, while drawing the random vectors, we excluded the focal individual’s data to avoid circularity (Fortin et al., 2005). We included three resource-independent behavioral parameters in the models to control for inherent biases in animal movement that may also affect habitat use. Step length (STEP, calculated between  $t$  and  $t-1$ ) and log-transformed step length (LOG.STEP) controlled for potential habitat selection biases arising from the ability of individuals to travel to available locations (Forester et al., 2009; Nicosia et al., 2017). Directional persistence (DIR.PERSIST) controlled for the inherent tendency of individuals to move in a constant direction and was calculated between  $t$ ,  $t-1$ , and  $t-2$  (following (Duchesne et al., 2010; Nicosia et al., 2017; Suraci et al., 2019) as:

$$\cos(\theta_t - \theta_{t-1})$$

where  $\theta_t$  is the absolute (angle relative to North) of the vector resulting in the current step  $t$ , and  $\theta_{t-1}$  is the absolute angle of the preceding vector resulting in step  $t-1$ .

We estimated selection ( $\beta$ ) coefficients using conditional logistic regression (CLR) via cox proportional hazards models in package ‘survival’ 2.43-3 (Therneau, 2018) for R statistics software (R Core Team, 2019). Successive strata were not independent due to temporal autocorrelation (Craiu et al., 2008), thus deflating standard errors associated with  $\beta$  coefficients. Therefore, we calculated robust standard errors using generalized estimating equations (GEE; Prima et al., 2017) by specifying intra-group (‘cluster’) correlation. We classified clusters by collaring events following a recommendation to use one cluster per

individual when the number of individuals exceeds 30 (Prima et al., 2017). Two individuals were opportunistically recollared in Coyote Valley. Clusters represented 38 collaring events across 36 bobcat individuals (total  $n_{strata} = 35,701$ ).

Next, we modeled the relative probability of a bobcat selecting a particular location as a function of all natural and disturbance landscape variables described above. All covariates were standardized (mean = 0, standard deviation = 2; Gelman and Hill, 2007). We performed pairwise Pearson correlations to ensure that covariates were not strongly collinear ( $|r| \leq 0.40$  for all pairwise relationships). We first independently modeled the two topographic covariates (ELEVATION, SLOPE) to determine which covariate performed best. We identified the best fit topographical model as that with the lowest quasi-likelihood under independence (QIC) score, a criterion indicated by Craiu et al., 2008 for use in GEE-based analyses. SLOPE performed best, and thus was included in all downstream modeling. Next, we fit a set of 20 candidate models (Supplemental Table S2) representing hypotheses regarding the potential influence of 10 landscape covariates (SLOPE, CROPS, ORCHARD, GRASS, TREES, SHRUBS, EUCALYPTUS, WATER, ROADS, and HOUSE) on bobcat movement. We selected the top model as that with the lowest QIC. We provide parameter estimates and 95% confidence intervals (derived from robust standard errors) on the logit scale, as estimated by CLR.

## 2.6. Housing density scale

To assess the scale at which housing density exerted the strongest influence on bobcat habitat selection, we calculated housing density individually at 16 different scales between 50 and 1000 m radius (at 50–100 m increments) buffers surrounding each used and available location. We tested the relative effects of these 16 different buffer sizes individually while controlling for directional persistence and step length using the CCLR framework. We identified the most parsimonious model (100 m buffer size) by comparing the QIC as described above.

## 2.7. Functional responses: housing density and vegetation cover

We wanted to determine whether bobcats exhibit a functional response to changes in low- to medium-housing density. We considered a functional response for both study areas collectively, but we also considered distinct functional responses within Aromas Hills and Coyote Valley because the two study areas have differing spectra of housing densities. In Aromas Hills, bobcats regularly moved through low-density neighborhoods (<5 houses/ha). In contrast, Coyote Valley residential development is largely high-density (>5 houses/ha) that bobcats rarely permeated. We tested for functional responses using a piecewise linear spline regression model that split housing density into two or three covariates with different slopes on either side of a breakpoint (Kohl et al., 2018; Smith et al., 2019b). We selected optimal breakpoints using a grid search approach of the breakpoint by comparing the QIC values of candidate spline models against models with a simple linear effect (on the log link scale) for housing density.

Next, because land acquisition, primarily of agricultural parcels, is active in both study sites, we considered a functional response to varying degrees of composite vegetation cover (i.e., trees and shrubs). Our aim was to calculate recommended vegetation restoration guidelines for parcels. We specifically tested for the functional response on the scale of one acre (a common management unit) by extracting the composite value for proportion cover by trees and shrubs in a one-acre circular buffer around each location. We performed the same grid search method described above.

## 2.8. Road crossings

We used 5-minute relocation data to identify the date, time, and location of road-crossing events for each individual that crossed one of

seven arterial primary or secondary roads. We focused this analysis only on major arterial roads with noted high traffic volume and road mortalities in the study areas (e.g. Serieys and Wilmers, 2019). Highway 101 was the only primary road in both study areas and is an 8–10 lane freeway with numerous culverts and underpasses. Average daily traffic is roughly 84,000 vehicles/day in Coyote Valley, and 52,000 vehicles/day in Aromas Hills (dot.ca.gov). All other roads were secondary (Supplemental Fig. S1) and average all daily average traffic volumes exceeded 2000 vehicles/day (Monterey Road: 9000; Route 129: 10,200; Route 25: 2400; Route 156: 3100; Bailey Road: 5525; Santa Theresa Road: 7500 vehicles/day). We defined a road-crossing location as any intersection of a line segment between two consecutive 5-minute bobcat locations and a line feature representing the arterial road. These locations were thus rough approximations of actual crossing locations. We classified road-crossings as occurring during the day or night based on local sunrise and sunset times.

We calculated the expected number of road crossings per hectare using a two-dimensional kernel density estimator (KDE) with a 250 m search radius of identified road-crossings in ArcGIS 10.3. The expected number of crossings ranged from 0 to 11.31, which we reclassified according to easily interpretable categories of areas of infrequent crossings (<1/ha), regular crossing areas (1–2/ha), and road-crossing hotspots (>2/ha).

## 3. Results

### 3.1. Movement sampling

We captured 38 bobcats (22 adults, 16 juveniles; 21 males, 17 females; Supplemental Table S3) across both study areas (Coyote Valley: 26; Aromas Hills: 12). One juvenile's collar fell off within two days, and we did not collar one juvenile. Therefore, we collected 652,700 5-min GPS-collar locations from 36 individuals (22 adults, 14 juveniles; 20 males, 16 females; Supplementary Table S3) filtered to 32,373 three-hour observations for habitat selection analyses. We monitored GPS-collared bobcats for an average of 143.8 tracking days (range: 16–369; median = 131 days).

### 3.2. Movement-explicit habitat selection

Both natural and anthropogenic landscape features strongly influenced bobcat habitat selection while individuals were moving (Table 1). Alternative models exhibited  $\Delta QIC > 17$  (Supplemental Table S2). Their

**Table 1**

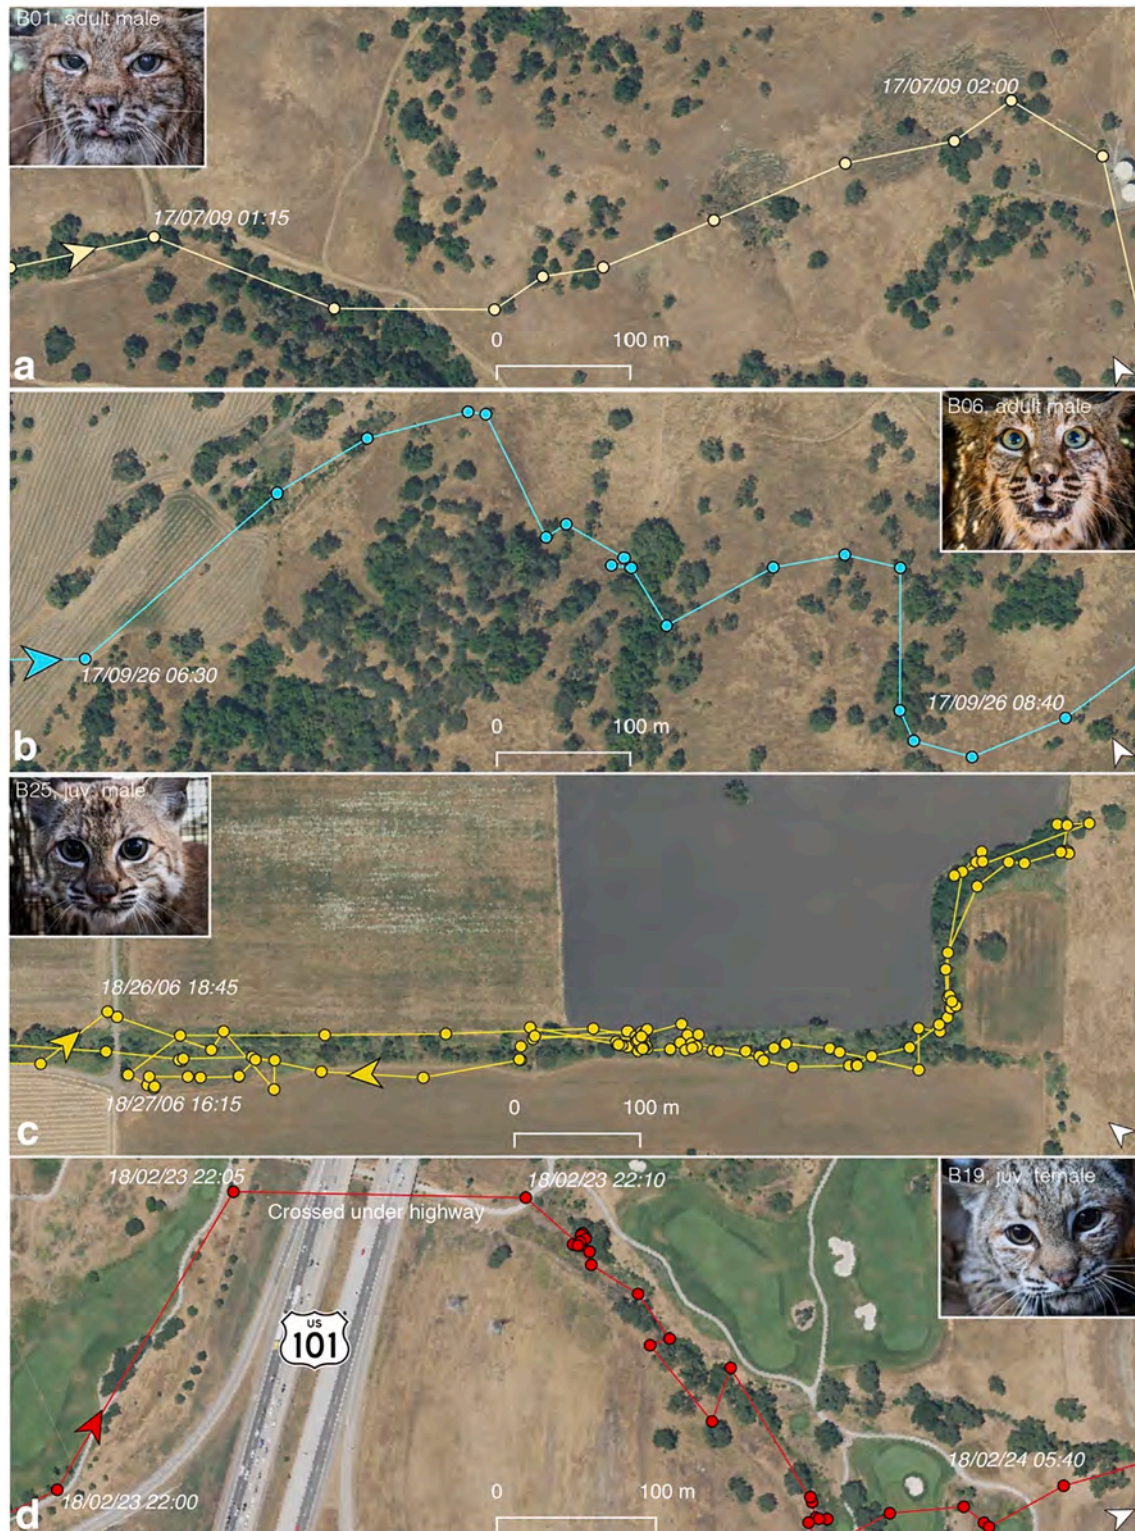

The top habitat selection model comprising landscape covariates and three resource-independent behavioral parameters. Water is measured as the distance from the nearest water source, and thus a negative selection coefficient represents a positive association. Behavioral parameters controlled for inherent biases in animal movement that influence habitat use. Directional persistence (DIR.PERSIST) controlled for the inherent tendency of individuals to move in a constant direction. Step length (STEP) and log-transformed step length (LOG.STEP) controlled for the habitat selection biases arising from the ability of individuals to travel to available locations.

Covariate	Assoc.	$\beta$ estimate	Robust SE	Lower 95% CI	Upper 95% CI	p- Value

LOG(STEP)		0.40	0.13	0.14	0.65	0.003

strong selection for trees ( $\beta = 1.43$ ) and shrubs ( $\beta = 1.30$ ) was remarkably apparent even when mapping each individual's movement data over satellite imagery (Fig. 2). Bobcats strongly avoided highly transformed landscapes — even those that remained largely vegetated. Specifically, bobcats avoided row crops ( $\beta = -0.55$ ), eucalyptus ( $\beta = -0.26$ ), and orchards ( $\beta = -0.15$ ). Bobcats selected for proximity to

water ( $\beta = -0.49$  [the coefficient is negative because the covariate is calculated as the distance from water]) and steeper slopes ( $\beta = 0.18$ ). Bobcats selected against high density housing ( $\geq 5$  houses/ha;  $\beta = -0.18$ ).

**Fig. 2.** Bobcat movement is evident at the scale of a single tree or shrub. A–B) Approximately 1 h of 5-min interval data for adult males. C) Approximately 22 h of 5-min data for a juvenile male. D) Juvenile female crosses under Highway 101 following sparse vegetation.

### 3.3. Functional responses: housing and vegetation

For the combined study areas, and for Coyote Valley specifically, we found no support for a functional response to housing. Coyote Valley's dense, multifamily residential development was impermeable to bobcats with the exception of three juveniles that took single forays into these areas. In Aromas Hills, a clear functional response emerged (Fig. 3a). Probability of selection increased from 0 to 0.95 houses/ha (i.e. between 2 and 3 houses within 100 m; knot = 0.4 standard deviations above the mean;  $\Delta$ QIC of  $-8.15$ ), after which the probability of avoidance increased as housing density increased.

Bobcats across both study areas exhibited a strong functional response to vegetation ( $\Delta$ QIC =  $-1216.0$ ; Fig. 3b). The relative probability of selection increased for vegetation cover (on the scale of one acre) as the proportion of vegetation increased, saturating at 69% (0.47 standard deviations above the mean), and thereafter, declining gently.

### 3.4. Roads: permeability and features of hotspots and barriers

We documented 29 bobcats (22 adults, 13 juveniles, 19 males, 16 females) cross arterial roads 3333 times (Supplemental Tables S4–S5). The majority (80%) of crossings occurred at night. Adults crossed more frequently than juveniles (adults: 0.85 crossings/day; juveniles: 0.52 crossings/day), while females crossed more frequently than males (females: 0.86 crossings/day; males: 0.58 crossings/day). Seventy-nine percent of crossings were across secondary roads, while 21% were across Highway 101. We did not detect road avoidance using habitat selection models. We identified 14 road-crossing hotspots: 10 in Coyote Valley and four in Aromas Hills. Five hotspots crossed Highway 101. Nine crossed secondary roads. All crossing hotspots (Fig. 4a–c) shared certain features. They were in topographical depressions, often in drainages or stream beds (12/14), and in every case, trees or shrubs flanked both sides of the road. Four crossing hotspots across Highway 101 were characterized by extensive overpasses across riparian areas (that bobcats could cross under). In the remaining hotspot, a large culvert was present.

While biologists did not specifically record whether cats passed under or over roads, we assume animals used this infrastructure in the majority of cases (e.g. Fig. 2d). Along stretches of Highway 101 that did not have crossing infrastructure, particularly an 8 km stretch in Aromas Hills, we did not document attempted crossings by collared bobcats and rarely road mortalities. Two Aromas Hills bobcats moved directly adjacent to the highway along the stretch absent of crossing infrastructure, but the highway delineated the boundary of their movements.

The deadliest and least-crossed arterial road was Monterey Road

(Fig. 4d) although this road had only 10.7% the average daily traffic volume as the adjacent primary road, Highway 101. However, Monterey Road characterized by a lack of potential crossing infrastructure, frequent wildlife road mortalities, and a prominent concrete median topped with mesh wire fencing ( $\sim 1.5$  m tall). Crossing Monterey Road accounted for only 1.6% of total successful crossing events, but seven of thirteen road mortalities in Coyote Valley. Of the twenty-five Coyote Valley bobcats, all were captured  $< 3.2$  km from Monterey Road (median = 792 m). Yet we observed only five individuals successfully cross the road, three of which were eventually killed on the road. Unexpectedly, Monterey Road formed a stronger movement barrier for bobcats than Highway 101.

### 3.5. Mortality and poisons

We documented 28 bobcat mortalities (18 Coyote Valley, 10 Aromas Hills; 9 GPS-collared, 19 opportunistic; Supplemental Tables S3, S5). Of the nine GPS-collared bobcats, four were hit by cars, two died of notoedric mange, two were predated, and one was attacked by domestic dogs. Of the opportunistic mortalities, 13 were hit by cars and four died of mange. Although the majority (68%) of the mortalities were detected opportunistically (and thus source of mortality potentially skewed by detection bias), in Coyote Valley, vehicle collision was the leading source of mortality ( $n = 12$ ) while in Aromas Hills, mange was the leading source of mortality ( $n = 5$ ).

Bobcat death due to notoedric mange has previously been linked with secondary anticoagulant rodenticide (AR) exposure (Riley et al., 2007). Therefore, we assessed AR exposure in bobcats when possible. We recovered livers from 18 individuals and detected exposure to ARs in 17 (94.4%) of these individuals tested. Bobcats, like other predatory species, are secondarily exposed to these globally ubiquitous poisons via consuming poisoned prey (Hindmarch et al., 2018; Riley et al., 2007; Serieys et al., 2015). Five different commercial compounds were detected — second-generation brodifacoum, bromadiolone, and difethialone, and first-generation diphacinone and chlorophacinone. Individuals were exposed to 1–5 compounds (median = 3.5; Supplementary Table S4), indicating repeat exposure events because AR baits are formulated with single compounds. The total concentrations detected ranged from “level of detection” (LOD)—1.82 ppm, with a mean concentration of 0.37 ppm (median = 0.15, SD = 0.52). In contrast to previous liver-based bobcat studies (Riley et al., 2007; Serieys et al., 2015), we most frequently detected first-generation compounds diphacinone and chlorophacinone, and diphacinone specifically was present in every AR-positive bobcat, while chlorophacinone was detected in 78% of individuals ( $n = 14$ ; mean = 0.02 ppm). The mean concentration

**Fig. 3.** Functional responses to housing density and vegetation. a) Relative probability of selecting low housing density increases steeply up to one house/ha. The relative probability of selecting for areas without housing is approximately equivalent to the relative probability of selecting for housing densities of 5 houses/ha. b) Relative probability of selecting habitat with cover (composite tree and shrub) increases as vegetation increases.

**Fig. 4.** Road-crossing hotspots (a–c) and Monterey Road (d). Individual road-crossing events documented from unique bobcats are represented by a yellow circle. High resolution (5-min) relocation data were used to identify the date, time, and location of road-crossing events for each individual that crossed arterial roads. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

of diphacinone (mean = 0.15 ppm) was also relatively high compared with other compounds. With respect to second-generation compounds, 11 bobcats were exposed to brodifacoum (mean = 0.03 ppm), nine to bromadiolone (mean = 0.17 ppm), and three to difethialone (all 'LOD'). For six bobcats that died of mange, we detected 36% greater total concentration of ARs (mean = 0.42 ppm) as for bobcats that died of other causes (mean = 0.31 ppm).

#### 4. Discussion

We used advanced bio-logging technology to collect high-resolution bobcat movement observations in a human-modified landscape to provide rapid data-based recommendations for preserving “last-chance” corridors linking the Santa Cruz Mountains wildlife community with those in adjacent ranges. By using both 5-min and 3-h resolution movement data, we identified unexpected trends, such as the critical importance of individual trees and shrubs in promoting structural connectivity, whether within habitat patches or over roads. We observed varying degrees of permeability in matrices in the study area, where, for example, high-density housing development was impermeable and avoided, while low-density housing was not only permeable to bobcats, but even attractive and positively selected. Yet, complementing our movement data with mortality data demonstrated a pervasive, but an easily overlooked edge effect—nontarget rat poison exposure. Indiscriminate poisoning of nontarget wildlife is likely important

impediment to functional connectivity for numerous species beyond our focal bobcats. By integrating these diverse data on habitat selection, road interactions, and edge effects, this study reinforces that the maintenance of structural connectivity alone is insufficient for preserving corridors that abet wildlife conservation in fragmented landscapes.

##### 4.1. Selection for complex vegetation

In coastal sage scrub and oak woodland savannah habitat, native vegetation that adds complexity to the landscape was the most critical natural component of structural connectivity. Bobcat selection for natural vegetation was evident at the scale of a single tree or shrub. As previously observed in bobcats (Abouelezz et al., 2018; Litvaitis et al., 2015; Reed et al., 2016) and other ecologically-similar carnivores such as Eurasian lynx (*Lynx lynx*; Bouyer et al., 2015), leopards (*Panthera pardus*; Fattedbert et al., 2015), and pumas (*Puma concolor*; Burdett et al., 2010), bobcats strongly avoided areas simplified by monoculture (row crops and orchards) and opted instead for the more complex structure of natural vegetation. More complex vegetation offers better cover for stalking prey (Hopcraft et al., 2005; Smith et al., 2019a). Unexpectedly, vegetated riparian corridors <25 m wide provided sufficient cover for bobcats (of all demographics) to move through otherwise barren, row crop fields, an essential element to landscape connectivity in the fragmented landscape. We detected multiple juveniles residing exclusively in these narrow swaths of vegetation (Fig. 2c), suggesting that these

linear sections of vegetation are important to functional connectivity.

#### 4.2. Contrasting permeability of matrix infrastructure

Studies have repeatedly found that large felids will move through low-density housing (Burdett et al., 2010; Lewis et al., 2015; Smith et al., 2019b) but in Aromas Hills, such conditions actually proved preferential to bobcats. In contrast, high-density residential areas were impermeable with exception to three juveniles that took single forays into densely developed areas. Possible explanations for selection of low-density residential areas could be that landscaping creates more complex, better-irrigated habitat, or that bobcats are attracted to synanthropic prey near houses. In southern California, bobcats selected urban areas for nighttime foraging of rabbits (*Sylvilagus* spp.; Dunagan et al., 2019). While low-density residential areas can offer increased resources, these areas may represent ecological traps (Battin, 2004) because bobcats are more likely to be exposed to rodenticides in residential areas than in unaltered habitat (Serieys et al., 2015). The characteristics of matrices can thus have dichotomous effects on habitat selection with repercussions for functional connectivity if the resources bobcats seek are poisoned.

The influence of roads revealed the nuanced effects of matrix infrastructure versus activity in mediating connectivity. Roads are ubiquitous and affect the ability of all wildlife species to live and move within human-dominated landscapes (Clark et al., 2015; Kramer-Schadt et al., 2004; Poessel et al., 2014). However, it is often impossible to disentangle the barrier effects of the structural features of roads from those associated with traffic on those roads (Riley et al., 2014a). We found that crossing hotspots occurred where complex vegetation (trees or shrubs) intersected the road rather than where traffic was light. Highway 101 was a strong impediment to movement in Aromas Hills (particularly along an 8 km stretch that did not have any available safe-crossing infrastructure) while Coyote Valley bobcats readily crossed the freeway. In Aromas Hills, only two collared individuals found two safe-crossing areas. In Coyote Valley, 11 bobcats found at least nine culverts or underpasses that provided safe-crossing locations (three of which were crossing hotspots) without encountering vehicles. The Highway 101 bridges and culverts in Coyote Valley typically occur where riparian strips intersect the highway, such that natural vegetation funneled bobcats toward features that offer safe crossing for numerous species (Grilo et al., 2008; Smith et al., 2015).

In contrast, Monterey Road bears substantially less traffic but was a stronger barrier to movement and killed more bobcats. We identified a single culvert that was always flooded, which discourages carnivores from passing through (Tigas et al., 2002). When wildlife attempt to cross over the road, they encounter a concrete median topped with chain-link fencing. The combination of forcing bobcats to cross through traffic and erecting an obstacle half-way across proved particularly deadly.

#### 4.3. Edge effects as threats to functional connectivity

The impacts of habitat fragmentation extend beyond the boundaries of anthropogenic development and can cryptically reduce fitness (Flesch, 2017) and increase mortality (Benson et al., 2019) thereby constraining functional connectivity. As previously documented elsewhere for bobcats and wildlife in North America generally, human activities, and specifically vehicles, were the predominant source of mortality we documented (Hill et al., 2019; Serieys et al., 2015). Secondly, notoedric mange, which has been linked with AR exposure in 99% of investigated cases in California bobcats (Serieys et al., 2015), was another prominent source of mortality; in Aromas Hills, it even eclipsed vehicle collisions as the leading source of mortality. We were unable to statistically model cause-specific mortality and survival on our mortality data given that: i) our sample size of tagged mortalities was low, and ii) untagged opportunistic mortalities may bias our findings.

Bobcat deaths from vehicles and mange in our study areas attest to

the multiple harmful edge effects wildlife experience in human-dominated landscapes (Hill et al., 2019). The prevalence of mortality due to notoedric mange associated with rodenticide exposure was unexpected and demonstrates that in vulnerable landscapes, cryptic threats to functional connectivity cannot be overlooked. The deadly spillover of common pesticides into natural populations is more prevalent than frequently recognized because it can easily go undetected (Berny, 2007). Rodenticide exposure for sampled bobcats was high (94%) even though the California Department of Pesticide Regulation restricted the use of second-generation anticoagulant rodenticides in 2014 to reduce harm to wildlife (section 6471, Title 3, California Code of Regulations, [www.cdpr.ca.gov](http://www.cdpr.ca.gov)). The observed prevalence was consistent with that found in a more extensive study of bobcats (88% of livers, n = 172) in southern California prior to these new regulations (Serieys et al., 2015). Clearly, these restrictions were insufficient to protect our study population from ongoing harm. While overall exposure rates were similar between the two studies, one critical difference is that we detected first-generation ARs (diphacinone) in every sample while the prior study recorded first-generation ARs in fewer than half of all exposed bobcats. This suggests that end users reacted to the new regulations not by reducing the use of ARs but by substituting first-generation ARs for the restricted ones. Exposure was likely higher in Aromas Hills than in Coyote Valley due to intensive application of ARs in agricultural areas, which are far more extensive in the former. Even if bobcats avoid crop fields and orchards areas specifically, poisoned prey can travel to adjacent natural areas or riparian corridors that bobcats favor.

Anticoagulants, and diphacinone in particular, have been linked with immune dysfunction and altered gene expression in bobcats (Fraser et al., 2018; Serieys et al., 2018), and these consequences explain increased mange vulnerability. The altered immune function and gene expression associated with ARs highlights the complex nature of edge effects, and that certain edge effects can indirectly kill wildlife through altered immunity and disease dynamics. Yet negative effects of ARs are not limited to bobcats. Just in California, ARs have directly killed predators that include bobcats, pumas (Benson et al., 2019), coyotes (Riley et al., 2003), gray foxes (*Urocyon cinereoargenteus*, Riley, NPS Unpubl. data), San Joaquin kit foxes (*Vulpes macrotis*; Cypher et al., 2014), fishers (*Pekania pennanti*; Gabriel et al., 2012), barn owls (*Tyto alba*), Cooper's hawks (*Accipiter cooperii*), great horned owls (*Bubo virginianus*), red-shouldered hawks (*Buteo lineatus*), striped skunks (*Mephitis mephitis*), and Turkey vultures (*Cathartes aura*; California Fish and Wildlife Unpubl. data). Wildlife exposure to pesticides demands intervention if managers want to maintain or restore ecological connectivity near the wildland-urban or wildland-agricultural interface.

#### 4.4. Conservation and management implications

Our movement data have already guided parcel acquisition of a key habitat patch in Coyote Valley, thus successfully aiding in restoring one "last-chance" corridor. Our functional response and habitat selection analyses for vegetation indicates that in barren agricultural fields that undergo rehabilitation, faster growing shrubs (as opposed to slow-growing oak trees) can be used to more quickly add complex vegetation to the landscape and thus rapidly restore a matrix component to natural habitat. Our study thus offers a compelling example of how rigorous data collection and analysis of animal behavior can focus highly targeted conservation actions. Moving forward, by recognizing the effects of vegetation and infrastructure on connectivity, considerable capacity exists to reduce mortality and to restore and preserve movement corridors, and corresponding gene flow within Coyote Valley and Aromas Hills. The lessons learned here apply more broadly to bobcats and other highly mobile terrestrial predators across the urban-wildland interface of North America.

The findings that anthropogenic and natural landscape features can exert strong influence on bobcat movement are a cause for both concern and optimism. Although matrix components that include crops, roads,

and medium-high-density housing impede bobcat movement, culverts, low-density housing, and the restoration of trees and shrubs can mitigate these effects even in broadly-transformed landscapes. Corridors can be very narrow so long as they contain shrubs and trees in addition to grass. Yet preserving structural connectivity alone will not conserve Santa Cruz Mountains wildlife. Functional connectivity requires healthy, abundant populations to generate fit dispersers (Pulliam, 1988). Exposure to people is poisoning wildlife and bobcat preferential selection of low-density housing and narrow corridors in agricultural fields is potentially luring them into toxic ecological traps. We investigated AR exposure in a single species, but repeatedly, research has found that where one species is affected, others are too (Gabriel et al., 2018; Riley et al., 2007). Further, these poisons threaten numerous endangered species (Benson et al., 2019; Cypher et al., 2014; Gabriel et al., 2012, 2018). Ongoing monitoring, local outreach to encourage reduced AR use, and alternative interventions, such as integrated pest management approaches, are needed to maintain functional connectivity for Santa Cruz Mountains wildlife populations.

Similarly, more must be done to reduce vehicle collisions. Our hot-spot analyses elucidate where road-crossing attempts are most likely, facilitating a targeted mitigation approach when prioritizing which culverts to retrofit or maintain as viable crossing structures. Retrofitting or maintaining culverts to prevent standing water could be a relatively simple solution to mitigate mortality. High median barriers were associated with increased mortality; the same barriers on the freeway edges could funnel animals toward available culverts. By bookending “safe-crossing” culverts with natural vegetation, some species may be encouraged to use them (Smith et al., 2015) while clearing vegetation along the roadside at dangerous crossing locations could deter crossing attempts.

Overall, we found substantial scope to reduce edge effects and preserve connectivity between the Santa Cruz Mountains and neighboring ranges even in the face of ongoing development. Specific actions to preserve these links beyond restoration of “last-chance” corridors are needed however; passivity will not succeed.

### Declaration of competing interest

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

### Data availability

Tracking data are available via the Movebank Data Repository (<http://www.movebank.org>).

David Waetjen, Ph.D., Programmer

Kathryn Harrold, Consultant

## Impact of Wildlife-Vehicle Conflict on California Drivers and Animals

Using observations of reported traffic incidents and carcasses the Road Ecology Center estimates the total annual cost of wildlife-vehicle conflict (WVC) in California to be at least \$276 million, up 20% from the year before. This report includes maps of WVC hotspots, discusses impacts to wildlife and people from WVC, and ranks highways in each Caltrans District for financial cost of WVC (spoiler, I-280 in District 4 is the costliest). Projects to reduce WVC can be the most effective of any safety project, with effectiveness often >90%. In addition, only 1-2% of California's transportation budget, including the new Senate Bill 1 funds, would be required to carry out these safety projects.

This report provides an overview of wildlife-vehicle conflict (WVC) hotspots on California highways in 2015 and 2016, based on a combination of traffic incidents involving wildlife that were recorded by the California Highway Patrol (CHP) and carcass observations reported to the California Roadkill Observation System (<http://wildlifecrossing.net/california>). Because Caltrans does not systematically record where they pick up the tens of thousands of wildlife carcasses per year they dispose of from state highways, these data are not included. Analytical details are available from Fraser Shilling ([fmshilling@ucdavis.edu](mailto:fmshilling@ucdavis.edu)) upon request.

## **Data collection acknowledgements**

This and previous reports and the analyses contained within would not have been possible without the concerted and coordinated efforts of hundreds of volunteer roadkill observers over the last 9 years who contribute to the California Roadkill Observation System (CROS, <http://wildlifecrossing.net/california>). Through their endeavors, they have collected >53,000 observations of >420 species, representing one of the largest and most comprehensive wildlife monitoring programs in California. Their accuracy rates for species identification are >97% and have measurably high locational accuracy (median  $\leq \pm 13$  meters). For scientific papers describing our roadkill/WVC work, see our published work cited below and at the end of this report (you can paste the “doi” value into a browser and access the papers). The report also benefited from the efforts of many unknown law enforcement personnel who described traffic incidents in enough detail that we can use their observations to help plan for reduced wildlife-vehicle conflict.

## **CROS is 9-Years Old, Published, & Globally Linked**

The Road Ecology Center at UCD is happy to announce that CROS is now 9 years old, and during this period, the volunteers have assembled an (ongoing) important dataset which can benefit California wildlife and drivers in the decades to come. We have also released a new journal article on CROS, published in the peer-reviewed journal *Frontiers of Ecology and Evolution*, covering the technical details of the project, including the accuracy of volunteer observations. The paper also covers details of our other project in Maine, called the Maine Audubon Wildlife Road Watch (<http://wildlifecrossing.net/maine>). Finally, we have partnered with other similar systems around the world in the Globalroadkill.net project (<http://globalroadkill.net>).

## The Authors

Fraser Shilling is the Co-Director of the UC Davis Road Ecology Center (<http://roadecology.ucdavis.edu>). He actively investigates the impacts of transportation systems on natural systems and human communities. He received his PhD in 1991 from the University of Southern California in the Division of Biological Sciences. Dr. Shilling directs the California Roadkill Observation System, the largest system in the world for volunteer observations of roadkill. David Waetjen is lead programmer and web guru for the Road Ecology Center. He received his PhD from UC Davis (Geography) in 2011. He develops web-systems and spatial analyses for wildlife, water, and sustainability applications. Kathryn Harrold is an independent wildlife consultant who is expert in how wildlife interact with roadways and how we can improve roads/highways to protect drivers and wildlife from conflict.

## Fourth Annual Special Report on the Impact of Wildlife-Vehicle Conflict (WVC) on California Drivers and Animals

### Top 5 Recommendations

1) Systematically collect data. The state data assembled here were not collected with the purpose of studying wildlife-vehicle conflict, the volunteer data were. California agencies should up their wildlife game and collect data about wildlife-vehicle conflict. This is especially true for Caltrans, which already collects and disposes of tens of thousands of wildlife carcasses annually, but does not record or report the data.

2) Require collection and analysis of wildlife-vehicle conflict data for highway/road projects, before they are approved and funded. Transportation and wildlife agency biologists have very little data upon which to base decisions for projects impacting wildlife and their habitat. Highway projects that are likely to increase WVC can be approved and built because these data are not required.

3) Protect driver safety and wildlife by building WVC-reduction projects. Very few driver safety projects have the overall effectiveness that WVC reduction projects do. There are hundreds of places on state highways and major roads where WVC is a priority, but statewide only 2-3 projects are built per year. We need ten times that rate in order to reduce risk to both drivers and wildlife.

4) Use our vast transportation resources to support this critical need. New funds from Senate Bill 1, \$5.3 billion annually, along with existing transportation project funds mean that we could easily build 10 times as many large WVC reduction projects per year, but we choose not to.

5) Systematically evaluate how well we are doing with WVC reduction so that we can keep improving. As we plan and build WVC reduction, we should transparently monitor reduced driver injuries and death and use of the structures by wildlife.

### Introduction

Using California state data on traffic incidents, the Road Ecology Center has mapped stretches of California highway that are likely to be hotspots for wildlife-vehicle conflicts (WVC). Animals entering roadways are often killed and pose a hazard to drivers, who may collide with the animal, or try to avoid the animal and have an accident suffering vehicle damage, injury, and even death. We estimated the total annual cost to society from >7,400 WVC incidents in

California on state highways and a small proportion of major roads to be ~\$276 million for 2016, which is a 20% increase over 2015. **It is important to note that this report does not cover ALL incidents in California, just the ones reported by the CHP and California Roadkill Observation System (CROS).** Allstate Insurance Co. estimates that California had >23,000 claims/year for collisions with wildlife in 2015-2016, which is >3 times the rate we describe here and if included, would result in a total cost to society of >\$500 million/year. Wildlife populations may suffer significant losses due to collisions and highways with high rates of WVC may cause ripple effects into surrounding ecosystems. In addition, animals are injured during collisions, which is damaging to the animal and potentially traumatic and life threatening to drivers.

By identifying stretches of highway where WVC are more likely, the Road Ecology Center is assisting Caltrans and other responsible entities in developing mitigation to protect drivers and wildlife populations. Measures with proven effectiveness include building fencing and over/under-passes along priority highways to allow the safe passage of wildlife across highways and reducing speed limits in protected wildlife habitat. According to Caltrans and California Highway Patrol statistics, there are >7,000 reported accidents per year on California highways involving deer and other wildlife. We estimate that there are another few thousand with horses, cows, sheep and goats.

For the second year analyzing CHIPs data, we have determined rates and locations of both animal carcasses and reported traffic incidents. These incidents could be reports of animals running across the road, collisions with animals (primarily deer), or accidents resulting from people swerving to avoid a collision with an animal in the road. Our analyses include identification of geographical hotspots and calculated costs to the public from vehicle damage, injury and even death. This information shows where there are problems and should help in developing safety projects to fix these known problem areas.

The following sections include maps of the distribution of WVC densities, projected costs of WVC and hotspots along state highways and other roadways. The densities of WVC reported are the minimum for each highway segment and do not represent actual rates, which are likely to be much higher. By significantly increasing the systematic treatment of these hotspots and stretches of highway with high rates of collisions, Caltrans and other entities can contribute cost-effectively to driver safety and improve the environmental sustainability of state highways.

## Methods

### Traffic Incidents

Records of traffic incidents between February 2015 and February 2017 were obtained from state databases of traffic incidents (e.g., emergency responses to crashes), included in our customized “California Highways Incident Processing system” (CHIPs), and coded according to severity of the incident for the drivers/vehicles and for the animals. We separated the ~13,000 records of wildlife-vehicle collisions from the ~1.4 million traffic incidents using customized term queries (e.g., for “deer” AND “buck” AND “doe” AND “fawn”). We reviewed each record for information about fate of the animal, fate of the driver, type of accident (collision vs. swerve), and vehicle damage. Location and date/time information were from the record.

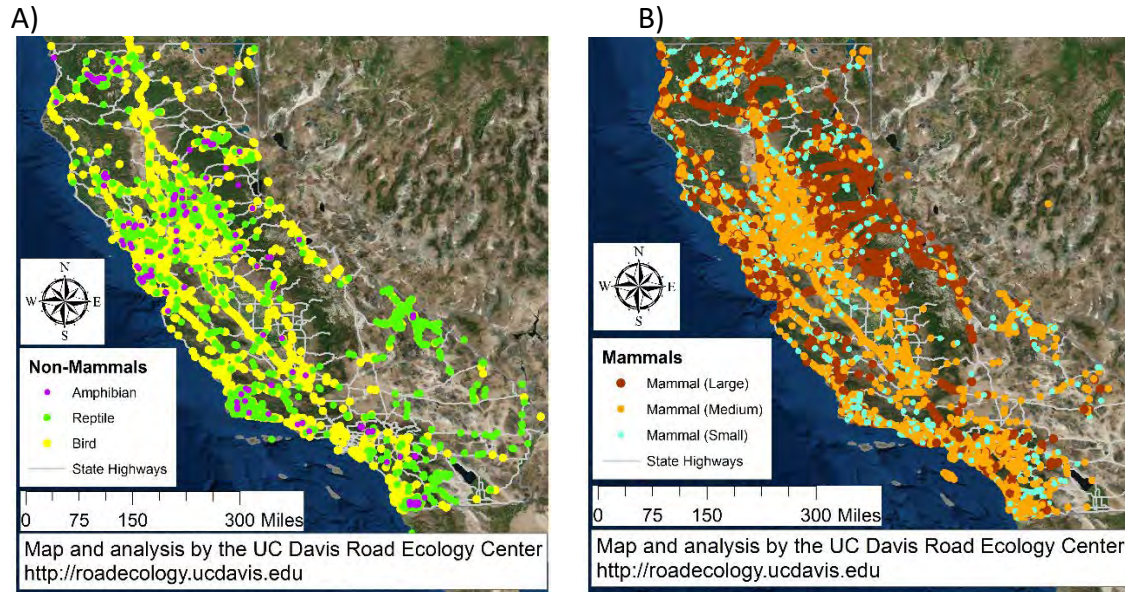

The California Roadkill Observation System project (<http://wildlifecrossing.net/california>) includes past and current participation by over 1,000 volunteer-scientists, including several hundred academic, agency, and NGO biologists and natural historians (Shilling and Waetjen, 2017). More than 53,000 WVC observations were contributed to the website by volunteers between August 2009 and the end of 2016 and by Caltrans Maintenance staff for the period 1987 to 2007. We selected recent observations of large-animal carcasses (last two years) and combined these observations with the CHP crash data.

The carcass observations and traffic incidents were used in a geographic information system (GIS) to identify stretches of highway where WVC occur more frequently (high density) and places where there are statistically-significant clusters of WVC (hotspots; Shilling and Waetjen, 2015). Density was calculated as number of incidents/mile and by using the Kernel Density Estimator (KDE) tool in ArcGIS. Hotspots were identified using spatial autocorrelation tests (Morans I, Getis-Ord, and KDE plus). Estimates of costs to society of incidents were calculated using the nature of the incident (e.g., “minor injury”) and coefficients for the average cost of these types of incidents used by the US Department of Transportation (USDOT, 2013).

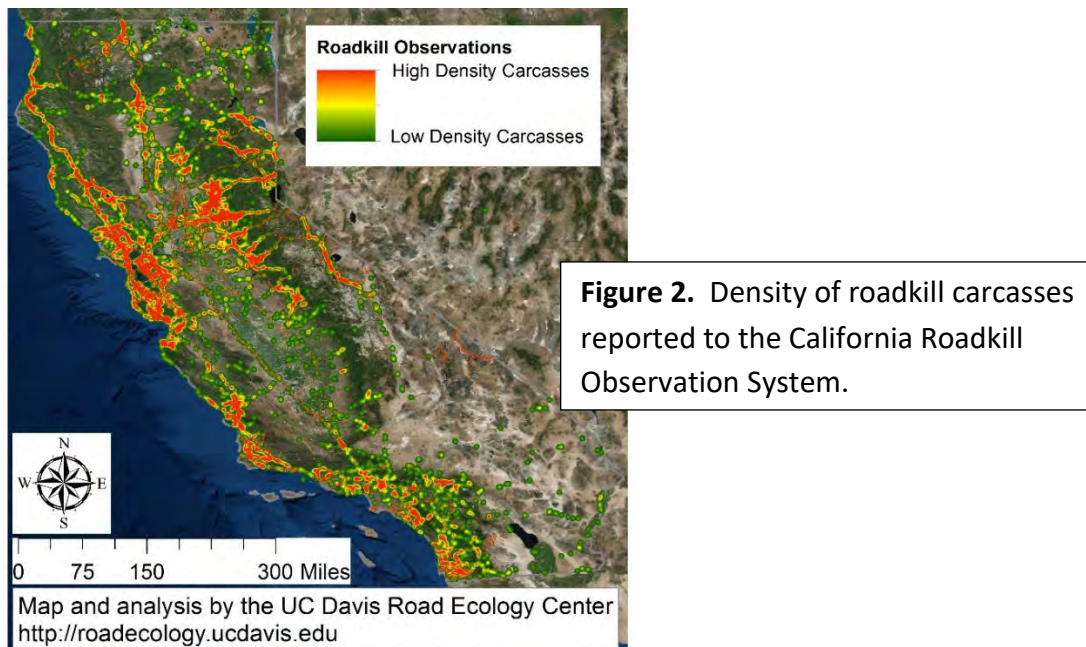

## Major Findings

### Statewide Carcass Observations

The maps below show >53,000 observations of animal carcasses on local roads and state highways (Figure 1) and the density of carcasses across the state (Figure 2). These are not the total roadkill that occurred, just the ones that people saw and reported to the California Roadkill Observation System (CROS) between 2009 and 2016.

**Figure 1.** Carcass observations for (A) amphibians, reptiles, and birds; and (B) mammals of various sizes.

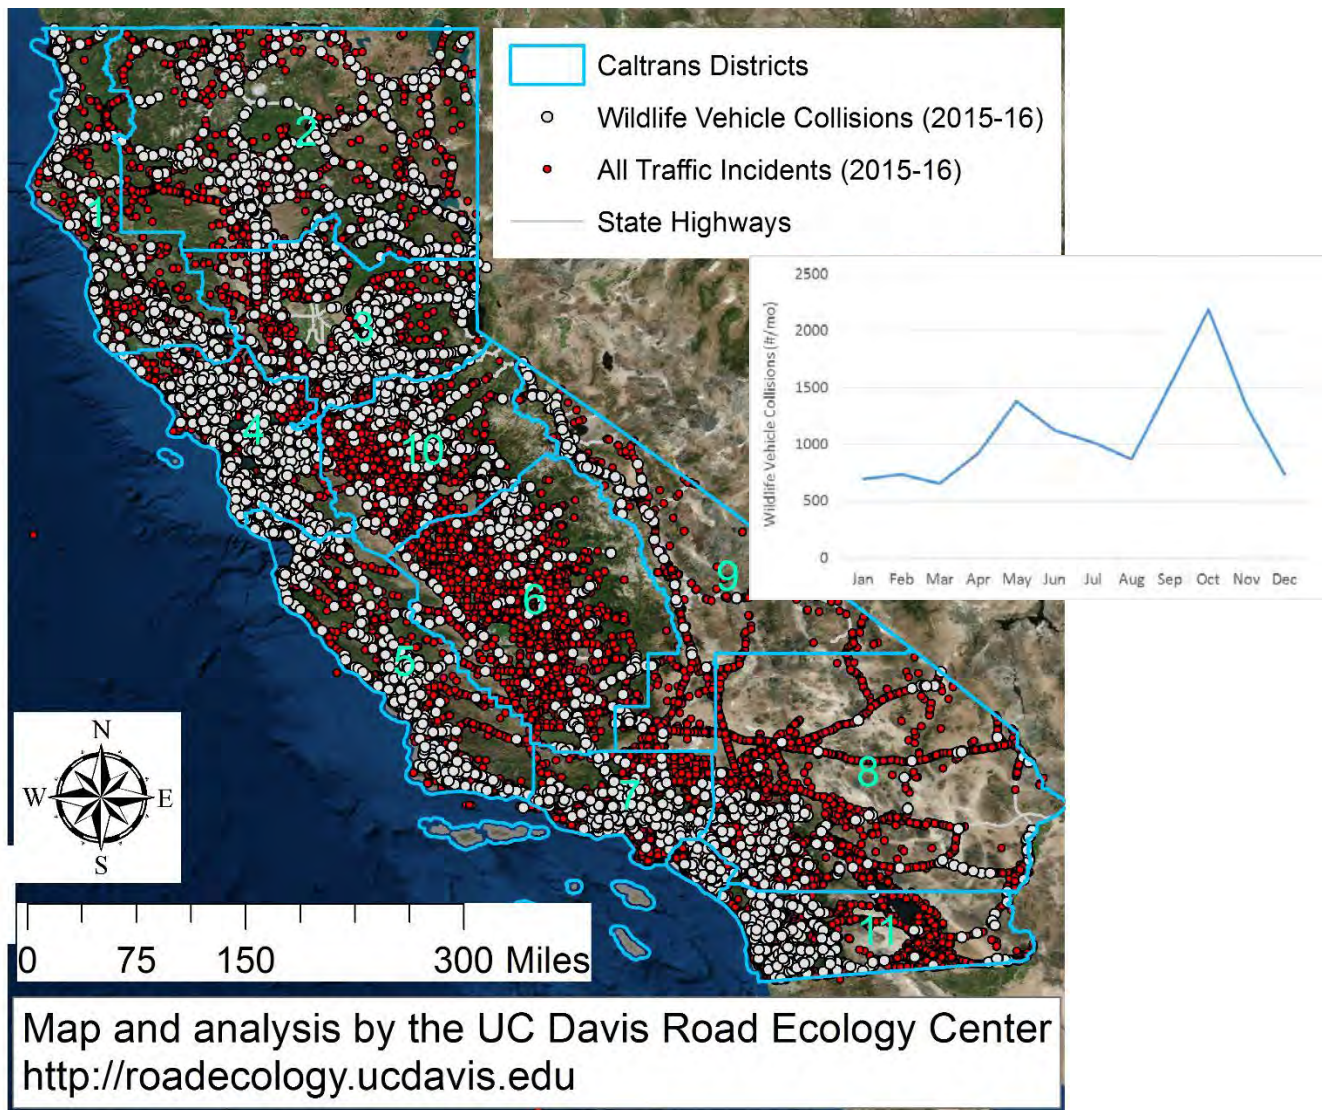

**Figure 2.** Density of roadkill carcasses reported to the California Roadkill Observation System.

## Statewide Highway Traffic Incidents

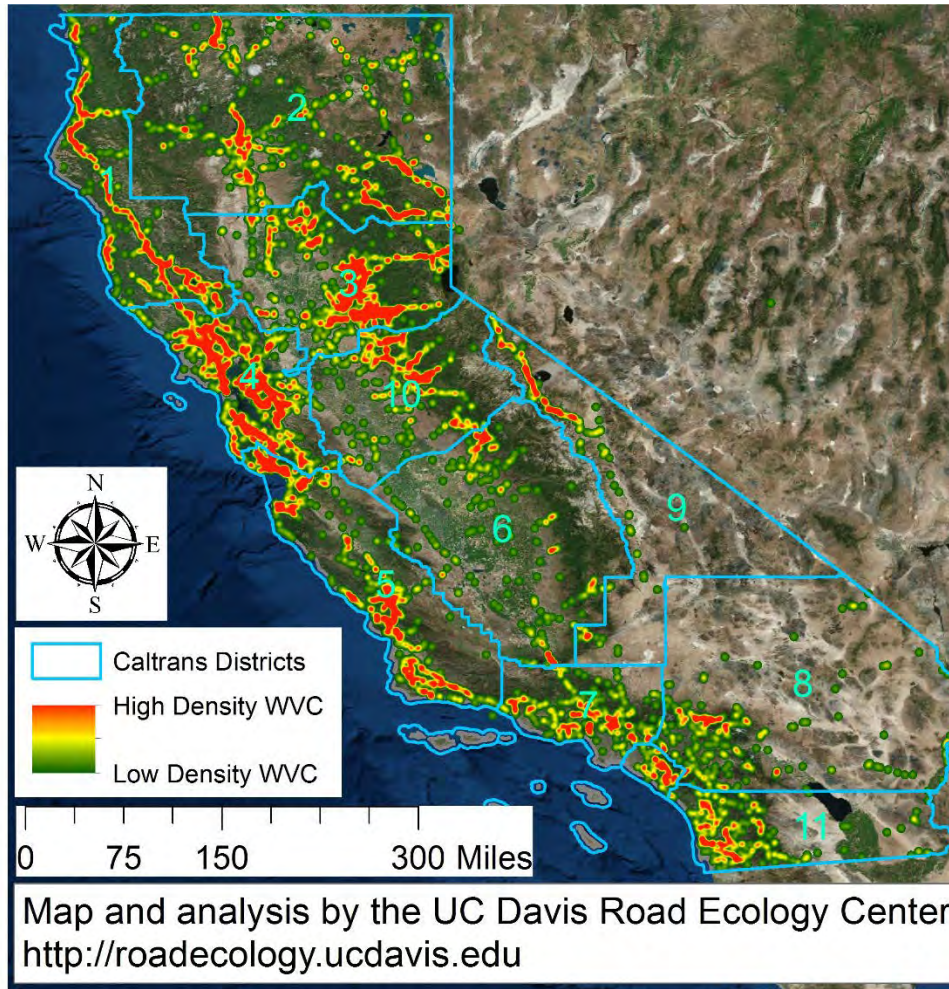

There were at least 1.4 million traffic incidents (of all types) across California reported to the California Highway Patrol in 2015 and 2016 (Figure 3, All Traffic Incidents). Of these, about half were collisions and more than 13,000 involved wildlife, including reports of animals standing next to, standing in, or running across roadway lanes, collisions with large animals, and swerving to avoid collisions, resulting in a crash (Figure 3, Wildlife Vehicle Collisions). October was the most dangerous month for conflict, with about twice as many incidents as other months (inset graph). This may be because of increased movement related to mating season and seasonal migration.

**Figure 3.** All traffic incidents (dark symbols) and those involving wildlife (white symbols) in the California Highways Incident Processing system (CHIPS) for 2015 and 2016. Caltrans districts are numbered and outlined in blue. Inset graph: number of WVC per month for 2015 - 2016.

## Statewide Wildlife-Vehicle Conflict Hotspots

Although WVC occur everywhere in California, the highest densities were reported in the San Francisco Bay Area (Caltrans District 4), Sierra Nevada Foothills (Caltrans Districts 3 & 10), North Coast (Caltrans District 1), and parts of the Central/South Coast (Caltrans Districts 5, 7, 11 & 12). These high-density areas are most likely where traffic volumes and wildlife populations are greatest, leading to more conflict. The map below shows the density of collisions with large wildlife in California (Figure 4).

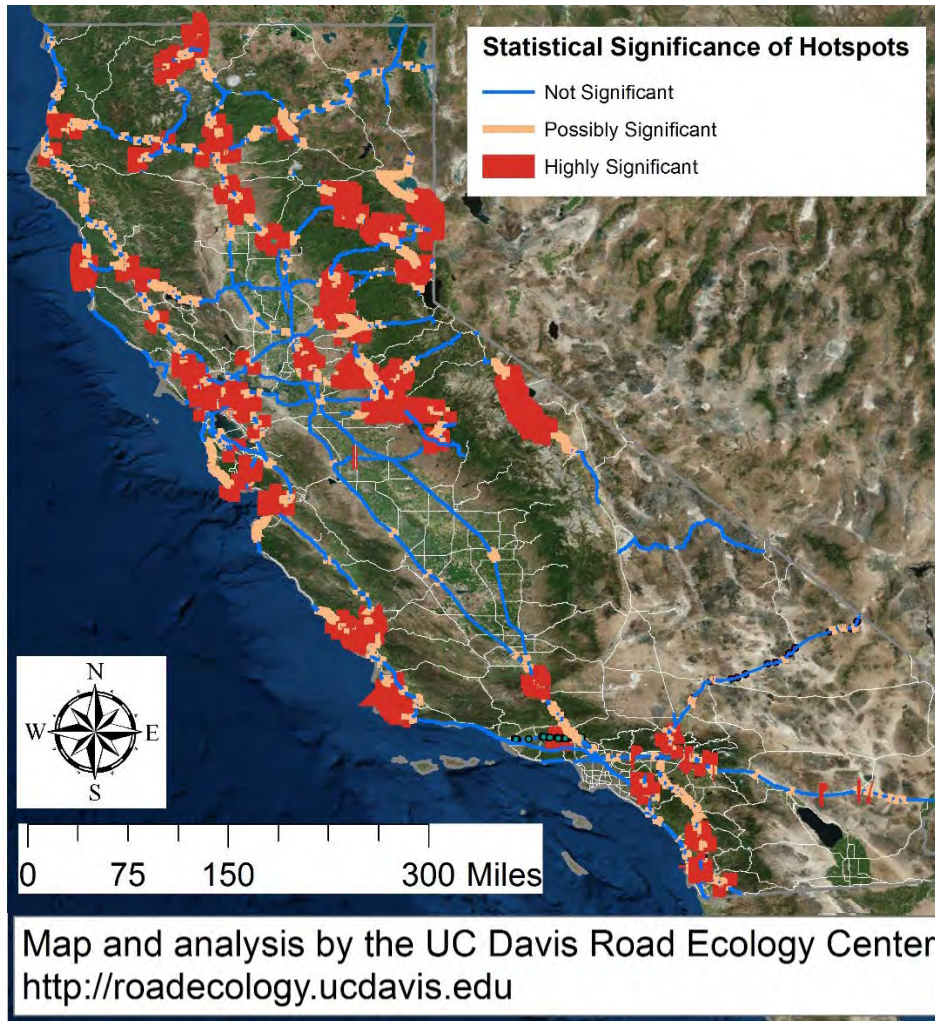

**Figure 4.** A) Density of all WVC for 2015 and 2016.

In order to inform statewide decision-making about resource-distribution to reduce WVC, we mapped the density of WVC across all highways/roadways (Figure 4). In order to inform decision-making about specific highways, we also mapped statistically-significant clusters of points along highways with the highest rates of WVC (Figure 5, below). For many highways,

there are back-to-back clusters of WVC, resulting in entire stretches of highway being highlighted as a hotspot (e.g., highway 395 on the east-side of the Sierra Nevada).

**Figure 5.** Statistically-significant hotspots for collisions of vehicles with large mammals on certain highways.

### Consequences of Collisions to Drivers and Society

Records analyzed show some individual drivers involved in collisions with animals, or who drive by injured animals and report them, experience emotional trauma and if the animal is larger, also face damage to their vehicle and injury (or even death) to themselves. Drivers may either collide with the animal, or swerve to avoid the animal and become involved in a collision with another vehicle or object (Table 1). We estimated the total cost of all WVC incidents to society, using summaries of types of accident (e.g., property damage only, major injury), the loss of

wildlife, and coefficients for each of these types of loss. Equivalent costs for accident types were obtained from the US Department of Transportation (USDOT, 2013) and a related project in South Dakota (Cramer et al., 2016). Because the number of fatalities may not be accurately reported in data obtained from state resources, we used an average value for California in 2015 (5.3/year, average 2005-2014) of the number of fatalities per year from collisions with wildlife, obtained from the Insurance Institute for Highway Safety (<http://www.iihs.org/iihs/topics/t/roadway-and-environment/fatalityfacts/fixed-object-crashes>, accessed 9/13/2016). In 2016, 5 fatalities were reported in crashes with wildlife.

The rates of property damage, injury and death reported here are probably underestimates and may be superseded by more detailed information from state sources. For example, Allstate Insurance Co. estimates that there were >23,000 claims/year for collisions with deer in 2015-2016, whereas our calculations are based on >7,000 reported collisions during this time period. If these additional 16,000 collisions resulted in the same average property-damage-only cost as used below (USDOT, 2013), there would be an additional >\$312 million cost to society (16,000 times \$17,343/crash), resulting in a total estimated cost to society from WVC of ~\$588 million/year.

From 2015 to 2016, we found an increase of ~20% in cost to society from WVC. This does not reflect a change in how the calculation was conducted, but instead an increase in the number of collisions. For example, there was a 25% increase in injury accidents from 2015 to 2016.

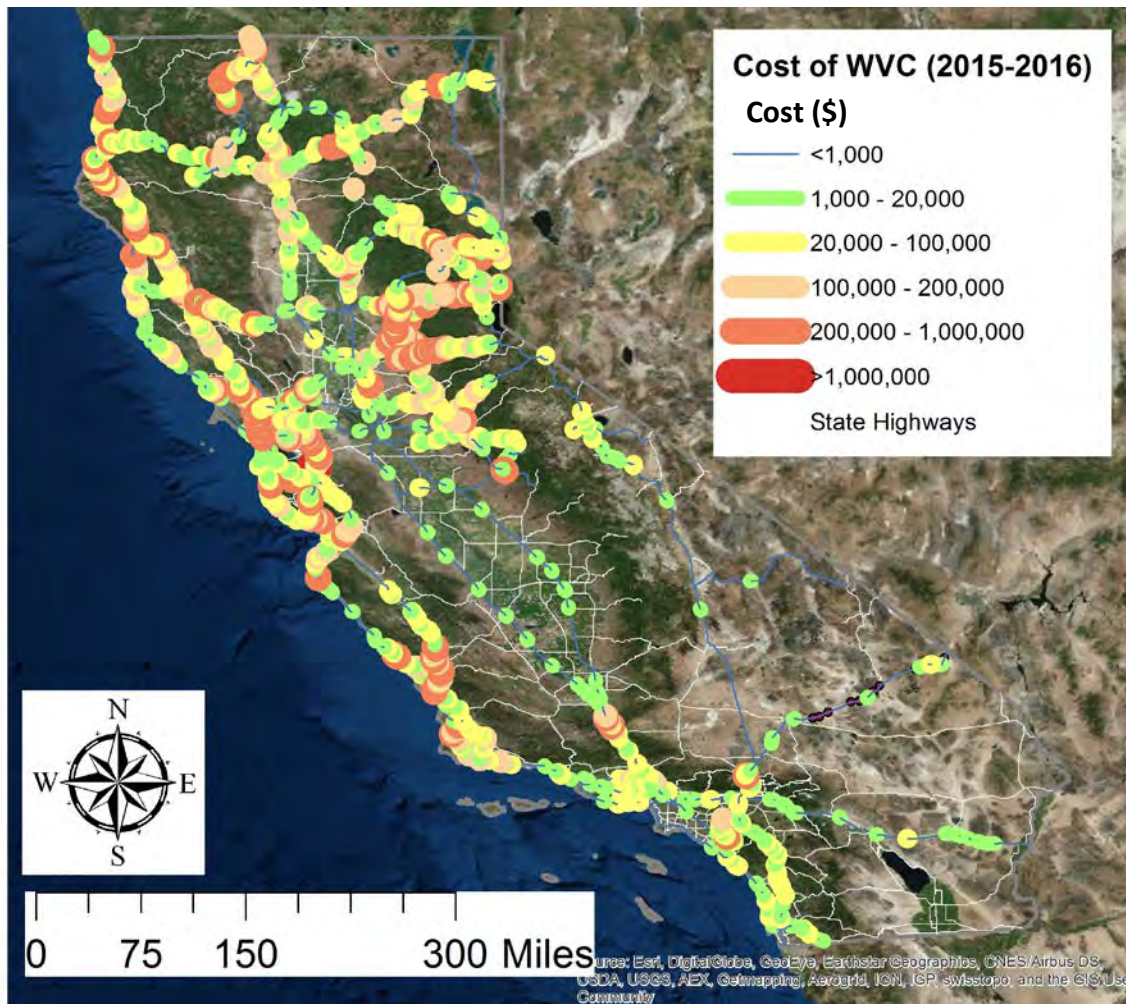

**Table 1.** Impact to drivers and estimated cost to society of reported collisions with animals on California highways and certain major roads. Equivalent costs for accident types were obtained from the US Department of Transportation (2013).

Type of Accident	Coefficient (cost as \$/event)	Number (2015/2016)	Cost 2015	Cost 2016
Lost animal value (all animals)*			\$36,165,000	\$37,733,000
Collision/Swerve (property damage)	\$17,343	5,368/7,479	\$94,467,321	\$130,055,157
Injury (minor)	\$105,228	235/285	\$24,771,329	\$30,011,602
Injury (major)	\$506,217	44/62	\$22,067,897	\$31,281,437
Fatality	\$9,395,247	5.3*/5	\$49,794,809	\$46,976,235
<b>Total</b>			<b>\$224,619,659</b>	<b>\$276,057,431</b>

\* This value includes both reported and estimated un-reported carcasses. Others have reported under-reporting rates for carcasses from collisions of 5-10 fold (e.g., Olson et al., 2014).

\*\* Average CA fatality rate from collisions with animals for 2005-2014

To aid Caltrans and county transportation agencies in mitigating costly WVC incidents, we mapped the cost per mile of WVC for select highways (Figure 6). To put the costs and corresponding colors into perspective, fencing of any highway segment in light orange to red would pay for itself within 1 to 4 years through reduced collisions. Fencing highway segments in yellow would pay for itself in 4 to 20 years. In both cases, the fencing would stretch from one logical end-point (e.g., bridge) to another, so actual costs would vary. Previous research has shown that fencing and crossing structures can reduce collisions >90% when fencing is maintained. In the Bay Area, long stretches of I-280, I-680, and US-101 could be fenced and significant cost-reductions (and reduced injury and death for people and animals) realized through reductions in WVC.

**Figure 6.** Cost of WVC per mile for select highways in California.

## Consequences of Collisions to Large Mammals, Animal Populations & Individual Animals

The majority of reported traffic incidents involving an animal (Figure 3) were with Mule deer (*Odocoileus hemionus*, 89%, Table 2), though at least 5 other mammals were also reported. In addition, these are just species and number of animals that were included in a CHP incident report. Others have reported under-reporting rates of collisions with ungulates (e.g., deer) of 5 to 10 fold (Donaldson and Lafon, 2008; Olson et al., 2014). This suggests that as many as 25,000 to 50,000 mule deer were killed during collisions in 2015 and an unknown number of other species. This is supported by the Allstate Insurance Co estimate of >23,000 claims/year for collisions with deer in California, where collisions are likely to occur more often than claims.

**Table 2.** The types and number of each type of wildlife involved in traffic incidents reported to CHP in 2016.

Wildlife type	Number	% of Total
Mule deer	6,119	89%
Coyote	377	9%
Black bear	135	2%
Elk	44	<1%
Mountain lion	43	<1%
Wild pig	21	<1%

For people who have collided with an animal, some will have observed that the animal does not always die immediately. We found that 21% (n=1,431) of animals involved in incidents were reported as injured by responding law enforcement (Table 3). There were an additional 30% (n=2,048) with an unknown fate after being involved in a traffic incident. We have found previously that as many as 40% of all animals could have been injured during the traffic incident. Only 131 animals were reported as dispatched by responding law enforcement officers, meaning that the remaining injured and some portion of the “unknown fate” animals stayed injured following the collision. This may still be an under-estimate of the total as there has been shown to be chronic under-reporting of collisions with ungulates, such as deer, in the US (Donaldson and Lafon, 2008; Olson et al., 2014).

**Table 3.** Animal outcomes following collisions with vehicles in 2016.

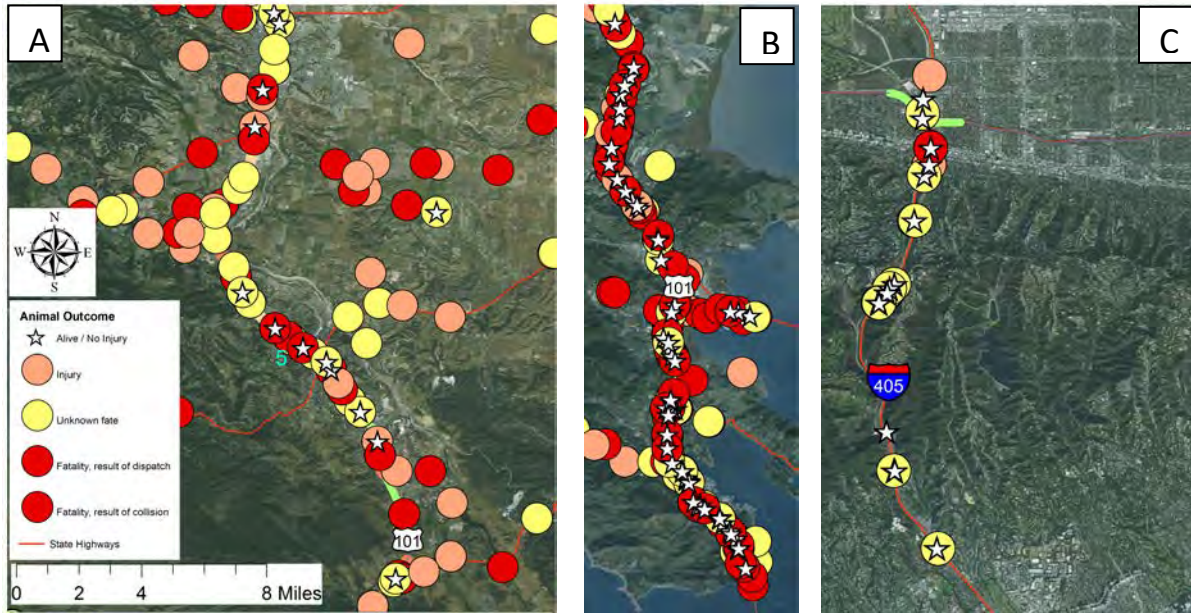

<b>Animal Outcome</b>	<b>#</b>	<b>%</b>
Unknown fate	2,048	30%
Alive / No Injury	500	7%
Injury	1,431	21%
Fatality, result of collision	2,618	39%
Fatality, result of dispatch	131	1.9%
Total	6,728	

These findings raise the question of whether these incidents where animals are injured in a collision are covered by California’s statutory definition of animal cruelty (California Penal Code, Sec. 597) which defines cruelty as including where animals are “mutilated, or cruelly killed” or where any animal is subject to “needless suffering”. Typically, wildlife are exempted from these statutes because they may be otherwise hunted and killed. However, the cruelty exemptions (Sec. 599c) cover permitted/licensed killing of game animals (e.g., for food) and not killing in general. Drivers are not being accused of being cruel, but it will help them as much as animals to do everything possible to prevent the collision and therefore stop the resulting cruelty.

A possible solution to this problem would be for the state to create a hotline where drivers can report an injured animal for potential rehabilitation, or in extreme cases, dispatch by CHP.

### **Where There is Smoke, There is Fire**

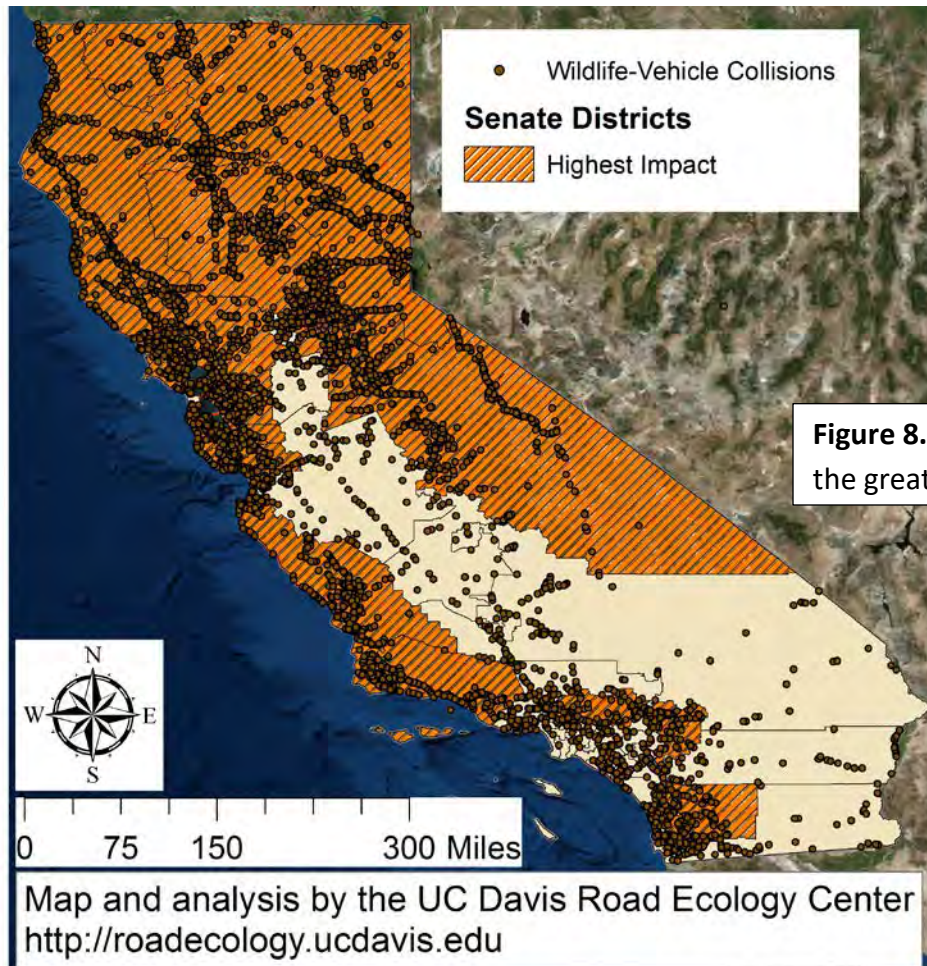

One way to predict where WVC might occur in the future, and therefore prevent it, is to record collisions and the presence of dead animals. Another possibility is to investigate where live animals occur near highways, before they are hit. We compared the observations by CHP officers of live animals (primarily deer) with reports of dead animals and collisions of vehicles with animals. In many cases, if a live animal was reported present and adjacent to traffic lanes, collisions occurred later in the same area (Figure 7). This suggests that after a live animal is observed on the roadside, there is a risk that the animal may try to cross the road and become involved in a collision with a vehicle. This relationship seems weakest in rural areas (Figure 7A) and strongest near urban centers (Figure 7B,C).

**Figure 7.** Comparison of observations of live (stars) and injured/dead (circles) animals on or adjacent to highways. A) US 101 north of San Luis Obispo. B) US 101 immediately north of Golden Gate Bridge (Marin County). C) I-405 south of Sherman Oaks in the Los Angeles area.

## Regional Focus

The need for projects that reduce the risk to driver safety and lives, property damage, and impacts to wildlife is critical. Building these projects will require a combination of Caltrans, county, regional, and legislative action and funding. From this point of view, it is important to understand where these impacts and costs are greatest. In general, anywhere drivers and wildlife habitat are near each other, there is some risk of WVC. This risk is greatest when there are more drivers driving fast through or near wildlife habitat, such as the San Francisco peninsula, the Sierra Nevada foothills and the hills surrounding the Los Angeles basin. The map below shows the 15 California Senate districts where 90% of the cost and impact are located (Figure 8). Five of these districts have Republican senators and 10 have Democrat senators, suggesting that the problem and funding solutions are both bipartisan.

**Figure 8.** Senate Districts with the greatest impact from WVC.

The following sections highlight 3 regions in California, showing the top highway segments in each region for WVC and providing an estimate of how quickly projects designed to reduce WVC would pay for themselves.

## San Francisco Bay Area, Regional Highway Hotspots

This map shows the cost and clustering of WVC traffic incidents on select highways in the San Francisco Bay region (Figure 9). There are segments of highways that have rates and costs of WVC that mean if safety projects, such as fencing and wildlife crossings, were undertaken, they would pay for themselves through reduced WVC (Table 4). This is especially true for I-280, the fencing of which would pay for itself in less than 1 year due to reduced WVC.

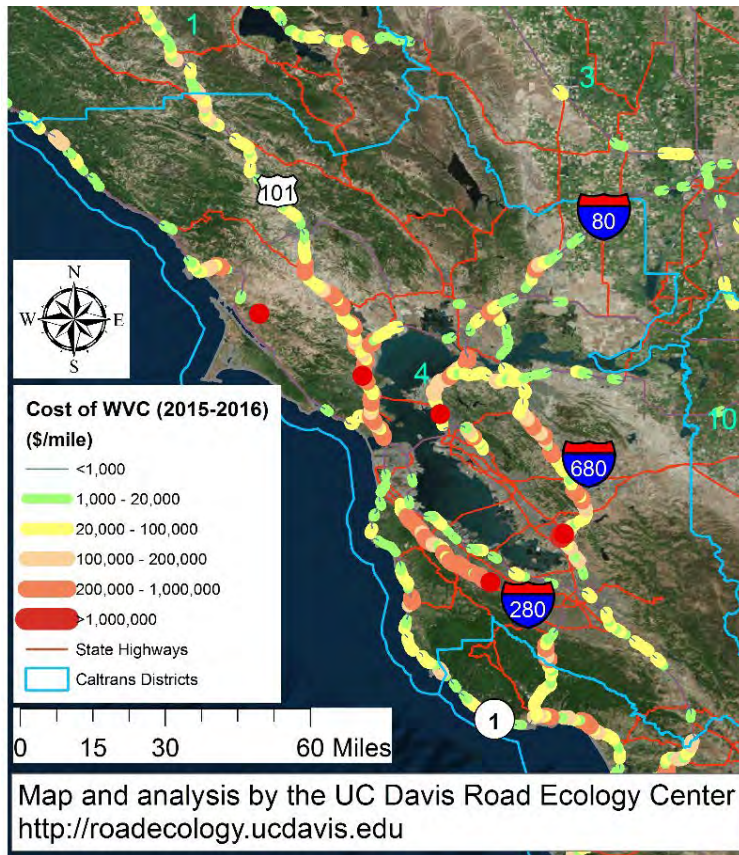

Figure 9. Cost (\$/mile) of WVC for select highways in the San Francisco Bay Area/Caltrans District 4.

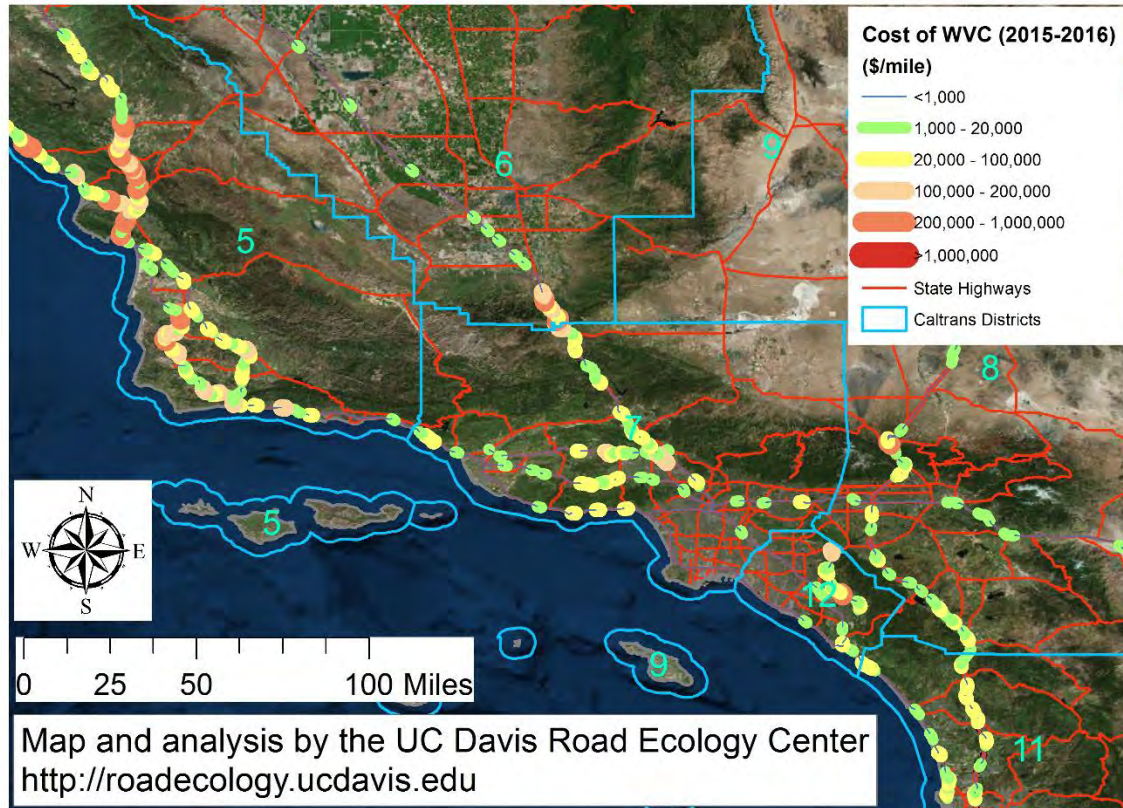

Table 4. Cost-effectiveness of WVC mitigation action on Bay Area highways, fencing only. New crossing structures would cost an additional 2-10 million for most highways in list. Enhancing existing structures would cost less.

Highway	Injury/Property Damage (#)	Injury/Fatal (#)	Two-year cost (\$)	Length (miles)	Cost/mile	Years to Pay Off (Fence)
I-280	386	26	\$20,113,971	23	\$874,520	0.5
SR101 (Marin Co)	225	11	\$14,700,264	28	\$525,009	0.8
SR13	81	4	\$1,996,915	6.5	\$307,218	1.3
SR24	114	4	\$2,569,234	11	\$233,567	1.7
I-680	221	6	\$13,950,875	72	\$193,762	2.1
SR9	119	7	\$3,039,900	20	\$151,995	2.6
SR17	62	2	\$1,712,173	27	\$63,414	6.3
I-80	129	5	\$2,977,412	57	\$52,235	7.7
I-580	55	4	\$1,545,997	30	\$51,533	7.8
SR1	142	6	\$3,290,756	85	\$38,715	10.3

## Southern California, Regional Highway Hotspots

This map shows the cost and clustering of WVC traffic incidents on select highways in Southern California (Figure 10). There are segments of highways that have rates and costs of WVC that mean if safety projects, such as fencing and wildlife crossings, were undertaken, they would pay for themselves through reduced WVC (Table 5).

**Figure 10.** Cost (\$/mile) of WVC for select highways in the Southern California region/Caltrans Districts 5, 6, 7, 8, 11 & 12.

Table 5. Cost-effectiveness of WVC mitigation action on Bay Area highways, fencing only. New crossing structures would cost an additional 2-10 million for most highways in list. Enhancing existing structures would cost less.

Area/Highway	Injury/Property Damage (#)	Injury/Fatal (#)	Two-year cost (\$)	Length (miles)	Cost/mile	Years to Pay Off (Fence)
SR2	33	2	\$868,385	6	\$144,731	2.8
US101	13	11	\$3,581,108	26	\$137,735	2.9
I-405	38	0	\$659,034	8	\$82,379	4.9
I-5	49	1	\$997,840	15	\$66,523	6.0
SR134	18	1	\$460,207	7	\$65,744	6.1
SR154	38	3	\$1,103,133	19	\$58,060	6.9
SR33	17	1	\$442,864	8	\$55,358	7.2
SR118	19	1	\$417,402	8	\$52,175	7.7
SR74	31	4	\$1,129,765	23	\$49,120	8.1
SR1	75	4	\$1,892,857	47	\$40,274	9.9

## Sierra Nevada Foothills, Regional Highway Hotspots

This map shows the cost and clustering of WVC traffic incidents on select highways in the Sierra Nevada foothills (Figure 11). There are segments of highways that have rates and costs of WVC that mean if safety projects, such as fencing and wildlife crossings, were undertaken, they would pay for themselves through reduced WVC (Table 6).

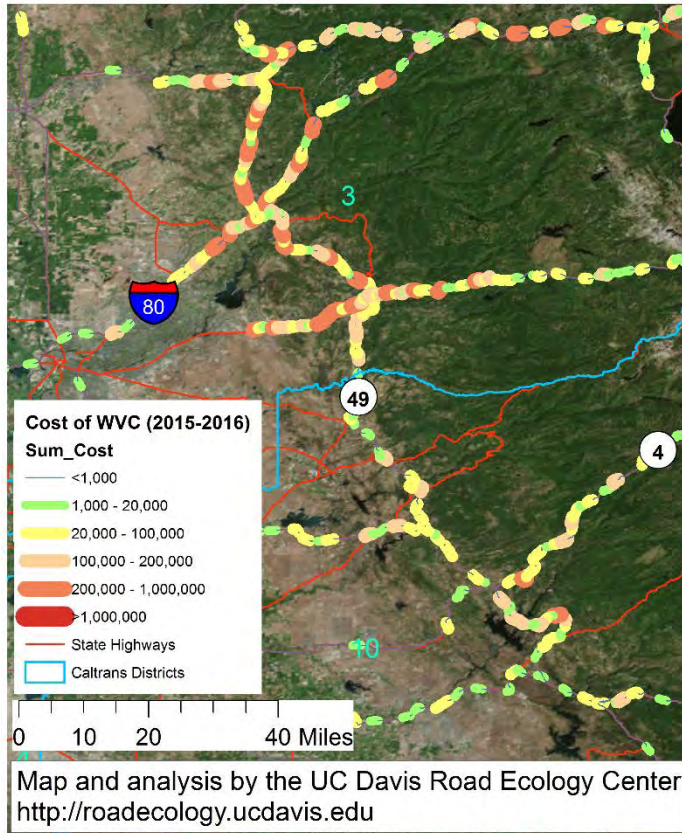

Figure 11. Cost (\$/mile) of WVC for select highways in the Sierra Nevada foothills/Caltrans Districts 3 & 10.

Table 6. Cost-effectiveness of WVC mitigation action on Sierra Nevada Foothill highways, fencing only. New crossing structures would cost an additional 0.5 to 1 million for most highways in list. Enhancing existing structures would cost less.

Highway	Injury/Property Damage (#)	Injury/Fatal (#)	Two-year cost (\$)	Length (miles)	Cost/mile	Years to Pay Off (Fence)
SR174	75	5	\$2,381,731	11	\$216,521	1.8
SR50 (West)	245	15	\$6,409,382	54	\$118,692	3.4
SR108	107	3	\$2,179,504	22	\$99,068	4.0
I-80	154	12	\$4,266,774	49	\$87,077	4.6
SR44	67	4	\$1,693,965	25	\$67,759	5.9
SR49	310	22	\$8,452,612	133	\$63,553	6.3
SR20	82	8	\$2,486,094	45	\$55,247	7.2
SR88	49	3	\$1,380,621	25	\$55,225	7.2
SR41	74	3	\$1,607,185	35	\$45,920	8.7
SR4	54	3	\$1,380,621	38	\$36,332	11.0

# Impact of Wildlife-Vehicle Conflict on California Drivers and Animals

Using observations of reported traffic incidents and carcasses the Road Ecology Center estimates the total annual cost (2017) of wildlife-vehicle conflict (WVC) in California to be at least \$307 million, up 11% from 2016. The estimated cost could be as high as \$600 million if accidents that are claimed to insurance companies (but un-reported to police) were included. This report includes maps of WVC hotspots, discusses impacts to wildlife and people from WVC, and presents new tools to help organizations and individuals use this information. Projects to reduce WVC can be the most effective of any safety project, with effectiveness often >90%.

Data Sharing/Collaboration: We are always happy to share data and map outputs for people interested in reducing wildlife-vehicle conflict for driver safety and/or wildlife conservation. We receive requests from highway planners, fish and wildlife scientists, students, and non-governmental organizations on a weekly basis. We can typically meet data requests for specific highways, counties, etc., but please keep in mind that this is an unfunded effort of the Road Ecology Center, so we will try to get back to you within a few days.

We have developed a globally-unique web-tool to visualize WVC incidents in CA. It shows WVC hotspot areas throughout CA and a real-time display of WVC events. You can find the website here: <https://roadecology.ucdavis.edu/hotspots>.

This report provides an overview of wildlife-vehicle conflict (WVC) hotspots on California highways between 2015 and 2017, inclusive, based on a combination of traffic incidents involving wildlife that were recorded by the California Highway Patrol (CHP) and carcass observations reported to the California Roadkill Observation System (<http://wildlifecrossing.net/california>). Analytical details are provided here and are also available from Fraser Shilling ([fmshilling@ucdavis.edu](mailto:fmshilling@ucdavis.edu)) upon request. This report also introduces a new, public web-system that allows the public and transportation agencies to view our scientific results for both legacy/long-term hotspots analysis and real-time tracking of WVC incidents.

## **Data collection acknowledgements**

We appreciate the support from the National Center for Sustainable Transportation (using USDOT funding) for development of the automated wildlife-vehicle conflict hotspot tool described here and elsewhere. This and previous reports and the analyses contained within would not have been possible without the concerted and coordinated efforts of hundreds of volunteer roadkill observers over the last 9 years who contribute to the California Roadkill Observation System (CROS, <http://wildlifecrossing.net/california>). Through their endeavors, they have so far (9/2018) collected >58,000 observations of >420 species, representing one of the largest and most comprehensive wildlife monitoring programs in California. Their accuracy rates for species identification are >97% and have measurably high locational accuracy (median <±13 meters). For scientific papers describing our roadkill/WVC work, see our published work cited below and at the end of this report (you can paste the “doi” value into a browser and access the papers). The report also benefited from the efforts of many unknown law enforcement personnel who described traffic incidents in enough detail that we can use their observations to help plan for reduced wildlife-vehicle conflict.

## **CROS is 9-Years Old, Published, & Globally Linked**

The Road Ecology Center at UCD is happy to announce that CROS passed its 9<sup>th</sup> birthday, and during this period, the volunteers have assembled an (ongoing) important dataset which can benefit California wildlife and drivers in the decades to come. We have published our data and findings in the peer-reviewed journals Ecological Informatics, Nature Conservation, and Frontiers of Ecology and Evolution, covering the technical details of the project, including the accuracy of volunteer observations. Finally, we have partnered with other similar systems around the world in the Globalroadkill.net project (<http://globalroadkill.net>).

## The Authors

Fraser Shilling is the Co-Director of the UC Davis Road Ecology Center (<http://roadecology.ucdavis.edu>) and actively investigates the impacts of transportation systems on natural systems and human communities. He received his PhD in 1991 from the University of Southern California in the Division of Biological Sciences. Cameron Denney is a newly-graduated M.Sc. student in Geography at UC Davis and pioneered our new “automated hotspots” web-tool. David Waetjen is lead programmer and web guru for the Road Ecology Center. He received his PhD from UC Davis (Geography) in 2011. He develops web-systems and spatial analyses for wildlife, water, and sustainability applications. Kathryn Harrold is an independent wildlife consultant who is expert in how wildlife interact with roadways and how we can improve roads/highways to protect drivers and wildlife from conflict. Undergraduate and recently-graduated students Parisa Farman and Paola Perez are pursuing careers in wildlife biology and environmental policy.

## Fifth Annual Special Report on the Impact of Wildlife-Vehicle Conflict (WVC) on California Drivers and Animals

### Top 5 Recommendations

- 1) **Systematically collect and share data.** The state data assembled here were not collected with the purpose of studying wildlife-vehicle conflict, the volunteer data were. California agencies should collect and share data about wildlife-vehicle conflict to help inform decision-making about this important conservation and safety problem. We are open to partnering with Caltrans, California Department of Fish and Wildlife and others to accomplish this.
- 2) **Require collection and analysis of wildlife-vehicle conflict data for highway/road projects, before they are approved and funded.** Transportation and wildlife agency biologists have very little data upon which to base decisions for projects impacting wildlife. Highway projects that are likely to increase WVC can be built because these data are not required.
- 3) **Protect driver safety and wildlife by building WVC-reduction projects.** Very few driver safety projects have the overall effectiveness that WVC reduction projects do. There are hundreds of places on state highways and major roads where WVC is a priority, but statewide only 2-3 projects are built per year. Ten times that rate would make a dent in the apparent risk to both drivers and wildlife.
- 4) **Form new partnerships** among University and NGO scientists, citizen groups, and local agencies interested in reducing WVC impacts. Local and statewide partners can help advocate for diversion of transportation funds to improve ecological sustainability of transportation.
- 5) **Systematically evaluate how well we are doing with WVC reduction** so that we can keep improving. As we plan and build WVC reduction, we should transparently monitor reduced driver injuries and death and use of the structures by wildlife.

### Introduction

Using California state data on traffic incidents, the Road Ecology Center has mapped stretches of California highway that are likely to be continuing hotspots for wildlife-vehicle conflicts (WVC). Animals entering roadways are often killed and pose a hazard to drivers, who may collide with the animal, or try to avoid the animal and have an accident suffering vehicle damage, injury, and even death. We estimated the total annual cost to society from >6,600 WVC incidents in California on state highways and a small proportion of major roads to be ~\$307 million for 2017, which is an 11% increase compared to 2016. **It is important to note that this**

**report does not cover ALL incidents in California, just the ones reported by the CHP and California Roadkill Observation System (CROS).** State Farm Insurance Co. estimated that California had >23,000 claims/year for collisions with wildlife in 2015-2016 (<https://newsroom.statefarm.com/download/234883/allstates2015-16deerstats-finalpdf.pdf>), which is >3 times the rate we describe here and if included, would result in a total cost to society of ~\$600 million/year, which would be similar to costs in other states where total costs have been evaluated (e.g., VA, Donaldson, 2017). In addition, we counted 268 injury accidents in the CHP data we used, which is less than the 383 injury accidents Caltrans reported using CHP data in their press release for the 2018 press release (<http://www.dot.ca.gov/paffairs/pr/2018/prs/18pr072.html>). So, our study under-estimates the injury portion of the total cost of these types of accidents by ~1/3. This contrast also points to the need for a standardized system for California to collect and report these data. Wildlife populations may suffer significant losses due to collisions and highways with high rates of WVC may cause ripple effects into surrounding ecosystems. In addition, animals are injured during collisions, which is damaging to the animal and potentially traumatic and deadly to drivers.

By identifying stretches of highway where WVC are more likely, the Road Ecology Center is assisting Caltrans and other responsible entities in developing mitigation to protect drivers and wildlife populations. Measures with proven effectiveness include building fencing and over/under-passes along priority highways to allow the safe passage of wildlife across highways and reducing speed limits in protected wildlife habitat. Using CHP data, we have found records of >6,600 reported accidents per year on California highways involving deer and other wildlife. We estimate that there are another few thousand with horses, cows, sheep and goats.

For the third year analyzing CHP data, we have determined rates and locations of both animal carcasses and reported traffic incidents. These incidents could be reports of animals running across the road, collisions with animals (primarily deer), or accidents resulting from people swerving to avoid a collision with an animal in the road. Because deer activity adjacent to highways is correlated with rates of collisions with deer (Donaldson et al., 2015), we included reports of live animals on or near highways (~10% of all reports). Our analyses include identification of geographical hotspots and calculated costs to the public from vehicle damage, injury and even death. This information shows where there are problems and should help in developing safety projects to fix these known problem areas.

The following sections include maps of the distribution of WVC densities, projected costs of WVC and hotspots along state highways and other roadways. The densities of WVC reported are the minimum for each highway segment and do not represent actual rates, which are likely to be much higher. By significantly increasing the systematic treatment of these hotspots and stretches of highway with high rates of collisions, Caltrans and other entities can contribute cost-effectively to driver safety and improve the environmental sustainability of state highways.

## Methods

### Traffic Incidents

Records of traffic incidents between February 2015 and December 2017 were obtained from state databases of traffic incidents (e.g., emergency responses to crashes), included in our customized “California Highways Incident Processing system” (CHIPs), and coded according to severity of the incident for the drivers/vehicles and for the animals. For this ~3 year period, we separated the ~19,800 records of wildlife-vehicle collisions from the ~2.5 million traffic incidents using customized term queries (e.g., for “deer” AND “buck” AND “doe” AND “fawn”). We reviewed each record for information about fate of the animal, fate of the driver, type of accident (collision vs. swerve), and vehicle damage. Location and date/time information were from the incident record.

The California Roadkill Observation System project (<http://wildlifecrossing.net/california>) includes past and current participation by over 1,000 volunteer-scientists, including several hundred academic, agency, and NGO biologists and natural historians (Waetjen and Shilling, 2017). More than 56,000 WVC observations were contributed to the website by volunteers between August 2009 and the end of 2017 and by Caltrans Maintenance staff for the period 1987 to 2007. We selected recent observations of large-animal carcasses (last three years) and combined these observations with the CHP crash data. We carefully controlled for duplicates, which were only rarely found because animal carcasses from crash incidents were usually collected fairly quickly by Caltrans.

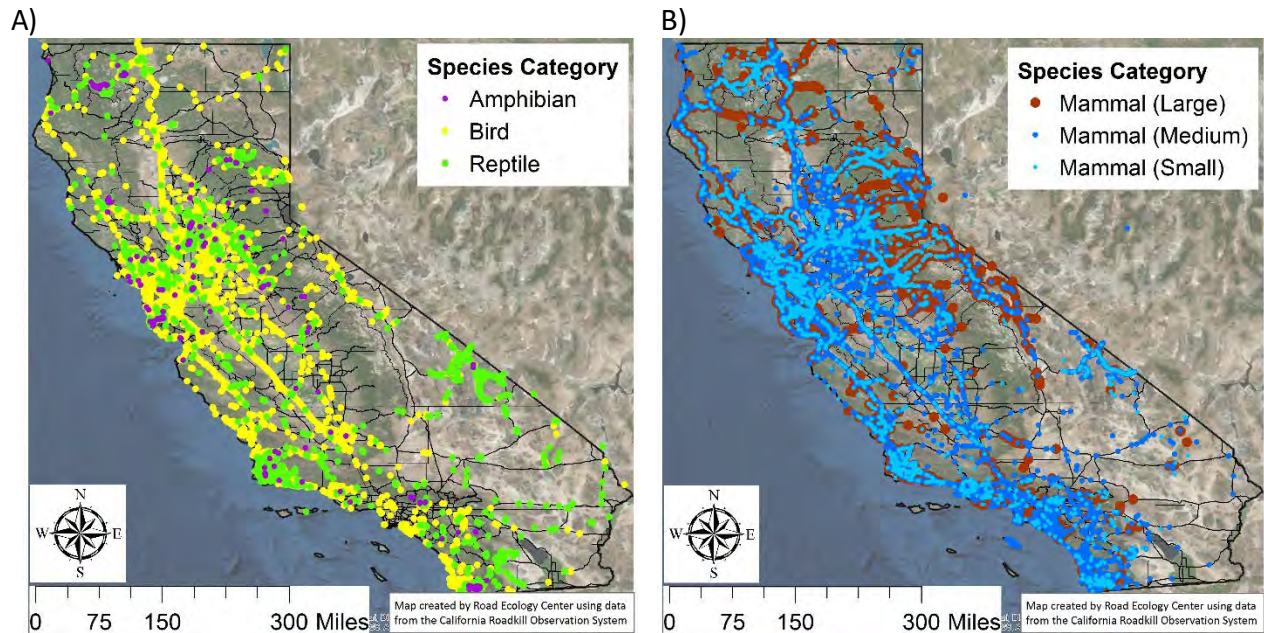

The carcass observations and traffic incidents were used in a geographic information system (GIS) to identify stretches of highway where WVC occur more frequently (high density) and places where there are statistically-significant clusters of WVC (hotspots; Shilling and Waetjen, 2015). Density was calculated as number of incidents/mile and by using the Kernel Density Estimator (KDE) tool in ArcGIS. Hotspots were identified using the spatial autocorrelation test Getis-Ord for 1 mile state highway segments. Specific methods are included in a methodology appendix. Estimates of costs to society of incidents were calculated using the nature of the incident (e.g., “minor injury”) and coefficients for the average cost of these types of incidents used by the US Department of Transportation (USDOT, 2013) and in published literature (Huijser et al., 2009) and technical reports (Cramer et al., 2016).

## Major Findings

### Statewide Carcass Observations

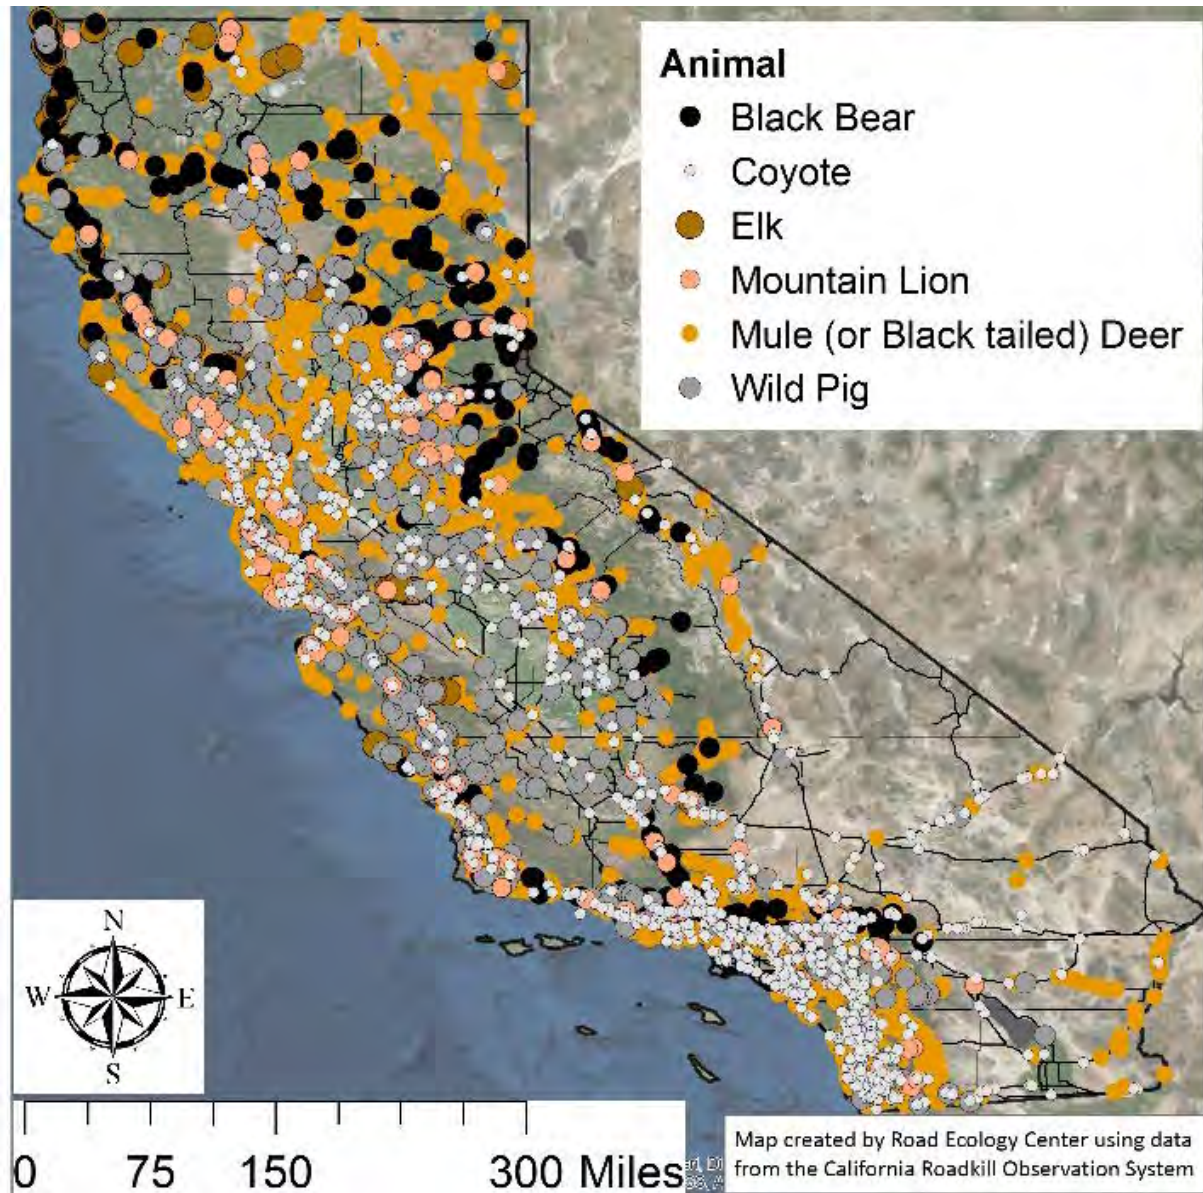

The maps below show >56,000 observations of animal carcasses on local roads and state highways (Figure 1). These are not the total roadkill that occurred, just the ones that people saw and reported to the California Roadkill Observation System (CROS) between 2009 and 2017.

**Figure 1.** Carcass observations for (A) amphibians, reptiles, and birds; and (B) mammals.

### Statewide Highway Traffic Incidents

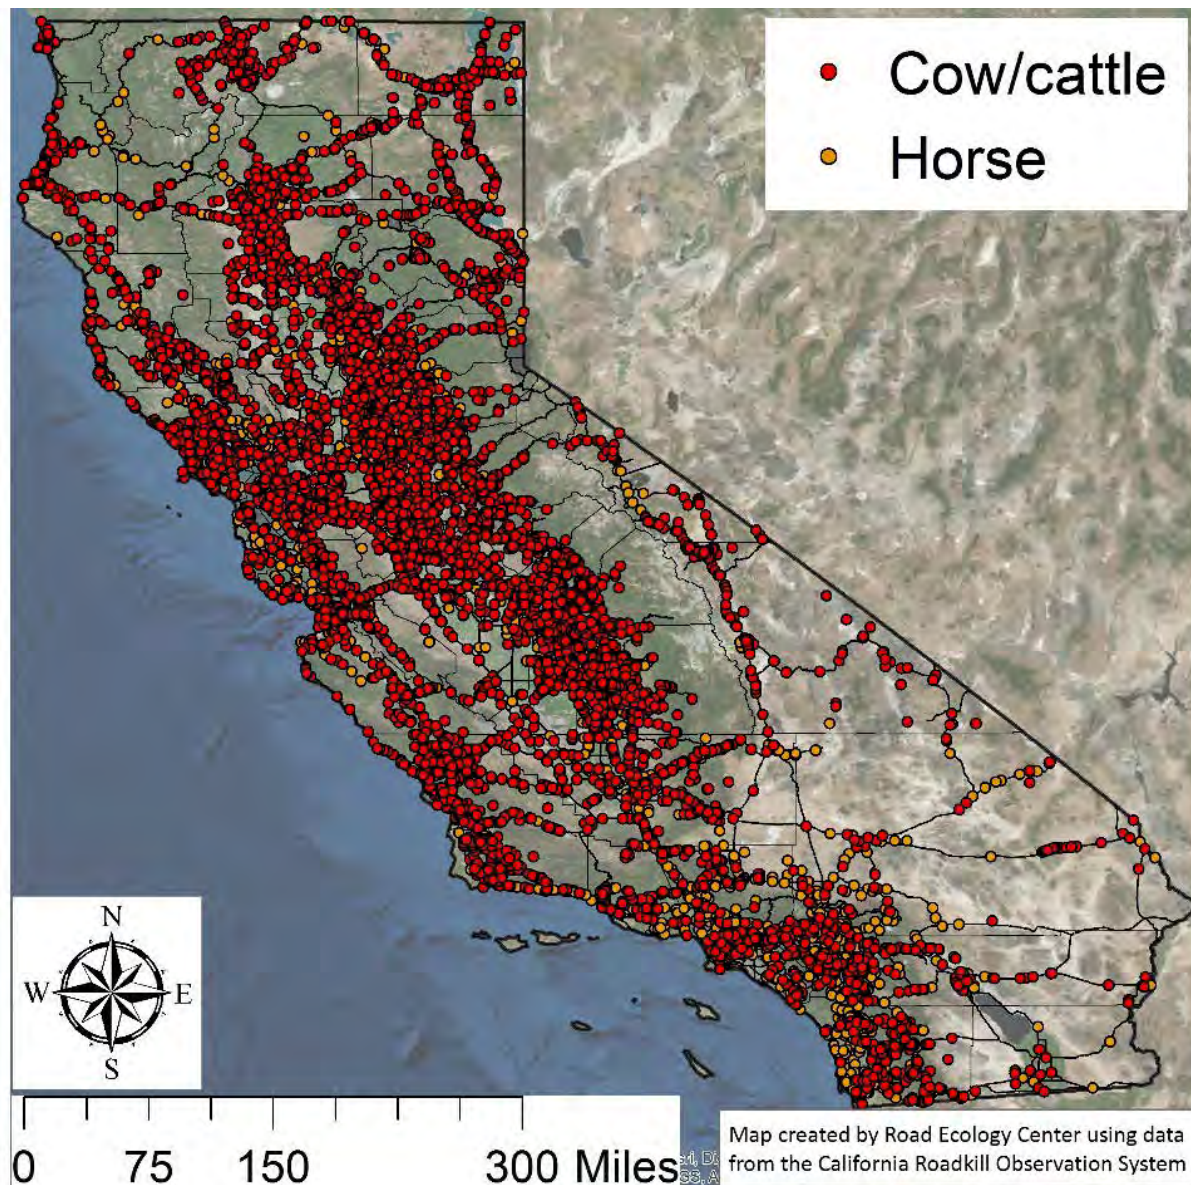

There were >2 million traffic incidents (of all types) across California reported to the California Highway Patrol in 2015-2017. Of these, about half were collisions and more than 19,800 involved wildlife, including reports of animals standing next to, standing in, or running across roadway lanes, collisions with large animals, and swerving to avoid collisions, resulting in a crash (Figure 2, Wildlife vehicle conflicts). The Fall is the most likely time for WVC, due to increased movement related to mating seasons and seasonal migration.

**Figure 2.** Wildlife-vehicle conflict (WVC) incidents on state highways (2015-2017)

For the first time, we also developed hotspot maps for animal-vehicle-conflict (AVC) involving domestic animals in free range areas, or that have escaped enclosures. Cattle, horse, sheep, pigs and goats can all become involved in conflict incidents with traffic. Because some of these animals can be quite large, larger than most wildlife (except elk and some bears), collisions with them can be particularly severe for the drivers. We found that AVC occurs everywhere in California (Figure 3) and at fairly high rates.

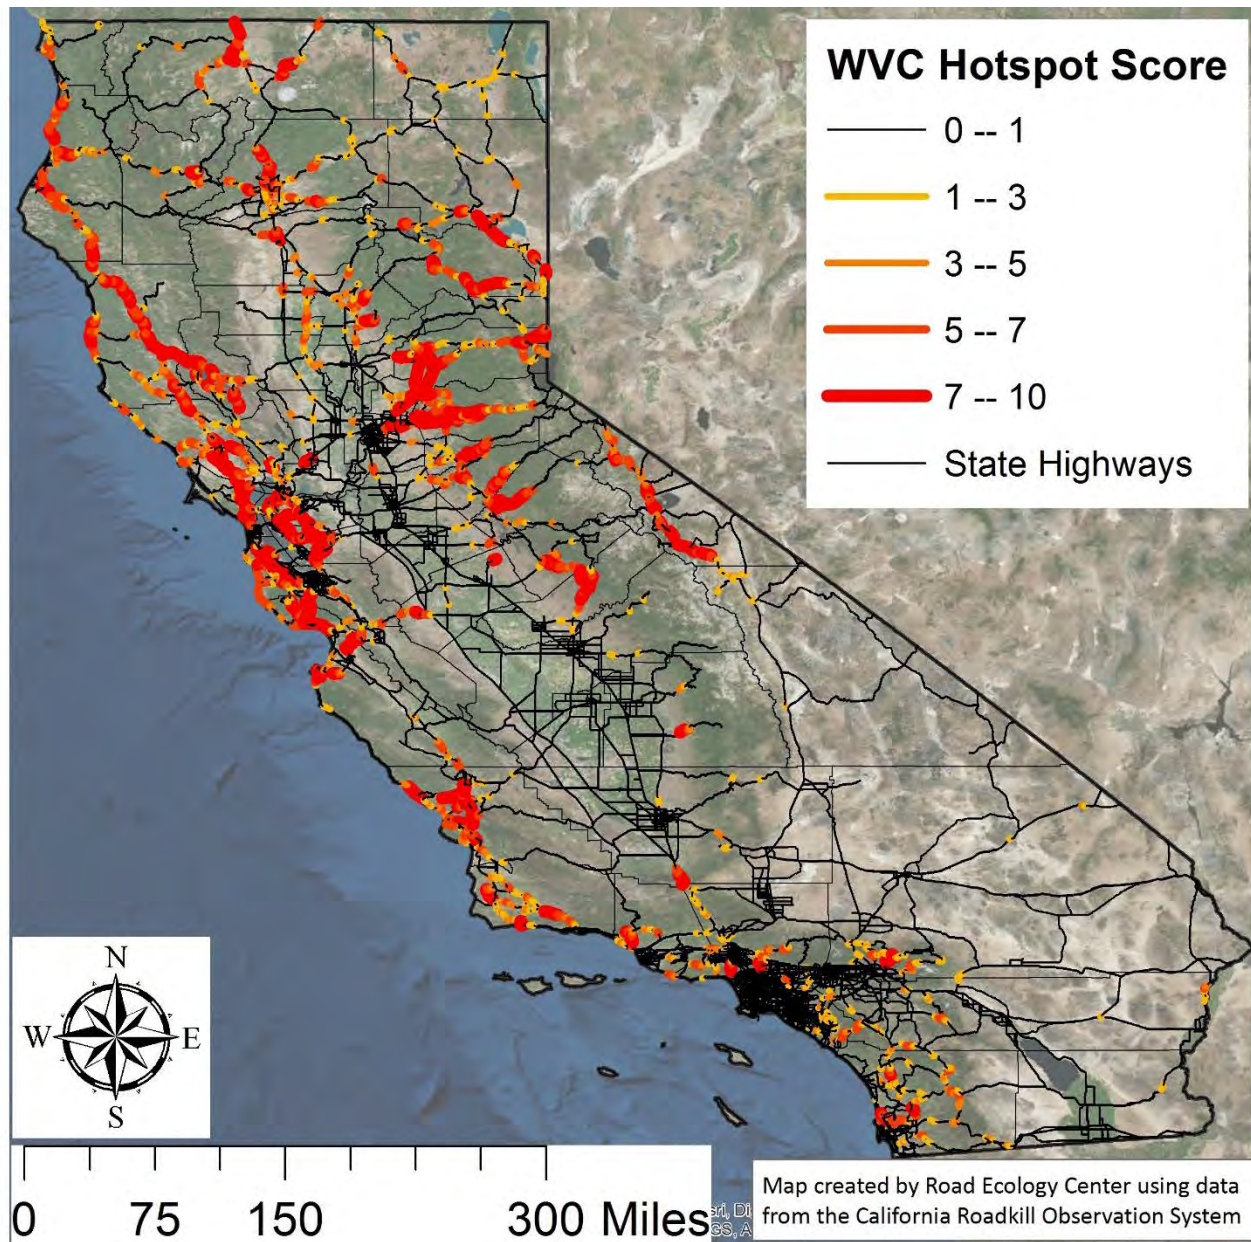

**Figure 3.** Animal-vehicle conflict involving domestic animals (cows/cattle and horses) for 2015 - 2017.

### Statewide Wildlife-Vehicle Conflict Hotspots

Although WVC occur everywhere in California, the highest densities were reported in the San Francisco Bay Area (Caltrans District 4), Sierra Nevada Foothills (Caltrans Districts 3 & 10), North Coast (Caltrans District 1), and parts of the Central/South Coast (Caltrans Districts 5, 7, 11 & 12). These high-density areas are most likely where traffic volumes and wildlife populations are greatest, leading to more conflict. The map below shows the high-density clusters of collisions with large wildlife in California (Figure 4).

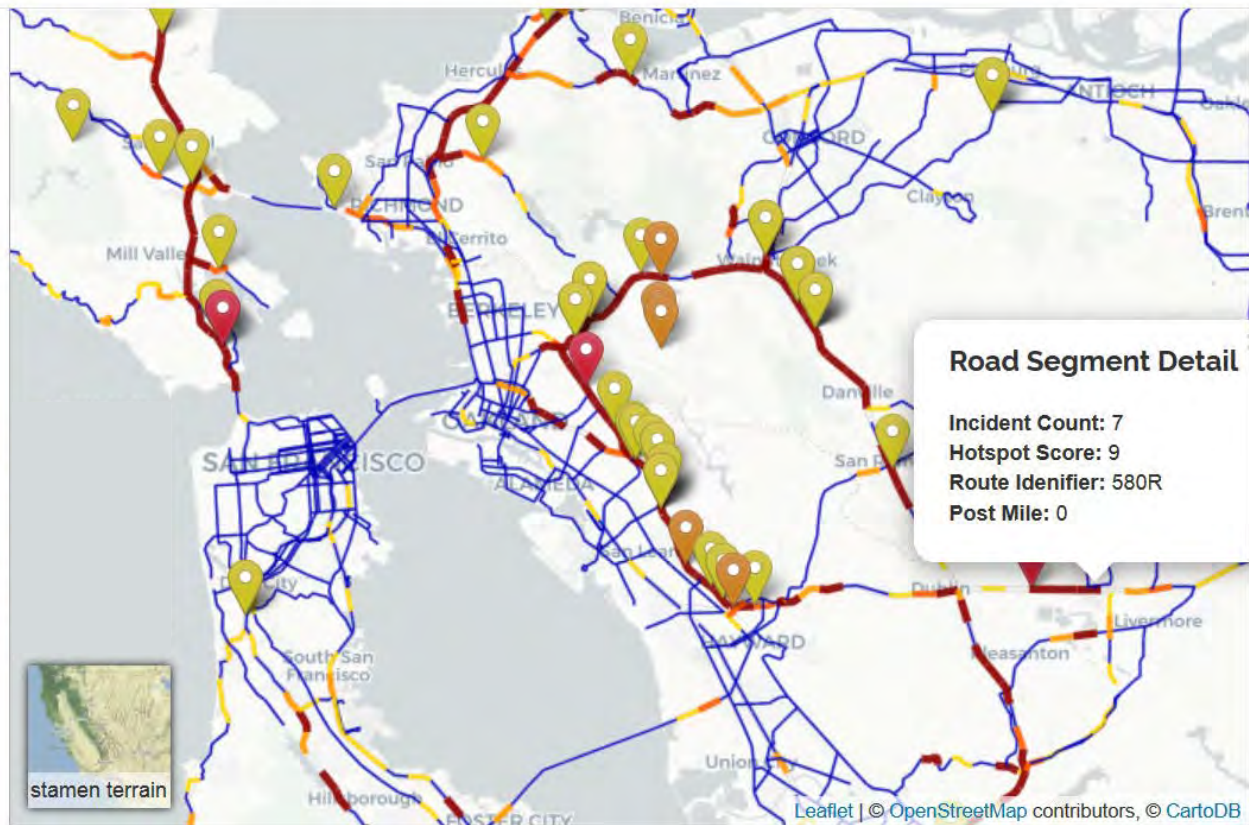

**Figure 4.** Statistically-significant, high-density WVC hotspots for 2015 to 2017. Hotspot score is a value that combines the total density of WVC incidents (#/mile) and the statistical significance of clusters of incidents. You can see these data here: <https://roadecology.ucdavis.edu/hotspots>.

### Real-Time, Automated Web-Map of WVC

To better inform the public and transportation agencies about highway segments with greater risk of WVC, we developed an easy-to-use, online system that provides two important sources of information: 1) mapped hotspots using legacy data (2015 to end of 2017); and 2) locations of recent (<1 week & <24 hours) locations of conflict with mule deer and other large mammals (Figure 5). You can find the website here: <https://roadecology.ucdavis.edu/hotspots>.

**Figure 5.** Zoomed in view of central San Francisco Bay Area showing incident densities and recent WVC incidents. The information box appears when the user clicks on a highway segment. <https://roadecology.ucdavis.edu/hotspots>.

We also developed the web-system so that it could be a continuous source of information for driver-assist, autonomous-vehicle, and app-based programs. For example, this information could be continuously fed into an app to inform drivers of locations of recent and long-term conflict, to inform their driving practice. It could also be used by driver-assist and autonomous vehicle systems to prioritize driver-warning and changes in sensitivity to the potential presence of large animals in the roadway.

### Consequences of Collisions to Drivers and Society

Records analyzed show some individual drivers involved in collisions with animals, or who drive by injured animals and report them, experience emotional trauma and if the animal is larger, also face damage to their vehicle and injury (or even death) to themselves. Drivers may either collide with the animal, or swerve to avoid the animal and become involved in a collision with another vehicle or object (Table 1). We estimated the total cost of all WVC incidents to society, using summaries of types of accident (e.g., property damage only, major injury), the loss of wildlife,

and coefficients for each of these types of loss. Equivalent costs for accident types were obtained from the US Department of Transportation (USDOT, 2013) and a related project in South Dakota (Cramer et al., 2016). We only counted 1 fatality in data from CHP, but Caltrans reported 12 fatalities from collisions with wildlife for 2017, using data from CHP (<http://www.dot.ca.gov/paffairs/pr/2018/prs/18pr072.html>), so we used this number.

The rates of property damage, injury and death reported here are probably underestimates and may be superseded by more detailed information from other sources. For example, State Farm Insurance Co. estimates that there were >23,000 claims/year for collisions with deer in 2015- 2016 (<https://newsroom.statefarm.com/download/234883/allstates2015-16deerstats-finalpdf.pdf>), whereas our calculations are based on >6,600 reported collisions during this time period. If these additional 16,000 collisions resulted in the same average property-damage-only cost as used below (USDOT, 2013), there would be an additional >\$277 million cost to society (16,000 times \$17,343/crash), resulting in a total estimated cost from WVC of ~\$584 million/year.

From 2016 to 2017, we found an increase of ~11% in cost to society from WVC, which was 20% higher than the year before. This does not reflect a change in how the calculation was conducted, but instead an increase in the number of fatal collisions.

**Table 1.** Impact to drivers and estimated cost to society of reported collisions with animals on California highways and certain major roads. Equivalent costs for accident types were obtained from the US Department of Transportation (2013).

Type of Accident	Coefficient (cost as \$/event)	Number (2017)	Cost (2017)
Lost animal value (all animals)*			\$37,377,000
Collision/Swerve (property damage)	\$17,343	6,411	\$111,185,973
Injury (minor)	\$105,228	224	\$23,665,146
Injury (major)	\$506,217	44	\$22,327,207
Fatality	\$9,395,247	12	\$112,742,964
<b>Total</b>			<b>\$307,298,290</b>

\* This value includes both reported and estimated un-reported carcasses. Others have reported under-reporting rates for carcasses from collisions of 5-10 fold (e.g., Olson et al., 2014).

### Consequences of Collisions to Large Mammals, Animal Populations & Individual Animals

The majority of reported traffic incidents involving an animal (Figure 2) were with Mule deer (*Odocoileus hemionus*, 88%, Table 2), though at least 5 other mammals were also reported. In addition, these are just species and number of animals that were included in a CHP incident report. Others have reported under-reporting rates of collisions with ungulates (e.g., deer) of 5

to 10 fold (Donaldson and Lafon, 2008; Olson et al., 2014). This suggests that as many as 25,000 to 50,000 mule deer were killed during collisions in 2015 and an unknown number of other species. This is supported by the State Farm Insurance Co estimate of >23,000 claims/year for collisions with deer in California

(<https://newsroom.statefarm.com/download/234883/allstates2015-16deerstats-finalpdf.pdf>), where collisions are likely to occur more often than claims.

One important observation was that almost twice as many black bears were reported involved in accidents in 2017 (170 animals) than in 2016 (89 animals), or 2015 (83 animals). In addition, there were more collisions with mountain lions in 2017 (64 animals) than in 2016 (44 animals), or 2015 (38 animals). It's not obvious why this occurred, but it is a disturbing trend for both wildlife and drivers

**Table 2.** The types and number of each type of wildlife involved in traffic incidents reported to CHP in 2016.

<b>Wildlife type</b>	<b>Number</b>	<b>% of Total</b>
Mule deer	5,862	88%
Coyote	353	5%
Black bear	165	2%
Wild Pig	145	<1%
Mountain lion	64	<1%
Elk	40	<1%

For people who have collided with an animal, some will have observed that the animal does not always die immediately. We found that 23% (n=1,495) of animals involved in incidents were reported as injured by responding law enforcement (Table 3). There were an additional 32% (n=2,119) with an unknown fate after being involved in a traffic incident. The rate of “unknown fate” for animals involved in a collision was much greater for elk, black bear and wild pig than mule deer, with the majority of these species having an unknown fate after collision. Only 149 animals were reported as dispatched by responding law enforcement officers, meaning that the remaining injured and some portion of the “unknown fate” animals stayed injured following the collision. This may still be an under-estimate of the total as there has been shown to be chronic under-reporting of collisions with ungulates, such as deer, in the US (Donaldson and Lafon, 2008; Olson et al., 2014).

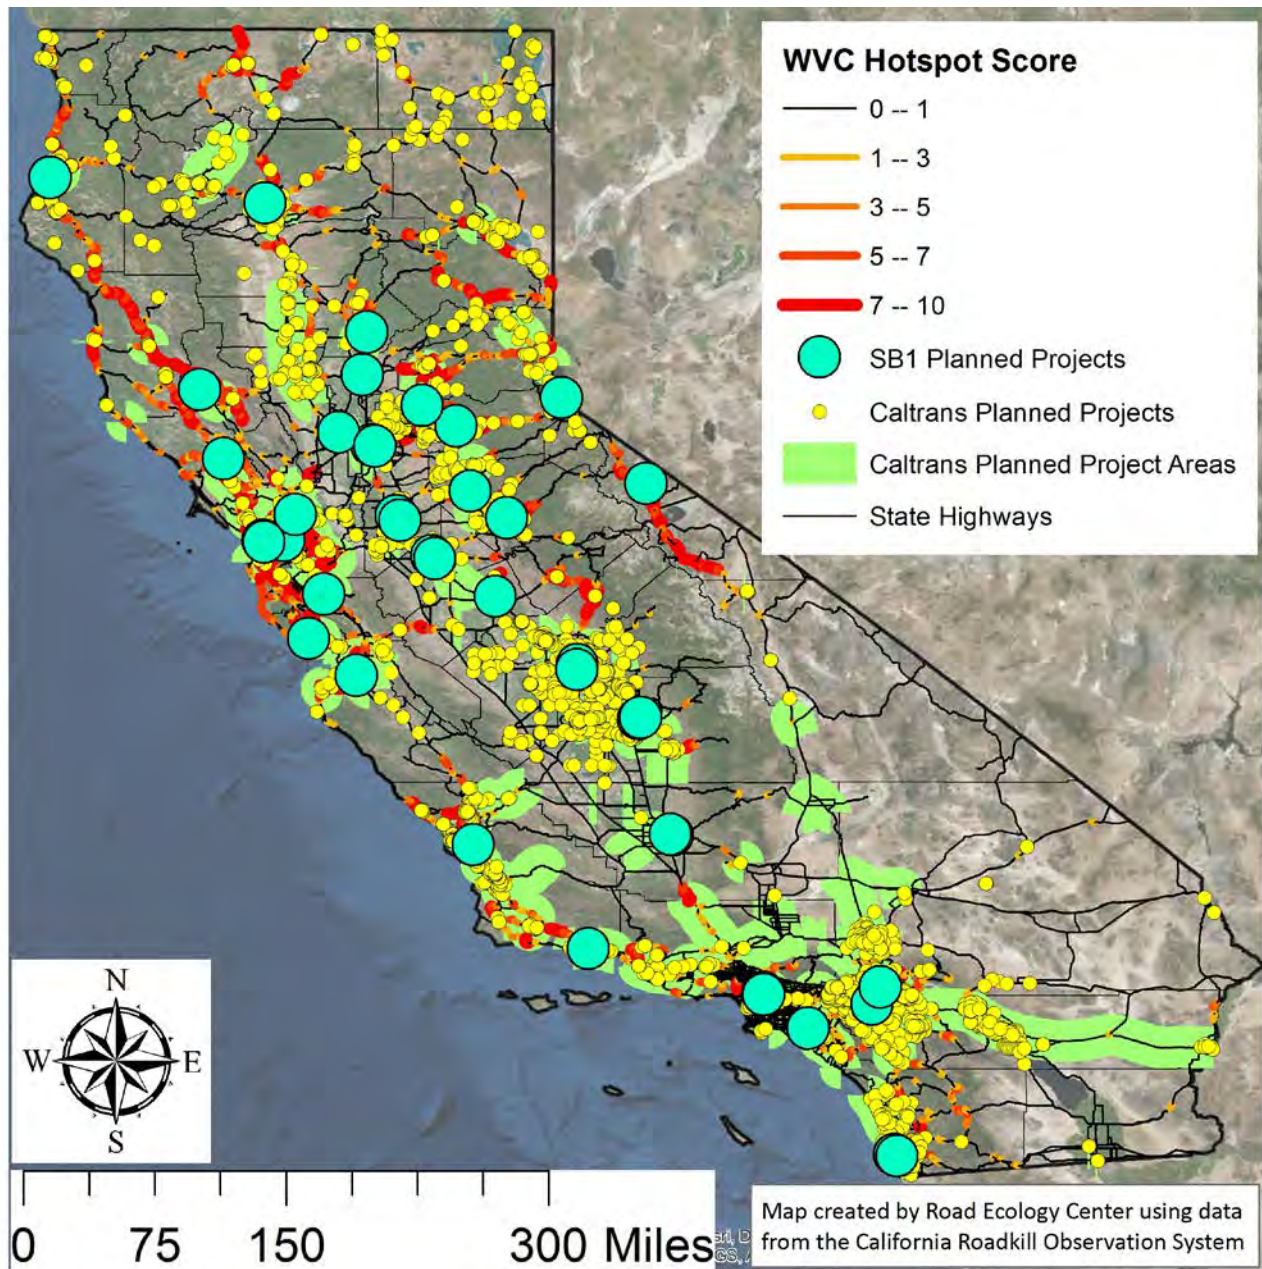

**Table 3.** Animal outcomes following collisions with vehicles in 2017.

<b>Animal Outcome</b>	<b>#</b>	<b>%</b>
Unknown fate	2,119	32%
Alive / No Injury	597	9%
Injury	1,495	23%
Fatality, result of collision	2,841	43%
Fatality, result of dispatch	149	2%
Total	6,604	

In last year’s report, we suggested that injuring animals in this manner could be considered cruelty. Although this may still be true, it makes sense to consider what solutions are available to reduce the unnecessary suffering of animals injured during collisions. A possible solution to this problem would be for the state to create a hotline where drivers can report an injured animal for potential rehabilitation, or in extreme cases, dispatch by CHP. Other countries (e.g., Germany, Sweden) have systems like this in place that could readily be adopted.

### **Regional/Local Focus**

The need for projects that reduce the risk to driver safety and lives, property damage, and impacts to wildlife is critical. Building these projects will require a combination of Caltrans, county, regional, and legislative action and funding. This risk is greatest when there are more drivers driving fast through or near wildlife habitat, such as the San Francisco peninsula, the Sierra Nevada foothills and portions of Southern California (see following pages). The map below (Figure 6) shows the location of planned, state-funded projects in California, which are potential locations for wildlife-vehicle collision mitigation. Unfortunately, there is not very good overlap between WVC hotspots and planned projects, including those planned under the Senate Bill 1 (SB1) fuel-tax funding source. This may not be surprising as neither the California Transportation Plan, nor SB1 mention widespread, adequate mitigation for this risk to driver safety and wildlife well-being. However, it is a problem that can be solved by spending SB 1 and other state funds on wildlife-crossing projects. There is an immediate and urgent need for leadership on this issue in California and widespread construction of wildlife crossings solutions to reduce harm to drivers and wildlife. We suggest an expenditure rate of “1% for wildlife”, which equates to ~\$500 million from transportation funds per year, coincidentally similar to the estimated cost per year of WVC.

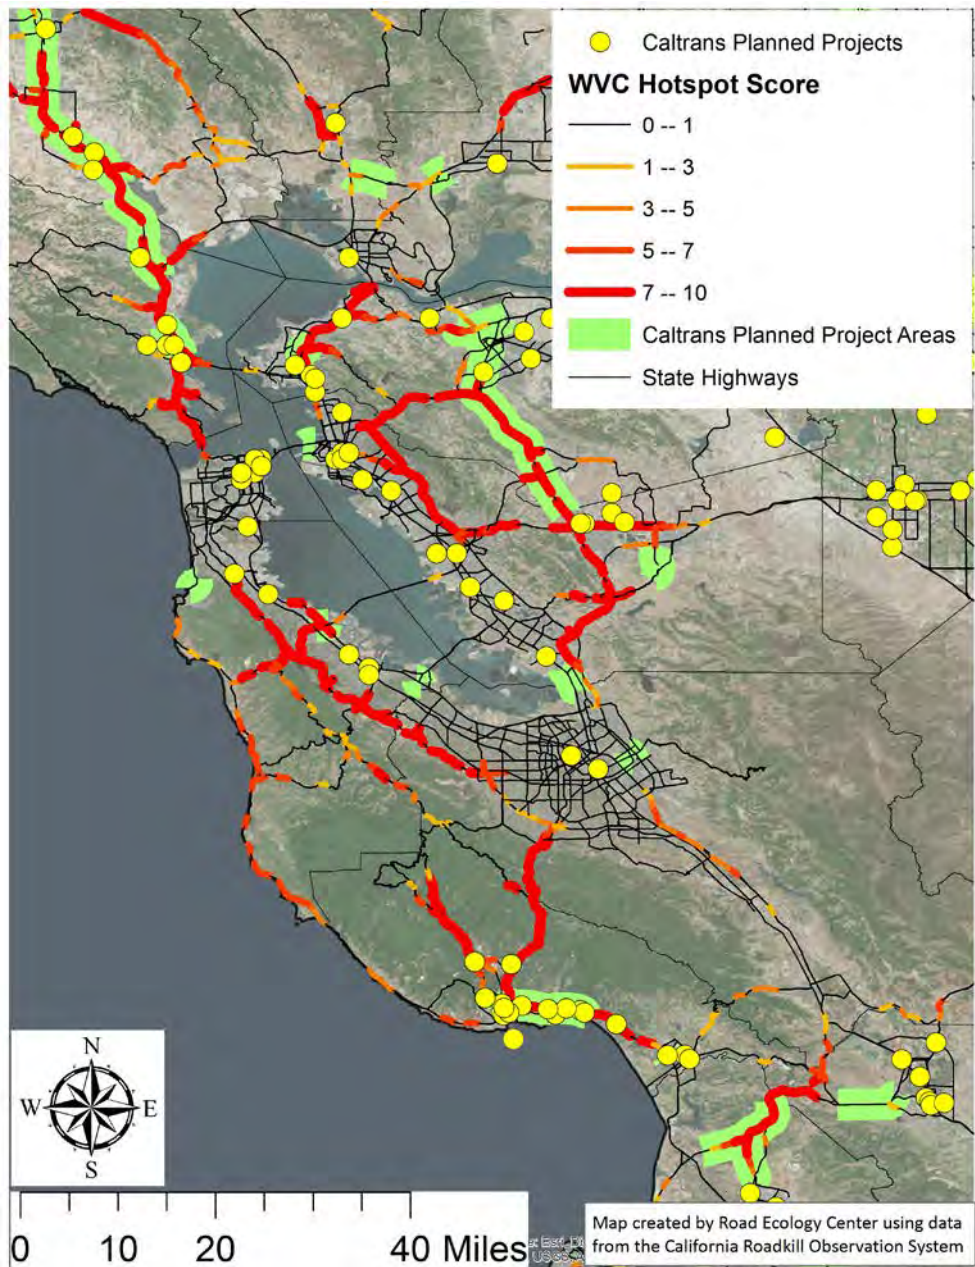

**Figure 6.** Locations of WVC hotspots and planned projects under the State Transportation Improvement Program (STIP) and Senate Bill 1, fuel-tax funding.

### San Francisco Bay Area, Regional Highway Hotspots

This map shows the hotspots of WVC incidents on select highways in the San Francisco Bay region (Figure 7). There are segments of highways that have high enough rates of WVC that if safety projects, such as fencing and wildlife crossings, were undertaken, they would pay for themselves through reduced WVC. This is especially true for I-280, the fencing of which would pay for itself in less than 1 year due to reduced WVC. Many major WVC hotspot areas have no planned highway projects, but projects should be planned to reduce risk and harm.

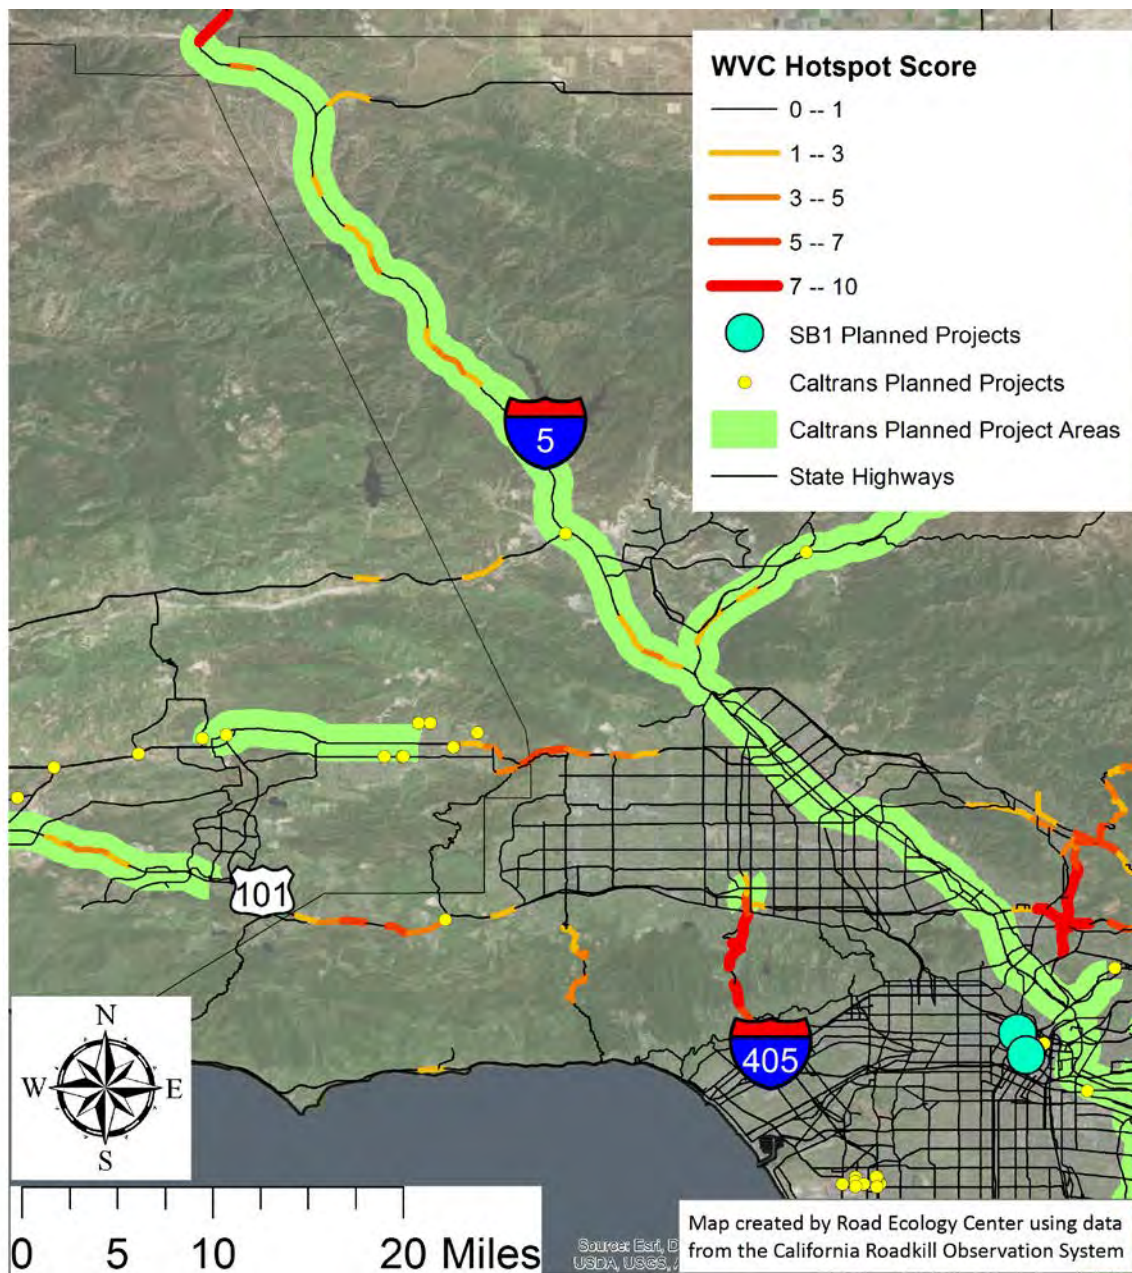

**Figure 7.** Overlap of WVC hotspot areas with state-planned/funded highway projects in the San Francisco Bay Area.

### Southern California, Regional Highway Hotspots

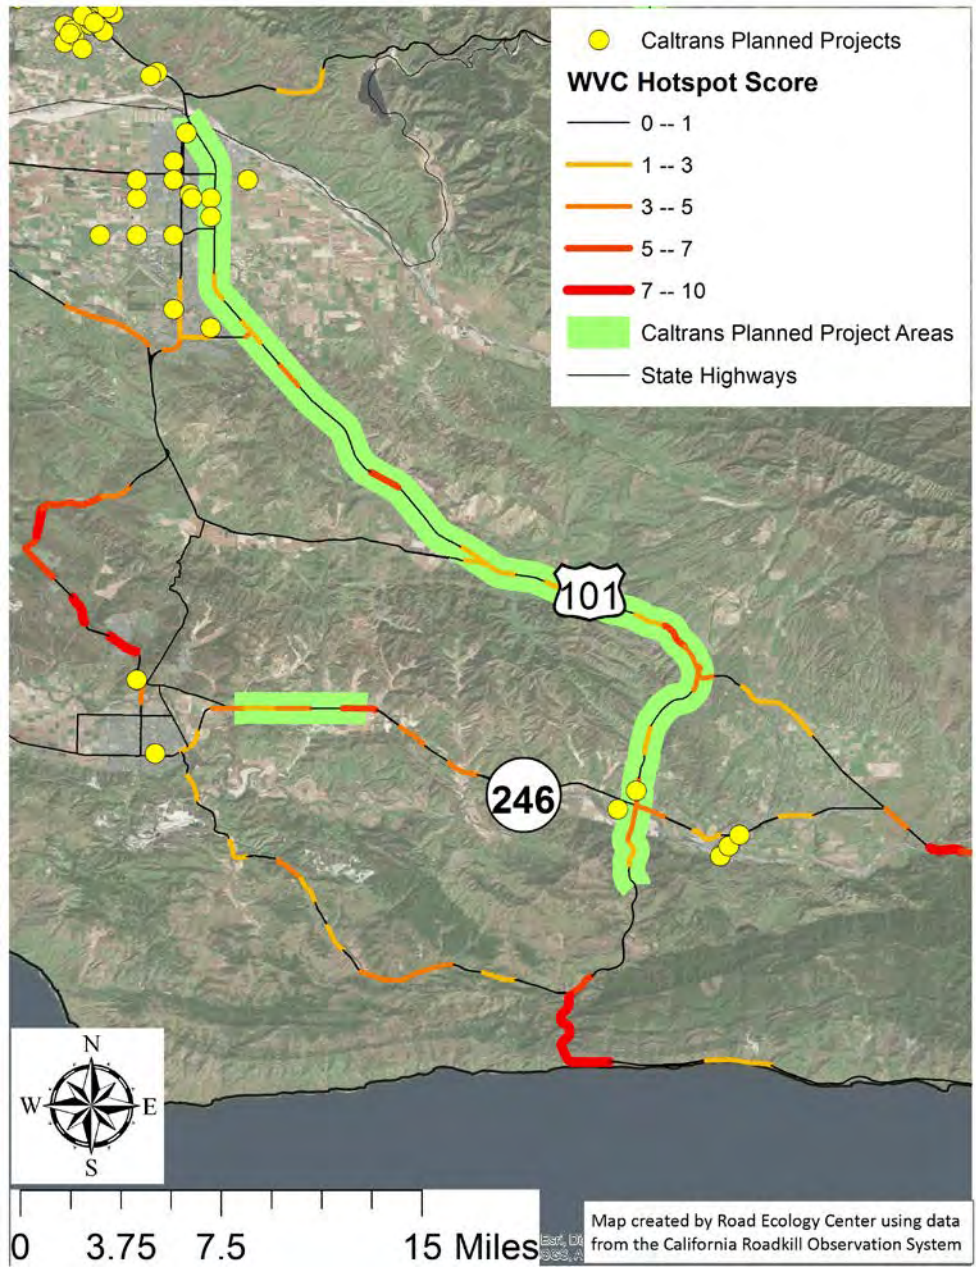

This map shows the clustering of WVC incidents on select highways in the northern Los Angeles basin and mountains (Figure 8). There are segments of highways that have high enough rates of WVC that mean if safety projects, such as fencing and wildlife crossings, were undertaken, they would pay for themselves through reduced WVC. There are several planned state-funded projects that could be used to build wildlife-crossing mitigation. There are also major hotspot areas with no planned highway projects, for which projects should be planned.

**Figure 8.** Overlap of WVC hotspot areas with state-planned/funded highway projects in the Southern California mountains north/west of Los Angeles.

### Central California, Regional Highway Hotspots

This map shows the clustering of WVC traffic incidents on select highways in central-coastal California (Figure 9). There are segments of highways that have high enough rates of WVC that if safety projects, such as fencing and wildlife crossings, were undertaken, they would pay for themselves through reduced WVC.

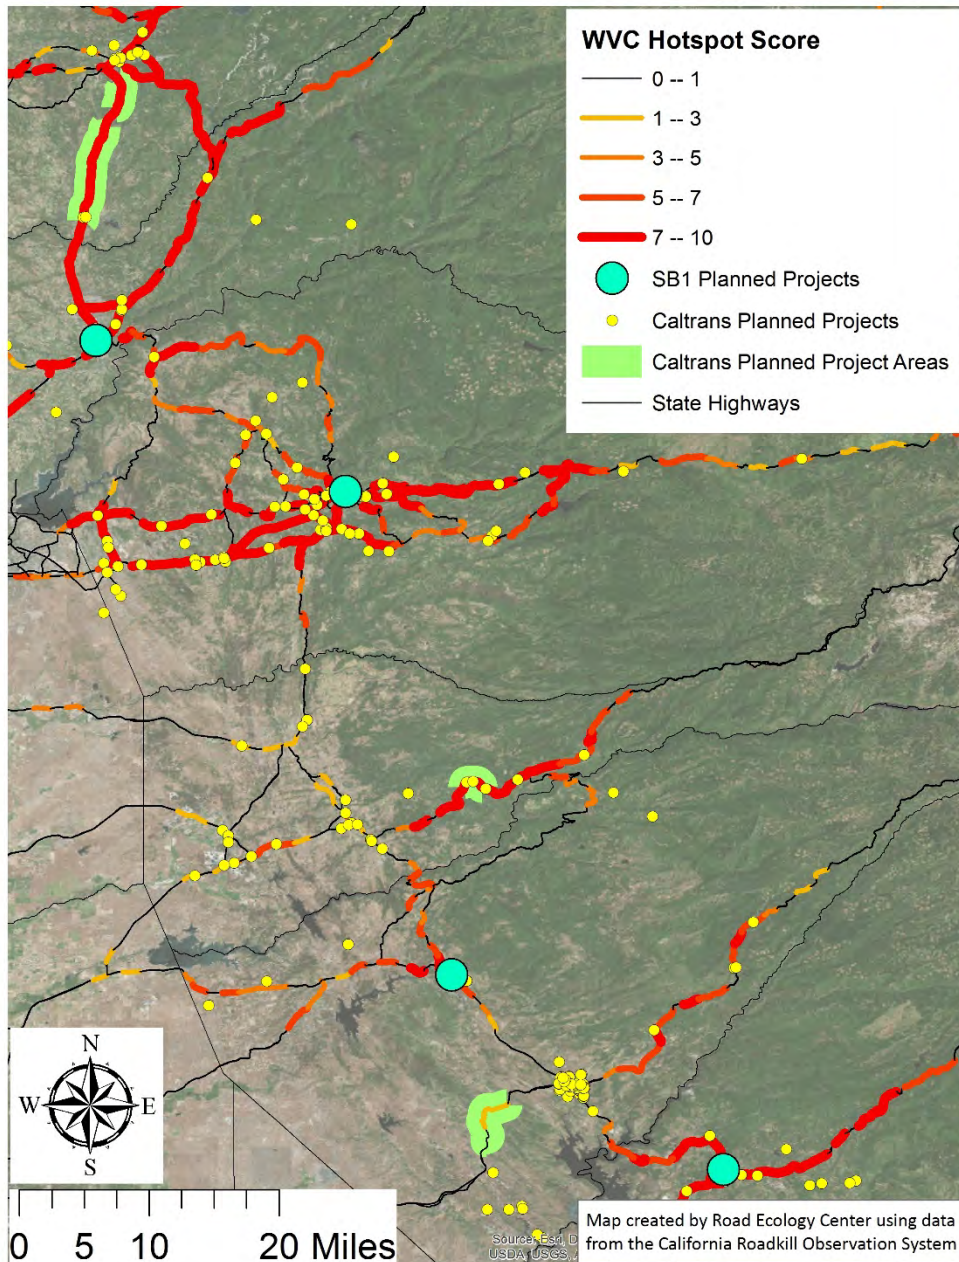

**Figure 9.** Overlap of WVC hotspot areas with state-planned/funded highway projects in the Central California coast near Lompoc.

### Sierra Nevada Foothills, Regional Highway Hotspots

This map shows the clustering of WVC incidents on select highways in the Sierra Nevada foothills (Figure 10). There are segments of highways that have high enough rates of WVC that mean if safety projects, such as fencing and wildlife crossings, were undertaken, they would pay for themselves through reduced WVC. There are several planned SB1-funded projects that could be used to build wildlife-crossing mitigation. There are also major hotspot areas with no planned highway projects, for which projects should be planned.

**Figure 10.** Overlap of WVC hotspot areas with state-planned/funded highway projects in the Sierra Nevada foothills east of Sacramento.

## Appendix 1: (More) Detailed Methods

### Data Sources

State highway network (SHN) and post-mile (PM) spatial datasets were obtained from Caltrans (<http://www.dot.ca.gov/hq/tsip/gis/datalibrary/index.php#Highway>). All traffic incident data from California Highway Patrol (CHP) resources, beginning in 2/2017, were collected by the UC Davis Road Ecology Center's "California Highways Incident Processing System" (CHIPS) and ingested into a database. This database was then queried for incidents involving animals to create a dataset of Animal-Vehicle Conflict (AVC). The CHIPS AVC data includes collisions between vehicles and wildlife/domestic animals, carcasses found on highways, traffic hazards caused by animals, and other types of traffic incidents involving animals.

Each CHIPS data point contains several fields relating to the incident it represents. These fields include latitude, longitude, street or intersection name, animal species, and any details the CHP officer noted regarding the incident. Many points have multiple entries in the details field, meaning CHP documented updates to the incident as it progressed. These descriptions provide a thorough narrative of the incident, as well as details on the time that events occurred through the eyes of a CHP officer. Other fields in the AVC dataset are manually entered by the Road Ecology Center if they are included in the descriptions. Attributes include data like vehicle damage, driver and animal outcomes, and type of incident (e.g., swerve vs. collision).

CHIPS data represents incidents on California's state, interstate, and federal highways. CHP does respond and document incidents on some unincorporated roads near highways, but incidents more than 50 meters from a highway were excluded from this study.

It is important to note that CHIPS AVC data are a subset of reported incidents on California highways. Unreported incidents and incidents on roads falling outside of the jurisdictions of CHP are not included. CHP has jurisdiction on all federal, state, and interstate highways and public roads in certain unincorporated areas. Therefore, CHIPS incidents are not a record of all AVC in California, but events which induce a documented report within CHP jurisdiction.

Of the AVC incidents, ~90% of the incidents involved mule deer. It can be inferred that animals large enough to cause damage to a vehicle are more likely to be reported to CHP. A minimal number of incidents involve small animals, such as pigeons, geese, and dogs. These are included in the analysis dataset, but do not represent the entirety of incidents with those smaller animals. Thus, this analysis does not represent AVC with smaller species, since those incidents are unlikely to be reported.

Assuming CHP consistently and accurately documents incidents across the state highway network, CHIPS data provides a spatially unbiased dataset of AVC involving large animals on California highways.

### Geoprocessing

The datasets from the previous section were processed using the programming language R and ESRI ArcMap 10.6. The following geoprocessing steps were performed to create the automated hotspot analysis for AVC.

## **Network Segmentation**

The basis for the AVC network analysis is the highway network. In order to create a uniform unit for analysis, one-mile segments were created for highway networks. The Caltrans SHN was used for the AVC analysis of California. The highway lines were split at each one-mile PM. This created a fairly uniform set of segments, split at well-known locations.

## **Assigning Incidents to Segments**

A custom R script was written to assign AVC incident points to spatially corresponding road segments. The R script uses the `snapPointsToLines` function in the `maptools` library. Points >50 meters from any segment were filtered out. This approach did not attribute incidents to incorrect road segments. The number of AVC incidents for each segment was summed in an attribute field to the segment, which is the metric of primary importance in the WVC analysis. A maximum distance of 50 meters was chosen when snapping incident points to road segments. Since CHP often records data on road shoulders, and the highway network is often on the centerline of roads, or between separated highway lanes, and GPS receivers have an accuracy radius, point locations are usually a short distance away from network lines. However, incorporating points further than necessary would have included WVC points on roads not in the analysis, inaccurately inflating density distribution.

## **Clustering Statistics – Hotspot Score**

To provide a different view of the spatial distribution of AVC along the network, the `GetisOrd`  $G_i^*$  statistic was used to statistically analyze clusters and to contribute to a hotspot score for each one-mile road segment. An R script ran a local `Getis-Ord` calculation for each segment on the network, analyzing the number of incidents snapped to each segment. The default neighbor radius is one mile (1609 meters), and a binary weighted matrix including the value of the segment. The script adds a  $G_i^*$  z-score value to each segment, denoting if the segment is in a relative “hotspot” or “coldspot”.

The  $G_i^*$  statistic is well-suited to identify hot and cold locations in density distribution, the resulting z-score is not clearly understood by all audiences. Moreover, some additional nuances of WVC distribution should be incorporated into an easily shared “hotspot score”.

Using the  $G_i^*$  value, a “hotspot score” was created to more effectively communicate the results. First, segments with a) zero incident density or b) a negative  $G_i^*$  value are assigned a hotspot score of zero. This avoids over-smoothing the score, to reveal highway segments with no incidents in a region of high incidents. Then, a percentile of each  $G_i^*$  value within the distribution of remaining non-zero segments is calculated. Finally, an integer value from 1-10 is given to each segment by rounding up the percentiles. The hotspot score is a means of synthesizing incident density and spatial clustering, but presenting it in a way that is easily understood by all audiences. The process can be implemented on any network, and will categorize network segments into 10 equally sized categories, where each segment with a score greater than zero has incident densities and positive  $G_i^*$  values.

# Impact of Wildlife-Vehicle Conflict on California Drivers and Animals

Using observations of reported traffic incidents and carcasses the Road Ecology Center has estimated the **total annual cost** of reported (large) wildlife-vehicle collisions for 2018 in California to be **at least \$232 million** and the cost to society over the last 4 years to be **>\$1 billion**. The cost is calculated using California Highway Patrol (CHP) reports of crashes with wildlife and US Department of Transportation equivalent values for different types of crashes (e.g., property damage vs. major injury). When including accidents that are claimed to insurance companies but un-reported to police, the estimated cost could be as high as \$500 million/year (estimated for 2017). This report provides an overview of wildlife-vehicle conflict (WVC) in general, including collisions with small and large animals and accidents resulting from drivers swerving to avoid colliding with an animal. We highlight WVC hotspots on California highways between 2015 and 2018, inclusive, based on a combination of >26,000 traffic incidents involving wildlife that were recorded by the CHP and >42,000 carcass observations reported to the California Roadkill Observation System (CROS, <http://wildlifecrossing.net/california>) between 2009 and 2018, inclusive. This report includes **maps of WVC hotspots**, discusses impacts to wildlife and people from WVC, addresses whether mapped “wildlife corridors & linkages” help explain where WVC occurs, and presents new tools to help organizations, state agencies and individuals collect and use this information. Projects to **reduce WVC** can be the most effective of any safety project, with effectiveness often >90%.

For the first time, we **statistically compared the location of WVC** with various computer **predictions of wildlife corridors/linkages** in California. In general, we found no significant correlation between the locations of WVC and these linkages. This may not be surprising because wildlife generally do not follow narrow or predictable paths through their habitat. California agencies have been looking for predictability in wildlife movement to help reduce the **cost of mitigation**. Fortunately, there are ample data available on wildlife movement from WVC databases and studies involving GPS-collared wildlife to identify mitigation locations.

**Data Sharing/Collaboration:** We receive requests from highway planners, fish and wildlife scientists, academic faculty, students, and non-governmental organizations on a weekly basis. We can typically meet data requests within CA for specific highways, counties, etc., but please keep in mind that this is an unfunded effort of the Road Ecology Center, so give us a few days.

We have developed 2 globally-unique web-tools to collect and to visualize WVC incidents in CA: 1) A re-vamped California Roadkill Observation System to support “one-click” reporting (<https://wildlifecrossing.net/california>) –take a picture of a roadkilled animal with your smartphone and upload with one click (which automatically creates a database record); and 2) A WVC hotspot tool that shows hotspot areas throughout CA and has a real-time display of WVC events, <https://roadecology.ucdavis.edu/hotspots>.

## UC Davis Road Ecology Center: Sixth Annual Special Report on the Impact of Wildlife-Vehicle Conflict (WVC) on California Drivers and Animals

### **Top 4 Talking Points**

- 1) **We can help the state systematically collect and share data.** The data assembled here from the CHP were not collected with the purpose of studying WVC, the volunteer data were. California agencies should collect and share data about WVC to help inform decision-making about this important conservation and safety problem. Using our extensive datasets and decade of experience collecting and analyzing WVC data, we are open to partnering with Caltrans, California Department of Fish and Wildlife and others to accomplish this.
- 2) **Legislated support is needed for highway/road projects that that have net WVC benefit.** In the past, WVC-reduction projects (like wildlife crossings) were only occasionally considered and as part of partial mitigation for transportation impacts. There is currently a state program to allow “advance mitigation credit” for WVC-reduction projects where impacts are reduced now, but balanced by doing more harm later. Transportation agency planners and biologists are increasingly discussing wildlife-crossing structures and other projects as stand-alone safety and sustainability projects, providing a net benefit to drivers and wildlife, without the need for the projects to mitigate for further harm later.
- 3) **Build WVC-reduction projects at known hotspots.** Very few driver safety projects have the overall effectiveness that WVC reduction projects do. There are hundreds of places on state highways and major roads where WVC is a priority. Unfortunately, we can’t use “wildlife corridor/linkage” computer models to tell us where these places are. Fortunately, we have the WVC and other wildlife movement data to help show us where to act.
- 4) **Allocate sufficient funds to build needed WVC-reduction projects.** With the passage of SB1, California voters provided state legislators and transportation agencies with an increase in funding (>\$5 billion/year!) to protect driver safety and the environment. We know that doing nothing, or very little to reduce WVC is costly – to drivers and to the environment (~\$300 million per year). There are myriad excuses for why “nothing can be done”, lack of funding is not one of them.

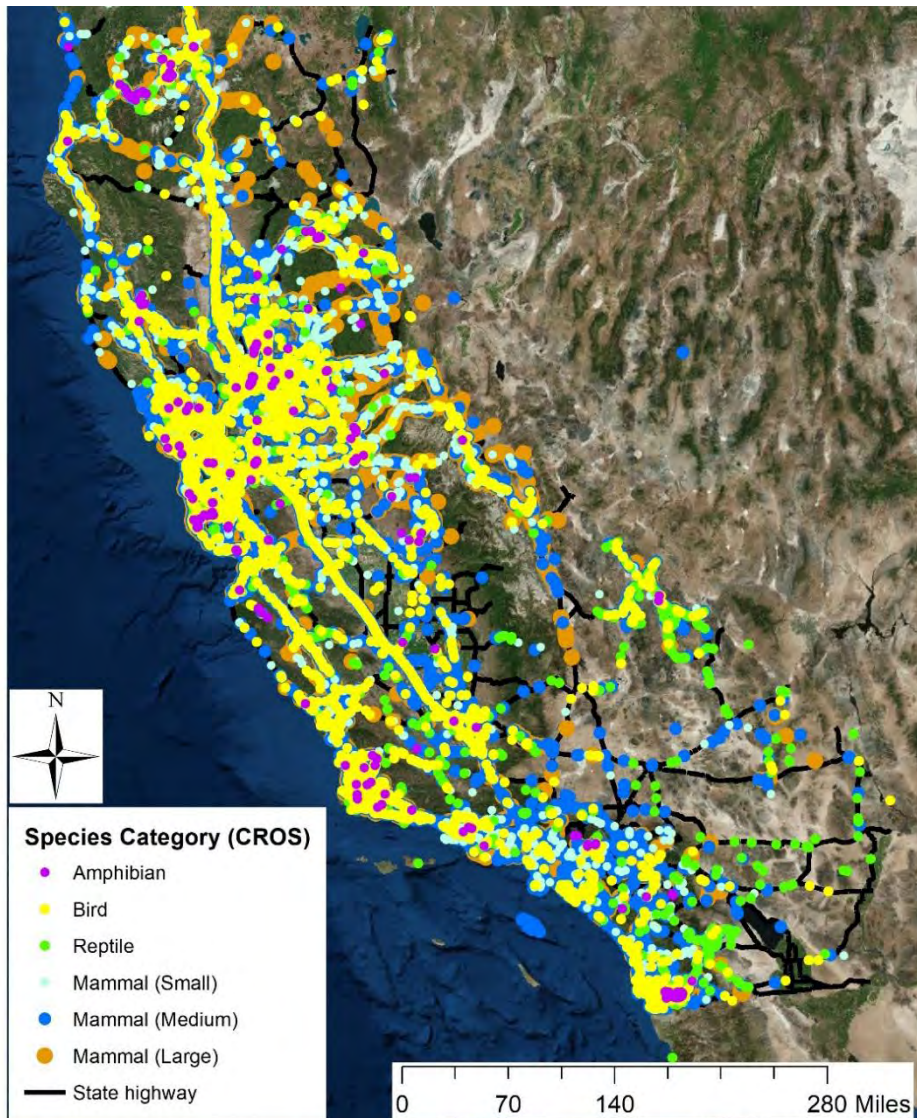

### **Introduction to Study**

Using California state data on traffic incidents and roadkill observations, the Road Ecology Center has mapped stretches of 15,160 miles of California highways that are likely to be continuing hotspots for wildlife-vehicle conflicts (WVC). Animals entering roadways are often killed and pose a hazard to drivers, who may collide with the animal, or try to avoid the animal

suffering vehicle damage, injury, and even death. Wildlife populations may suffer significant losses from highways with high rates of WVC, which may cause ripple effects into surrounding ecosystems up and down the food chain. In addition, animals are injured during collisions, which is damaging to the animal and traumatic and deadly to drivers.

By identifying stretches of highway where WVC are more likely to occur, the Road Ecology Center is assisting Caltrans and other responsible entities in developing mitigation to protect drivers and wildlife populations. Measures with proven effectiveness include 1) building fencing and over/under-passes along priority highways to allow the safe passage of wildlife across highways and 2) reducing speed limits in protected wildlife habitat. Using CHP data, we have found records of ~7,000 reported accidents per year on California highways involving deer and other large wildlife. We estimate that there are another few thousand with horses, cows, sheep and goats. Data from CROS allow state and local agencies to prioritize stretches of highway for mitigation of conflicts with particular species or groups (e.g., Ha and Shilling, 2017).

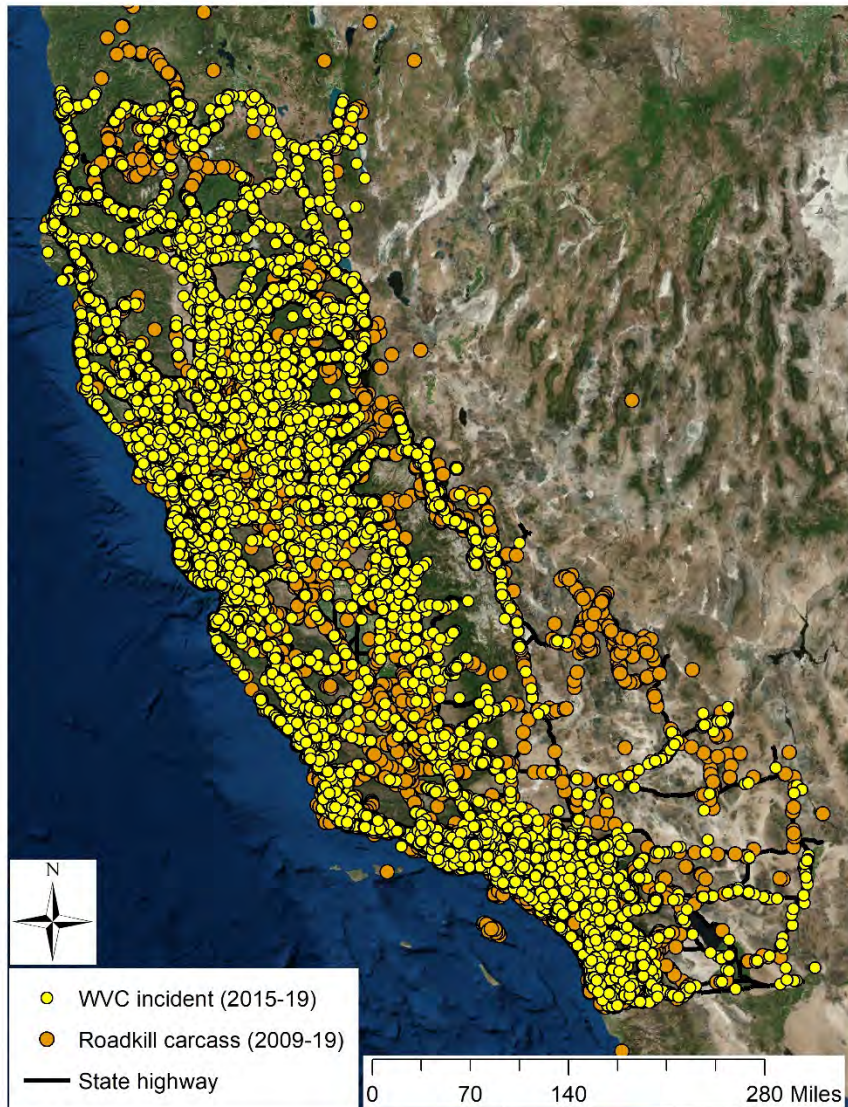

### Statewide Carcass Observations

Members of the public, agencies, and others made >60,000 observations of animal carcasses on local roads and state highways (Figure 1). These are not the total roadkill that occurred, just the ones that expert observers saw and reported to CROS.

**Figure 1.** Carcass observations for amphibians, reptiles, birds, and mammals.

## Statewide Highway WVC Incidents

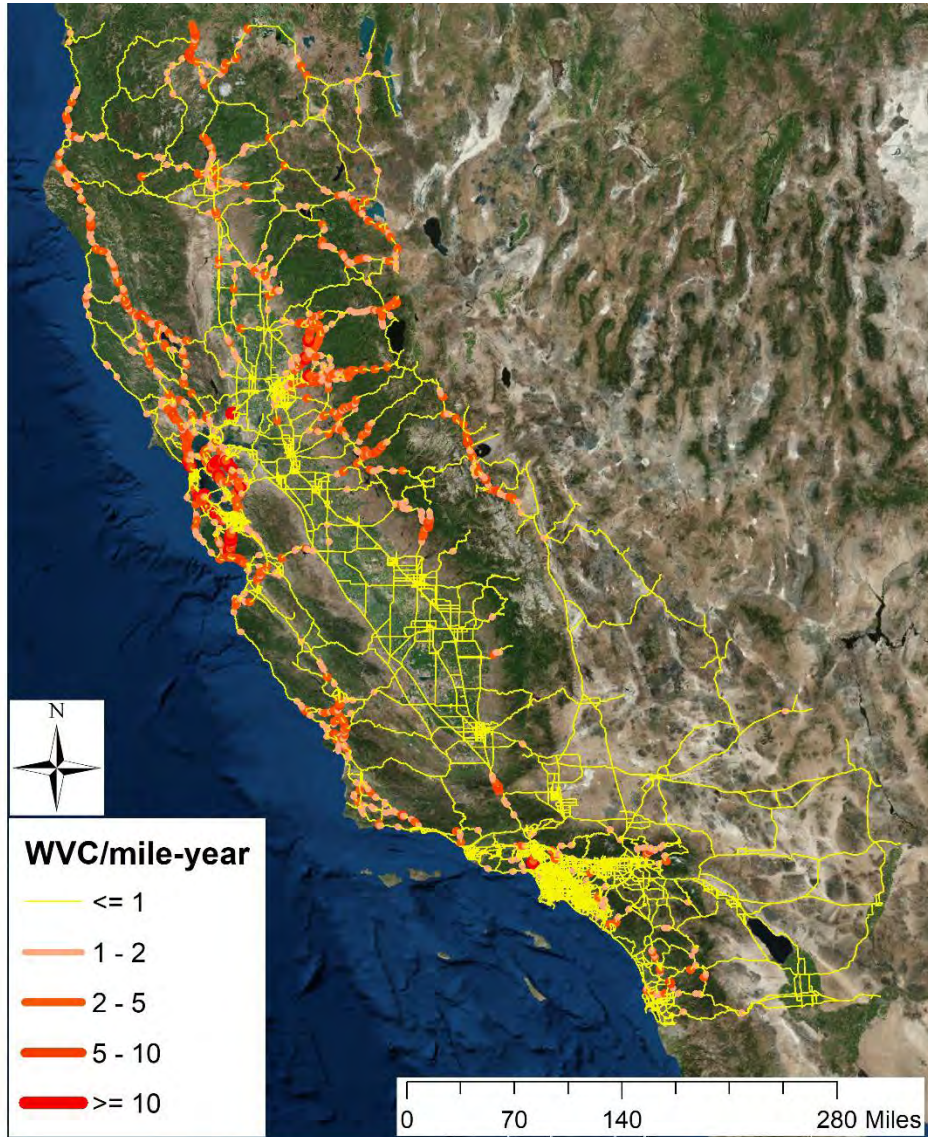

There were >2.5 million traffic incidents (of all types) across California reported to the CHP during 2015-2018. Of these, about half were collisions and 26,547 involved wildlife, including 1) reports of animals standing next to, standing in, or running across lanes (potential incidents); 2) collisions with large animals; and 3) swerving to avoid collisions, resulting in a crash (Figure 2).

**Figure 2.** Wildlife-vehicle conflict incidents on highways (2015-2018) and roadkilled animal observations on all roads (2009-2018).

Although WVC occurs on every major road and highway in California, the highest densities were reported in the San Francisco Bay Area (Caltrans District 4), Sierra Nevada Foothills (Caltrans Districts 3 & 10), North Coast (Caltrans District 1), and parts of the Central/South Coast (Caltrans Districts 5, 7, 11 & 12). These high-density areas are most likely where traffic volumes and wildlife populations are greatest, leading to more conflict. The map below shows the high-density clusters of collisions with large wildlife in California (Figure 3). There were 1,584 miles of state highway where  $\geq 4$  large animals were involved per mile per year in WVC incidents and 3,138 miles where  $\geq 2$  large animals were involved in WVC per year.

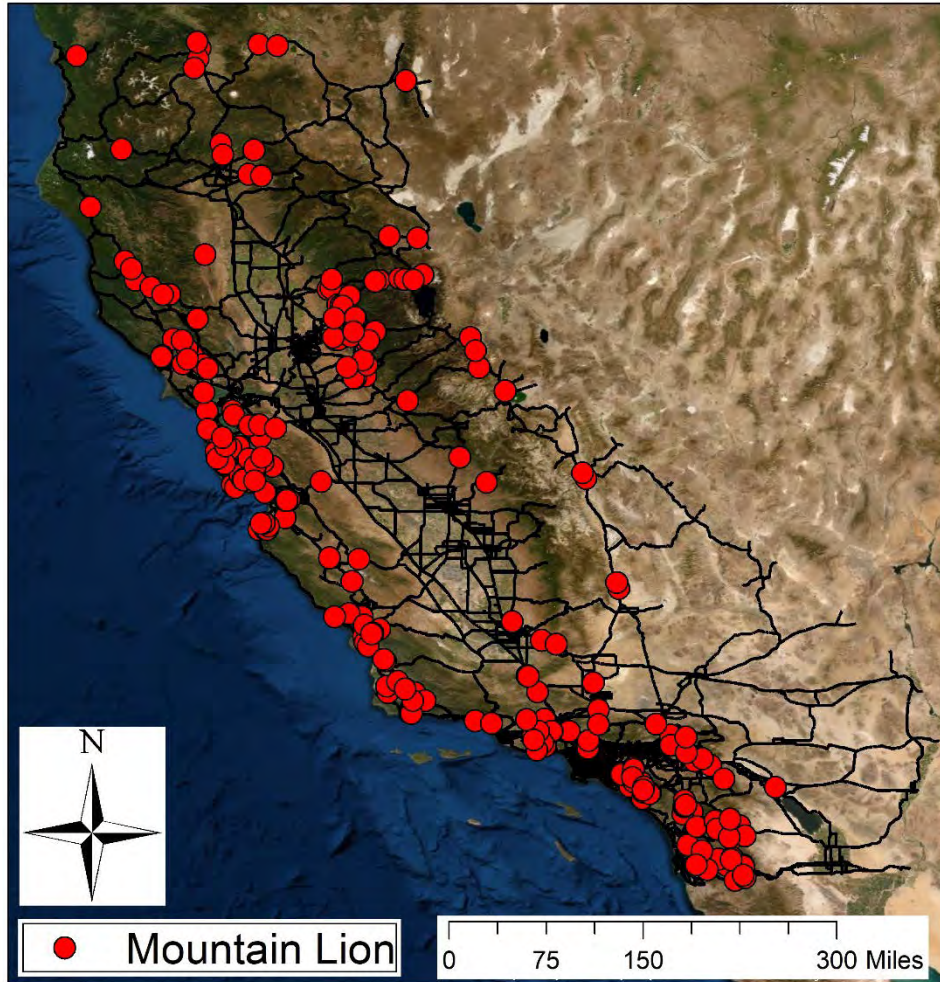

**Figure 3.** High-density WVC hotspots for 2015 to 2018. Hotspots can vary in length from 1 to several miles. Density is expressed as # incidents per mile per year. Greater than 2 WVC/mile-year is a recognized cost-benefit standard for transportation agencies to start planning for impact mitigation.

### Impacts to Specific Wildlife: Mountain Lions

Like most species at the top of the food web, mountain lions are especially vulnerable to WVC because they move around a lot and cross roads and highways. Mountain lions are important ecologically because they are the only large, widespread predator in most California ecosystems. They are also important socially, with great interest in their well-being in Southern California and Bay Area urban regions.

A critical problem for mountain lions in California is that there is no formal program, system or requirement to report when they are killed on roads, which happens frequently. As such, we only know the minimum killed each year on roads, when they are reported to CROS, and have

**Figure 4.** Mountain lions reported killed on roads, or involved in traffic incidents by the California Roadkill observation System, CDFW, CHP, or Winston Vickers and other biologists in Southern California (Vickers et al. 2015, and Vickers unpublished data).

no way of knowing the actual WVC impact to this important and charismatic species. Between 2015 and 2018, inclusive, 299 mountain lions killed on roads (~75/year) were reported by a combination of CROS volunteers, CHP, CDFW, and biologists in Southern California (Figure 4). The cover photograph for this report highlights the problem. It was taken by a wildlife biologist who happened upon the dead animal as part of her work. She reported the finding informally to colleagues in the

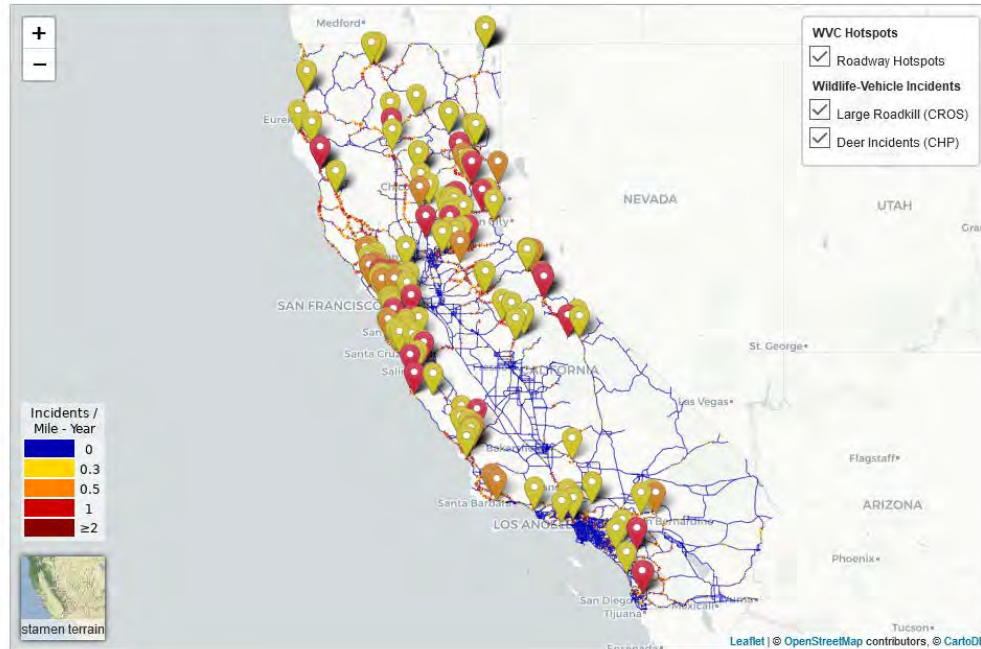

California Department of Fish and Wildlife, who similarly informally reported the observation to us. This story highlights the need in California for a systematic and legislated approach to reporting wildlife mortality on roadways in order that we can understand the distribution, impacts and risk to wildlife populations and species.

### Real-Time, Automated Web-Map of WVC

To provide more current information for California agencies and the driving public, we make our WVC data available in real time, the first tool of its kind in the world. You can see recent WVC events and WVC hotspots here: <https://roadecology.ucdavis.edu/hotspots/map>. The map was developed with support from the National Center for Sustainable Transportation and can support automatic ingestion by web-systems or driver-assistance programs.

## Real-time Deer Incidents & Wildlife-Vehicle Conflict (WVC) Hotspots

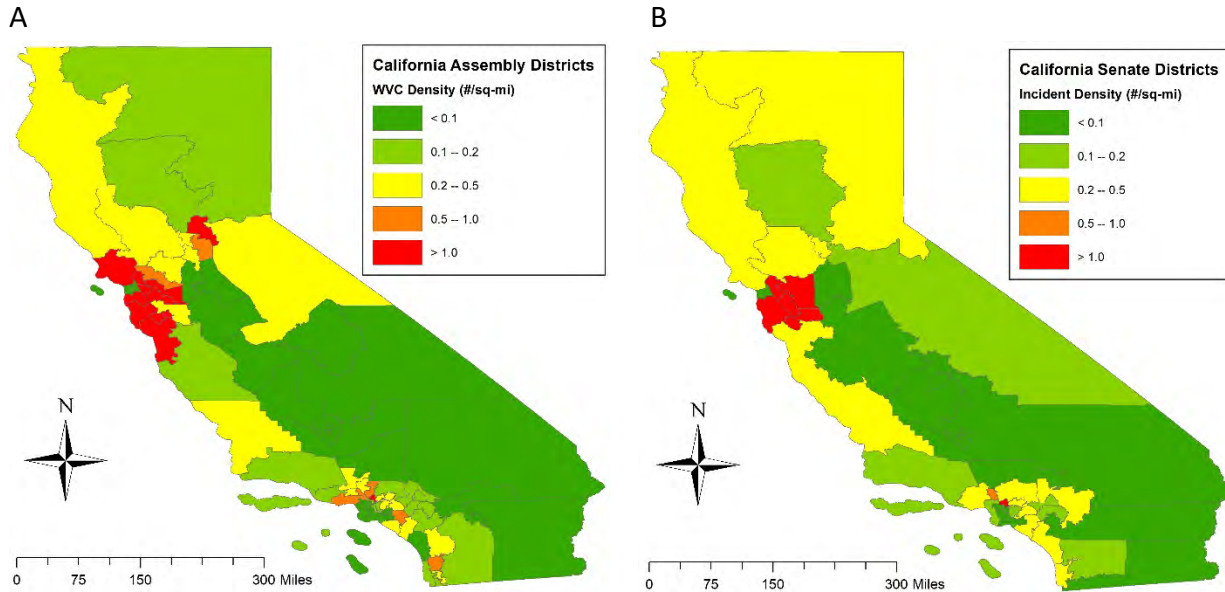

**Figure 4.** Locations of recent (7/22/2019) WVC incidents and roadkill carcasses (points) overlaying WVC hotspots, defined by annual WVC density (lines). Map available at: <https://roadecology.ucdavis.edu/hotspots/map>.

### Impacts within Assembly & Senate Districts

The ultimate authority for legislating reporting and mitigating impacts to driver and wildlife safety from WVC lies with the state Assembly and Senate. They have the ability to require state agencies to report WVC (e.g., crashes and carcasses), to require analyses (such as the one you are reading), to mitigate impacts at an adequate rate, and to spend available funds (e.g., from the SB1 Fuel Tax). We calculated the total number of WVC with large mammals within Assembly and Senate Districts for the 2015-2018 time period. The total number of WVC varied between a low of 1 for Assembly District 66 (Palos Verde) to 6,466 for Senate District 1 (rural NE California). Because the Districts vary widely in size, we also calculated the density of WVC (#/square-mile). This calculation revealed that the highest-densities of WVC are in Assembly and Senate Districts around the edges of the urban regions of the Bay Area, Sacramento and Southern California (Figure 4). The 10 Assembly Districts with the highest WVC rates were politically-mixed, with 6 represented by Democrats and 4 by Republicans. Our calculations showed that WVC as a conservation and safety problem is not limited to one political party or type of region (rural vs. urban).

**Figure 4.** Density of WVC by (A) state Assembly and (B) state Senate districts for 2015-2018, inclusive.

### Cost to Society

Any type of collision involves risk and actual damage to drivers and their vehicles. It is no different for collisions involving wildlife, whether the collision is with the animal, or with another object after the driver swerved to avoid hitting the animal. As in previous years, we used cost coefficients from the US Department of Transportation (Harmon et al., 2018, Crash Costs for Highway Safety Analysis. FHWA-SA-17-071) to estimate the total cost to society from collisions involving wildlife. These costs include the expense of vehicle damage, injury treatment and recovery, emergency response, lost work, loss of the wildlife and other costs. We found that the total cost was lower in 2018 than in previous years: ~\$232 million in 2018 vs. \$307 million in 2017 (Table 1). This was in part due to a lower estimated property damage cost to vehicles and a lower estimated number of fatal collisions, which is only estimated because California does not release these statistics. The total number of collisions did not change very much from year to year.

**Table 1.** Impact to drivers and estimated cost to society of reported collisions with animals on CA highways and certain major roads in 2018. Equivalent costs for accident types were obtained from Harmon et al. (2018).

Type of Accident	Coefficient (cost as \$/event)	Number (2018)	Cost (2018)
Lost animal value (all animals)*			\$37,300,000
Collision/Swerve (property damage)	\$11,900	6,412	\$76,302,800
Injury (minor)	\$125,600	271	\$34,037,600
Injury (major)	\$655,000	43	\$28,165,000
Fatality	\$11,295,400	5**	\$56,477,000
<b>Total</b>			<b>\$232,282,400</b>

\* This value includes both reported and estimated un-reported carcasses, with an estimated 5 times as many total as reported. Others have reported under-reporting rates for carcasses from collisions of 5-10 fold.

\*\* This is an estimate as CA does not release annual rates of fatal collisions with wildlife

Another way to measure costs is according to a California jurisdiction. We totaled all types of injury and non-injury accidents within California Assembly Districts. Except for District 10 (Marin County), the top-5 highest costs were associated with rural Districts (1, 5, 2, 35). District 10 was also among the top-10 districts with the highest number of total WVC and density of WVC, primarily because of US 101. Besides Assembly District 10, other Districts with high total number of WVC, density, and cost were District 16 (San Ramon, I-680, I-580, SR 24) and District 24 (Los Altos, I-280). The total cost over a 4-year period (2015-2018) for the top 10 Assembly Districts was ~\$445 million.

**Table 2.** Estimated number of WVC, injury accidents (from collisions with wildlife) and cost to society of reported WVC between 2015 and 2018, inclusive, for the Assembly Districts with the most WVC impact.

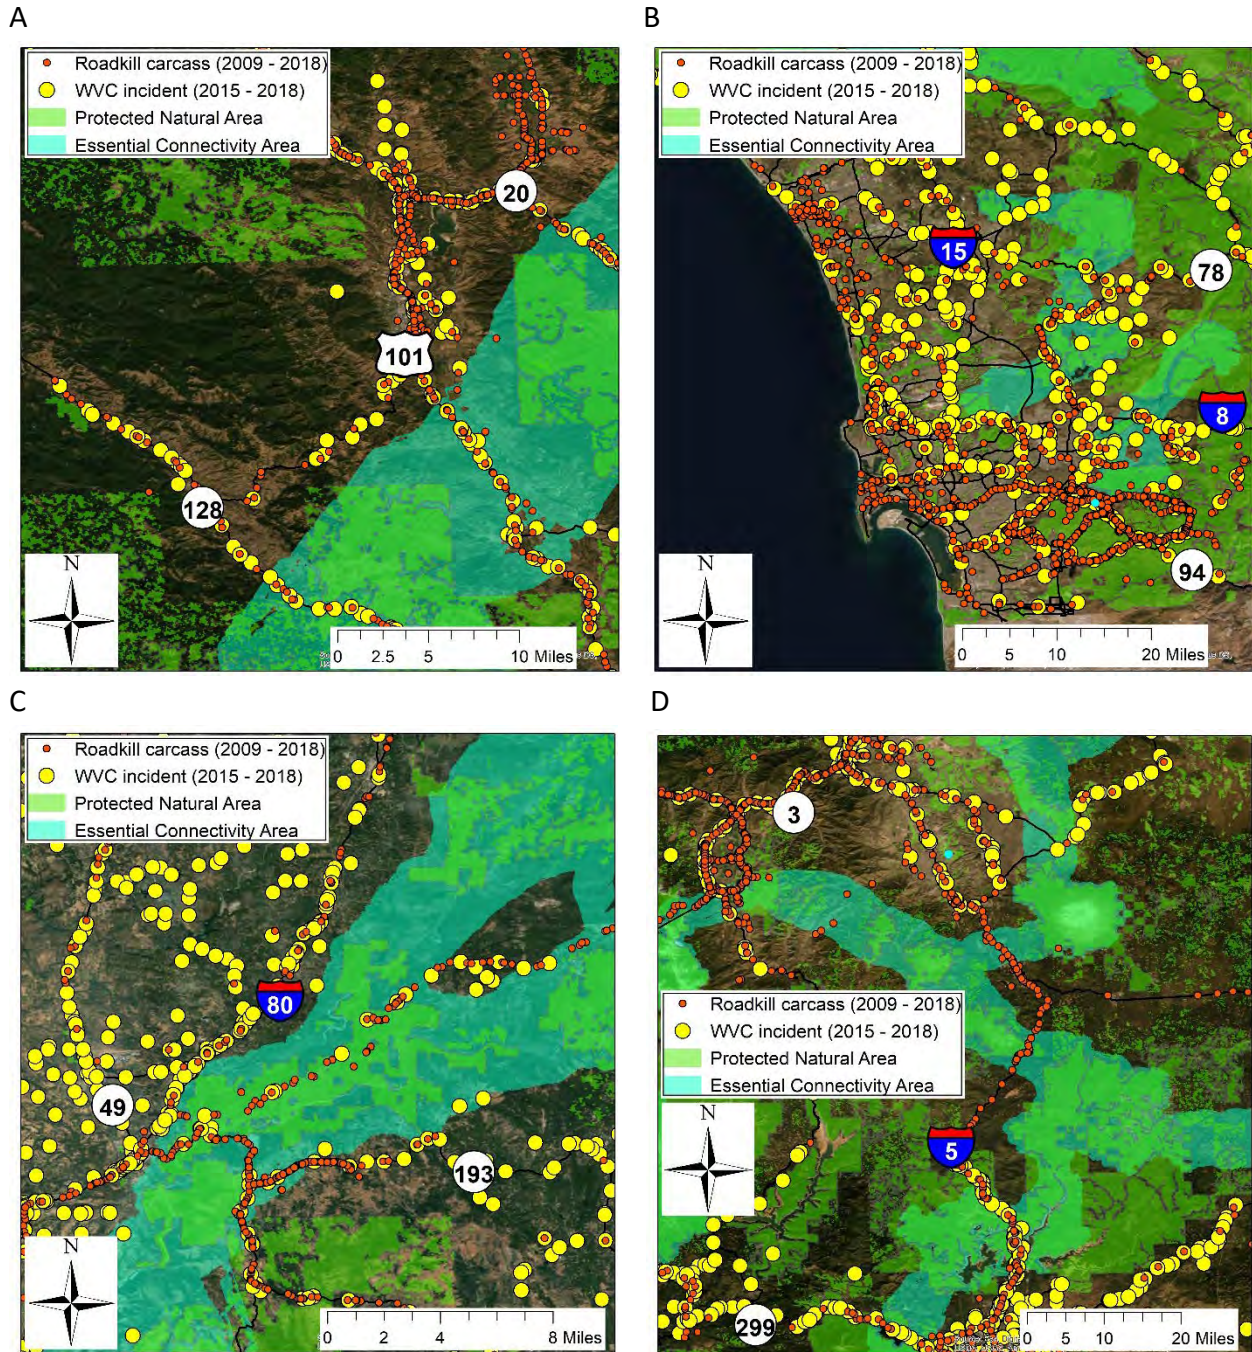

Assembly District	Total Collisions	Injury Accidents	Total Cost (\$)
1	4969	226	\$105,308,820
5	4395	202	\$93,547,800
2	2804	141	\$61,660,480
10	1555	60	\$31,040,220
35	1505	86	\$34,786,980
29	1493	48	\$27,098,140
16	1102	36	\$20,043,740
24	1039	66	\$25,853,820
4	1018	57	\$24,364,640
3	1016	51	\$21,287,780
			\$444,992,420

## Corridors, Linkages and Roadkill

Wildlife naturally move around their habitat, meeting daily, seasonal, reproductive, migratory, dispersal, and climate adaptation needs. A common misconception, even among conservation planners, is that wildlife will naturally follow “corridors” or “linkages” when roaming around on landscapes. This idea is related to the hypothesis that most species occupy “patches” of habitat and these patches are connected by corridors/linkages. Except for certain ungulates (e.g., mule deer in certain areas) there is little evidence that most or all of the roughly 180 mammal species in California (or anywhere else) follow predictable paths across landscapes, or only occupy mapped patches of habitat.

We compared densities of roadkilled animals on state highways with different connectivity values in the California Department of Fish and Wildlife’s Areas of Conservation Emphasis (ACE) and with the Essential Connectivity Areas in the California Essential Habitat Connectivity (EHC) project (Spencer et al., 2010). We tried all animals together and with different groupings (e.g., mammals). In all cases, we found no statistically significant relationship between location of roadkilled animals and linkage areas, or with connectivity values from ACE maps. Examples of the overlap between WVC/roadkill events and EHC linkage areas are shown in Figure 5. There were a few areas where concentrations of roadkill were associated with modeled linkages, which may indicate that these areas actually are important for wildlife movement. However, there were usually areas outside linkages that also had high concentrations of WVC/roadkill. The simplest explanation for these findings is that, in general, corridor and linkage maps don’t predict where animals are primarily moving and should not be used for mitigation planning that leaves out areas where animal movement is also provably occurring.

The importance of this finding is that many people in transportation and conservation planning use these maps as if they were related to wildlife connectivity movement and use the term “data” to describe the maps. In reality they are not data, nor are they based on data for all (or most) wildlife movement. In urban and agricultural regions, the “linkages” were more likely to seem related to locations of WVC, which is probably because these are the only natural habitat areas remaining in these regions. For example, if a stream with a healthy riparian area passes through an urban/residential area, then there tended to be a greater likelihood of predicted connectivity and concentration of WVC. The solution to the problem that our findings highlight is that maps of wildlife connectivity must be based upon where wildlife occur and are moving for them to have utility in wildlife conservation planning. Including additional areas where wildlife may occur after protection and restoration could also be useful.

**Figure 5.** Comparison of WVC/roadkill incidents and maps of essential connectivity areas and natural areas from the California Essential Habitat Connectivity project (Spencer et al., 2010). A) North Bay Area, B) coastal San Diego County, C) American River canyon, and D) Mt Shasta area.

## Summary

Monitoring wildlife movement and mortality is critical for improving wildlife connectivity and survival of wildlife species in the face of the combined threats they face, such as transportation systems, climate change, rodenticides, and habitat loss. We reported here on long-term,

successful methods for monitoring WVC in California, an annual (2018) analysis of locations and costs of WVC to wildlife and drivers and society. We provided key recommendations for ways to reduce WVC in California through support for a several-fold increase in mitigation projects with net benefit for wildlife and driver safety. Finally, we suggest that any WVC-reduction and wildlife connectivity mitigation be planned based on evidence-based connectivity design, not the current “linkage” models.

## **Acknowledgements**

We appreciate the support from the National Center for Sustainable Transportation (using USDOT funding) and the Institute of Transportation Studies (CA SB1 funding) for development of the automated wildlife-vehicle conflict hotspot tool and one-click reporting tool California Roadkill Observation System (CROS, <https://wildlifecrossing.net/california>). This and previous reports and the analyses contained within would not have been possible without the concerted and coordinated efforts of hundreds of volunteer roadkill observers over the last 10 years who contribute to CROS. Through their endeavors, they have so far (7/2019) collected >60,000 observations of >430 species, representing one of the largest and most comprehensive wildlife monitoring programs in California and the US. Their accuracy rate for species identification is >97% and have high locational accuracy (median <±13 meters). For the scientific article describing CROS, see citation below (you can paste the “doi” value below into a browser and access the papers). The report also benefited from the efforts of many unknown law enforcement personnel who described traffic incidents in enough detail that we could use their observations to help plan for reduced wildlife-vehicle conflict. Finally, we have partnered with other similar systems around the world in the Globalroadkill.net project (<http://globalroadkill.net>).

# Birdsong and anthropogenic noise: implications and applications for conservation

HANS SLABBEKOORN and ERWIN A. P. RIPMEESTER

*Institute of Biology, Leiden University, 2300 RA Leiden, The Netherlands*

## Abstract

The dramatic increase in human activities all over the world has caused, on an evolutionary time scale, a sudden rise in especially low-pitched noise levels. Ambient noise may be detrimental to birds through direct stress, masking of predator arrival or associated alarm calls, and by interference of acoustic signals in general. Two of the most important functions of avian acoustic signals are territory defence and mate attraction. Both of these functions are hampered when signal efficiency is reduced through rising noise levels, resulting in direct negative fitness consequences. Many bird species are less abundant near highways and studies are becoming available on reduced reproductive success in noisy territories. Urbanization typically leads to homogenization of bird communities over large geographical ranges. We review current evidence for whether and how anthropogenic noise plays a role in these patterns of decline in diversity and density. We also provide details of a case study on great tits (*Parus major*), a successful urban species. Great tits show features that other species may lack and make them unsuitable for city life. We hypothesize that behavioural plasticity in singing behaviour may allow species more time to adapt to human-altered environments and we address the potential for microevolutionary changes and urban speciation in European blackbirds (*Turdus merula*). We conclude by providing an overview of mitigating measures available to abate noise levels that are degrading bird breeding areas. Bird conservationists probably gain most by realizing that birds and humans often benefit from the same or only slightly modified measures.

*Keywords:* adaptation, biodiversity, city life, conservation, ecological speciation, homogenization, traffic noise, urbanization

*Received 17 March 2007; revision accepted 4 July 2007*

## Introduction

Urbanization concerns all environmental changes associated with urban development and is a global phenomenon affecting animals, including humans, as well as plants (Vitousek et al. 1997; Western 2001). Expectations are that in the next two decades an additional two billion people will need a place to live, and they will not live in the current cities but in newly developed urban areas (Meyer & Turner 1992; World Resources Institute 2004). Urbanization usually has a negative effect on rare species and favours others that become more and more common, which can be native generalist species, but often means non-native urban colonizers (Bolger et al. 1997; Sewell & Catterall 1998;

Lim & Sodhi 2004; Marzluff 2005). At a local scale, urbanization does not necessarily lead to a drop in species diversity because the heterogeneous urban habitat does provide quite a variety of niches. However, at a larger scale, urbanization leads to homogenization and a drop in diversity because the typical urban species turn out to be the same everywhere irrespective of the original fauna (Clergeau et al. 2006; McKinney 2006). For species that still occur within and outside of cities, it is known that urban challenges may be relatively stressful as reflected for example by a divergence in heterophil-leucocyte ratios (Ruiz et al. 2002) or increased baseline corticosterone levels in male birds of city environments (Bonier et al. 2007). Nevertheless, although many species disappear from urban areas because they depend on habitat features that do not exist anymore, others find a new niche among bricks and concrete and adapt to a life in the city (Luniak 2004).

Correspondence: Hans Slabbekoorn, Fax: 31 71 527 4900; E-mail: h.w.slabbekoorn@biology.leidenuniv.nl

Cities differ from rural or forested areas in a number of ways (Warren *et al.* 2006; Slabbekoorn *et al.* 2007). Urban areas are usually warmer, have artificial lighting regimes, more chemical pollution, and have relatively little and often exotic vegetation in a landscape dominated by street pavement and concrete buildings. Furthermore, cities harbour a different suit of parasites (Gregoire *et al.* 2002) and predators including domestic cats (Woods *et al.* 2003; Lepczyk *et al.* 2004), and a different set of food sources (Horak & Lebreton 1998). For example, urban house sparrows are reported to have higher cholesterol levels compared to rural ones, and food samples indeed reveal higher fat and protein content in urban diets (Gavett & Wakeley 1986). Consequently, food preferences also affect which species are more likely to do well under the urban food conditions; omnivorous and frugivorous birds are typically more successful than insectivorous and carnivorous species (Clergeau *et al.* 1998; Lim & Sodhi 2004).

One of the most prominent novel urban conditions concerns the ambient noise and the acoustic space available for animals to use acoustic signals (Slabbekoorn & Peet 2003; Katti & Warren 2004). All habitats are noisy to some extent, but the usual urban cacophony produced by cars, mopeds and all sorts of machinery is evolutionarily speaking novel and dramatically different from most natural habitats. Urban noise is typically loud and low in pitch which also applies to anthropogenic noise in areas around highways, railway lines and airports – which together form an ever denser network penetrating deeply into rural and forested areas (Forman & Alexander 1998; Reijnen & Foppen 2006). Anthropogenic noise could be an important factor driving bird species out of cities and away from highways, even when other habitat requirements are still sufficient.

Many studies have reported lower species diversity and lower breeding densities of birds along highways (Van der Zande *et al.* 1980; Reijnen & Foppen 1991, 1994; Illner 1992; Kuitunen *et al.* 1998, 2003). The negative impact of roads on birds has been linked repeatedly with traffic load (Reijnen *et al.* 1995, 1997; Forman *et al.* 2002; Peris & Pescador 2004), showing that the impact is not due to the mere presence of a road. However, direct evidence for traffic noise being the dominant detrimental factor is still lacking and other potential factors are visual disturbance, chemical pollution, road-kills and soil vibration. An interesting study concerns an impact assessment along a German motorway, which revealed a song-frequency-dependent pattern in breeding density in two transects parallel to the road (Rheindt 2003). Bird species with relatively low mean song frequencies were less abundant near the road, while species singing with higher frequencies occurred in higher numbers near the noisy road than in the more quiet transect. Although the lack of replication and statistical significance were limitations to this study, this is the first

direct indication that low-frequency traffic noise may constrain breeding opportunities of birds.

Few studies have tried to assess a negative impact of anthropogenic noise on birds while excluding other possibly contributing factors. A study in natural habitat of the Rocky Mountains, USA, showed a negative correlation between the number of species and anthropogenic noise levels (Stone 2000). Another recent study reported the first data on a decline in reproductive success due to anthropogenic noise without confounding parameters typically associated with highway or urban studies (Habib *et al.* 2007). The authors compared ovenbirds (*Seiurus aurocapilla*) in Canada, in two sets of territories of equal quality, except for either being located next to noise-generating compressor stations or next to noiseless well pads. Significantly more inexperienced first-year breeders were found at the noisy locations, while the pairing success at noisy territories showed a considerable decline, independent of the individual quality. This study unequivocally confirms a negative impact of human-generated ambient noise, but how does the sound affect the birds?

In this paper, we will address in what way birds may be affected by anthropogenic noise as well as how birds may counteract artificially altered noise conditions in their territories. We will discuss a case study of great tits (*Parus major*) which provides insight into how a successful urban species gets at least partly around the noise problem in cities across Europe. Subsequently, we will address to what extent urban habitat may drive divergence of urban populations and how sensible it is to make a case for ecological speciation in this context. The potential emergence of new urban species takes place over an evolutionary time scale and does not relate to conservation of today's biodiversity. Therefore, we will conclude with considering the available options to abate the negative impact of anthropogenic noise on current species at an ecological time scale.

### *Noise annoys*

Extreme noise levels can result in temporary and permanent hearing loss (Ryals *et al.* 1999), but also the ubiquitous condition of more moderate noise levels may have adverse impacts. In humans, traffic noise at the front door of people's houses is a significant predictor of ischemic heart disease (a hospital-based case-control study with controls matched according to sex, age and hospital: Babisch *et al.* 2005), and repetitive exposure to aircraft noise has been shown to reduce performance at school (Stansfeld *et al.* 2005). Even relatively modest noise levels of train- and car traffic can already negatively affect cognitive development and reading skills (Lercher *et al.* 2003). Clearly, humans pay a price for

living in noisy cities or along roads with heavy traffic loads with respect to physical and psychological welfare (Miedema & Vos 1998; Nilsson & Berglund 2006). This may also be true for animals, including birds.

Measurements to assess direct and detrimental physical effects of anthropogenic noise on birds, such as an increased heart-beat (Helb & Hüppop 1991), are rare or nonexistent. Nevertheless, a wide variety of animal species has been reported to be affected by anthropogenic noise as indicated by behavioural changes (e.g. birds: Slabbekoorn & Peet 2003; Brumm 2004; whales: Foote *et al.* 2004; Miller *et al.* 2000; frogs: Sun & Narins 2005; ground squirrels: Rabin *et al.* 2006). One of the behavioural changes concerns an increase in vigilance behaviour at the expense of time spent feeding (Rabin *et al.* 2006). For example, chaffinches (*Fringilla coelebs*) spend less time with their head down, pecking at food, during artificially increased noise levels (Quinn *et al.* 2006). The nature of the behavioural change in this experiment suggests that these birds did not change general alertness due to a novel stimulus but have to rely more on visual scanning for predators when the detection of auditory cues is limited by masking noise. Predation risk in noisy conditions may therefore have negative consequences for food-intake rates and ultimately lead to lower survival and lower reproductive success.

Anthropogenic noise may not only hamper the detection of heterospecific predators but also the detection of conspecifics. Many animal species, and especially birds, depend heavily on acoustic signals for intraspecific communication (Catchpole & Slater 1995; Marler & Slabbekoorn 2004). Typically, males defend a territory for access to food, hiding places and nest sites. Singing and song features such as repertoire size or spectral and temporal details may have a direct impact on how well they are able to do so. Encoded in acoustic variation, birds may convey a message about their species identity, fighting ability and motivation to defend a resource (e.g. Ten Cate *et al.* 2002; Ripmeester *et al.* in press). Successful transmission of such a message may prevent competitors from approaching and may save energy, time and risks of injury. In addition, females also pay attention to these messages and are known to select their mates based on male song features (Riebel 2003). Therefore, whether songs are heard properly or not may have serious consequences for territory tenure and mate attraction (Klump 1996), potentially affecting individual fitness and population viability.

However, there are many signalling strategies available to birds to avoid or reduce masking by ambient noise (Brumm & Slabbekoorn 2005). Species-specific abilities in this respect may explain why some species resist urban noise conditions and others do not. A widespread strategy,

for example, concerns the Lombard effect: birds as well as humans raise their signal amplitude with noise level. Recently, urban nightingales (*Luscinia megarhynchos*) in the city of Berlin, Germany, were found to raise their song volume in response to traffic noise; as a result they appear to sing louder on weekday mornings than in weekends (Brumm 2004). Another way to adjust to fluctuating noise conditions concerns a temporal shift in singing activity. Several urban bird species are reported to start singing earlier during the day than their forest counterparts (Bergen & Abs 1997), but the potential relationship with avoiding traffic peaks has not been investigated in enough detail yet. However, European robins (*Erithacus rubecula*) sing both, during day and night time, and whether or not birds are active during the night was recently shown to be dependent on day-time noise levels in a study in the city of Sheffield, UK (Fuller *et al.* in press). There was less of an effect in this study of ambient light pollution, to which nocturnal singing in urban birds is frequently attributed. Although it is not clear yet whether nocturnally active robins reduce their day-time activity and whether they gain any fitness benefits by doing so, it seems plausible that this strategy may enable them to avoid masking noise and breed in noisy territories. In general, a division between species surviving in urban conditions and those fleeing the cities may very well depend on how effectively members of a species can adjust their signalling behaviour to the volume, temporal fluctuations or spectral characteristics of traffic noise.

#### *Signalling flexibility in urban great tits*

Over the last five years, we have studied patterns of song variation among individual great tits (*Parus major*) within an urban population in Leiden, The Netherlands, and among 20 different urban and forest populations across Europe. We first found in the single-population study that individual variation in the frequency range correlated to local urban noise levels (Slabbekoorn & Peet 2003). Birds of noisier territories sang with higher minimum frequencies, thereby avoiding masking by low-pitched traffic noise (Fig. 1). We speculated at the time that these results could mean that urban birds could have diverged from forest birds, and that flexibility through learning may be the behavioural mechanism underlying the correlation. Subsequently, we confirmed that urban birds across Europe have diverged from nearby forest birds in several parameters, among which the minimum frequency. A surprising 10 out of 10 independent city–forest comparisons revealed a consistent shift (Slabbekoorn & den Boer-Visser 2006).

The habitat-dependent acoustic shift in great tits could be an evolutionary or ontogenetic shift, or it could be based on the ability to adjust at an even shorter temporal

**Fig. 1** Sonograms of a three-note song type recorded in an urban habitat, with a relatively high minimum frequency (3.8 kHz, left graph) and of a three-note song type recorded in a forest habitat with a relatively low minimum frequency (2.7 kHz, right graph). The centre panels illustrate the energy concentration of each of the spectral components present in the song, normalized at an equal amplitude and contrasted, at an arbitrary level, against the energy distribution of a typical anthropogenic sound spectrum of urban traffic noise. Noise levels gradually increase towards lower frequencies, and the figure illustrates that critical signal-to-noise ratios leading to perceptual problems are more likely for notes of low frequency. As a consequence, song types without relatively low notes will on average be heard better in noisy cities.

scale (Patricelli & Blickley 2006). It is known from long-term field observations that great tits are probably capable of postdispersal adjustment of song-type repertoires guided by vocal interactions with neighbours (McGregor & Krebs 1989). Noisy conditions may affect such social influences through selective copying or selective reinforcement: song types of neighbours that are not heard well may not be copied, and song types sung but hardly eliciting a response from neighbours may be dropped. Recently, we found that adult males are even more flexible than previously thought. We played back unfamiliar song types and assessed the repertoire of a series of males before and after playback (Franco & Slabbekoorn, unpublished). The song-type repertoire size remained relatively constant over the season, but the rates at which different song types were sung varied and the repertoire composition was sometimes modified dramatically within a week. This shows that great tits have a larger repertoire memorized than they actually sing at a time or that they can make up new song types late in life. Most importantly, this means they have remarkably flexible singing behaviour. They are capable of mobilizing a large set of song types to adjust to new neighbours or possibly to new noise conditions.

The singing behaviour and repertoire flexibility of great tits has likely evolved to fit their social system in the context of the original forest habitat. They may be just lucky in the sense that these features turn out to be very suitable for coping with dramatic and, evolutionarily speaking, sudden rises in anthropogenic noise levels. The ability to spectrally adjust their song after dispersal to the local circumstances of a breeding territory, and this potentially throughout life, may be key to urban success. At the same time, despite the fact that they remain in cities breeding at relatively high densities,

it is not certain that great tits are not at all negatively affected by anthropogenic noise (see Box 1). However, their acoustic counter-strategy seems at least sufficient for urban populations to survive under potentially sub-optimal conditions (also see Junker-Bornholdt *et al.* 1998). Our results from the single-population study have now been independently replicated in two other North American bird species that are also very successful in urban environments (house finch, *Carpodacus mexicanus*: Fernández-Juricic *et al.* 2005; song sparrow, *Melospiza melodia*: Wood & Yezerinac 2006). An earlier study on chaffinches did not find a correlation between traffic noise levels and call characteristics (Skiba 2000). Nevertheless, this species, which can be very common in cities, does show the same increase in minimum frequency of their songs with varying levels of natural river noise (Brumm & Slater 2006). We are now waiting for data showing that bird species which are less successful in noisy areas are lacking the ability of spectral adjustment through repertoire changes.

#### *Divergent phenotypes in great tits: a case for urban speciation?*

Behavioural plasticity may allow urban birds enough time to evolve and adapt to human-altered environments. Although it is possible, currently there is no evidence that the acoustic divergence between city and forest tits involves any microevolutionary changes and associated genetic differentiation. However, habitat-dependent divergence in a sexual trait like song in birds may play an important role in population divergence and ecological speciation (Slabbekoorn & Smith 2002a, b), and we may be able to consider urban speciation. Species with a distribution across ecological gradients may evolve different subpopulations in different habitats. These

**Box 1 Is singing low important to great tits?**

There is a general relationship in birds between body size and frequency of pitch: larger species typically sing lower. Small birds with small vocal organs may be lacking the power, the essential size of the vibrating source, or the suitable resonance features of the vocal tract, that allow the production of low-pitched sounds. This creates the possibility of using low frequencies as a way to signal condition or size to competitors and potential mates (Ten Cate *et al.* 2002). However, we do not know whether intraspecific variation in male body measures is related to the minimum frequency in great tits, nor do we know if female great tits prefer males singing low-pitched songs. If it were hard for great tits with a territory to sing low, you may expect that they sing songs relatively high in pitch when the motivation to sing is low. Such a situation occurs at the end of the breeding season, in both urban and forest habitat. Males still sing their stereotypic song types but the resources at stake in their territory have decreased in value until the start of the next breeding season. A decline in motivation to sing is clear from a decline in number of repeated songs (phrases) in a strophe, independent of habitat: in the city of Rotterdam from six to three phrases, and in the forest called the Liesbos from six to four phrases on average (ANOVA:  $F_{2,100} = 27.4, P < 0.001$ ). Interestingly, controlling for habitat differences, we found that the minimum frequency increases dramatically when recordings from relatively early in the season (early April: 'Early') are compared to recordings from late in the season (late May: 'Late', ANOVA:

$F_{2,100} = 7.8, P < 0.01$ ). We therefore hypothesize that it may be an important signal of quality to have low-pitched notes in the song type repertoire, which may cause a trade-off especially for the urban birds in noisy territories. Low-frequency noise may constrain the capacity to signal individual qualities: urban birds may need to choose between being heard well or being rated high as a competitor or mate. High noise levels may increase the number of intruding competitors needing physical combat and may affect the number and quality of potential mates that are attracted. Consequently, although great tits are successful in cities, and even though they show a remarkable flexibility in spectral adjustment to local noise conditions, this does not mean that traffic noise interference is not harmful to individual birds.

subpopulations may show genetic divergence in fitness-related traits related to morphology, physiology, neurobiology or life-history. Congruent geographical patterns of variation in sexual and fitness-related traits may arise because varying environmental selection pressures in different habitats shape both types of traits. Congruent patterns may also emerge because acoustic changes are an inherent result of, for example, changes in bill morphology (Slabbekoorn & Smith 2000; Podos *et al.* 2004). As a consequence, under both conditions, songs may guide female birds to the locally adapted males, accelerating the process of reproductive divergence. The fact that many birds learn their songs from conspecifics adds a layer of complexity (Baker & Cunningham 1985; Slabbekoorn & Smith 2002b), as it will accelerate phenotypic divergence among populations but may actually constrain genetic differentiation (Ellers & Slabbekoorn 2003). Nevertheless, divergence in learned song will still

increase the rate and chance of speciation for a subset of evolutionary scenarios (Lachlan & Servedio 2004; Ellers *et al.* unpublished).

In terms of gene flow, it may be improbable that urban habitat could generate phenotypically distinct and reproductively isolated subpopulations, as cities are typically scattered geographically and form a patchy network within a matrix of forested and agricultural area (Marzluff 2005). Habitat imprinting, on the other hand, may strongly influence dispersal patterns, and urban-borne birds may preferentially settle in urban territories (see e.g. Septon *et al.* 1995). In terms of consistent directional selection, despite considerable heterogeneity within urban habitat, some urban selection pressures are clearly distinct and dramatically different from those in more natural habitat. These consistent habitat-dependent selection pressures may have the potential for driving divergence of an urban phenotype despite ongoing gene flow.

We are not aware of any publications on gene flow, or dispersal, between urban and nonurban populations of great tits, but there are some studies on urban-related phenotypic divergence. Plastic environmental responses were found for carotenoid-derived plumage coloration, with urban birds being less yellow compared to forest birds (Horak & Lebreton 1998) and also for timing of reproduction and clutch size, with later and smaller broods in (sub)urban great tits compared to their forest counterparts (Riddington & Gosler 1995). Another study, not involving urban habitat, addressed the balance between the response to divergent selection pressures and levels of gene flow over a very short distance. A partial cross-fostering experiment with great tits of two qualitatively different parts of Wytham Woods in Oxfordshire, UK, allowed the separation of genetic and environmental sources of variation (Shapiro *et al.* 2006). Nestlings in the high-quality part of the forest were larger, heavier and in better condition than in the low-quality part irrespective of the part from which they originated. Interestingly, in addition, significant differences in condition and shape could be attributed to area of origin, suggesting genetic differentiation. The areas of varying quality in this comparison were only a few kilometres apart and interconnected by forest, which reveals the evolutionary potential of divergent selection in ecologically distinct habitat for driving populations apart. Another recent and small-scale study on great-tit populations also reported interesting findings with respect to the balance between divergent selection and gene flow. A biased influx of birds from the mainland to only one side of the Dutch island of Vlieland created a local abundance of breeding birds that were not locally adapted (Postma & van Noordwijk 2005).

#### *Evidence for microevolutionary changes in urban habitat*

The evidence for genetic differentiation related to anthropogenic selection pressures in cities is also still scarce when we look at bird species beyond great tits. A nice example of selection in an urban environment driving evolutionary change is found in an exceptional urban bird population on the campus of the University of California in San Diego, USA. Dark-eyed juncos (*Junco hyemalis*) have been breeding in this urban setting since the early 1980s (Yeh & Price 2004). The birds were presumably winter visitors that decided to stay instead of return to their natural breeding habitat: montane pine forest at least more than 70 km away (Nolan *et al.* 2002). Population comparisons and a common-garden experiment with hand-raised birds revealed that wing- and tail size, as well as a sexual trait (the amount of white in the tail) has diverged on campus beyond the extend attributable to phenotypic plasticity or drift (Rasner *et al.* 2004; Yeh 2004). However, there was only limited evidence for song divergence between this

small urban population of about 70 pairs and four forest populations (Slabbekoorn *et al.* 2007). Although there were strong indications for divergent selection pressures on acoustic signals related to sound transmission, sexual selection based on song may be relaxed, as suggested by a reduced response to playback of junco songs in the urban population (Newman *et al.* 2006). The urban juncos make a strong case for microevolutionary changes related to anthropogenic selection pressures, but they require more study and better replication to increase our insight into the role of song in urban speciation.

Another bird species for which there is growing evidence for urban-related population divergence is the European blackbird (*Turdus merula*), a very common city bird in most parts of Europe (Luniak *et al.* 1990). Urban blackbirds breed in higher densities and start breeding earlier in the year than their forest counterparts (Partecke 2003). A common garden experiment, with nestlings collected in the city of Munich and the nearby Lichtenauer Forest, revealed phenotypically plastic divergence but also suggested that some of the variation reflects genetic differentiation (Partecke *et al.* 2004, 2005, 2006a). The habitat-dependent difference in timing of reproduction corresponds to an earlier initiation of the development of the reproductive system in male and female urban birds (Partecke & Gwinner 2007). The prolonged breeding season allows urban individuals to have more breeding attempts per year than individuals from forests, who on the other hand have a larger clutch size and more fledglings per successful nest (Gregoire 2003). Urban blackbirds also live longer than forest birds (Luniak *et al.* 1990), have a smaller tendency to migrate (Stephan 1999; Partecke & Gwinner 2007) and have a lower acute corticosterone stress response (Partecke *et al.* 2006b). Finally, a pattern of habitat-dependent divergence starts to emerge from several studies at different geographical locations, with blackbirds from cities and forests being distinct from each other in several morphological measures (Lippens & van Hengel 1962; Partecke 2003; Ripmeester & Slabbekoorn, unpublished).

European blackbirds may become the first bird species for which there is evidence for urban habitat-related divergence in both, fitness-related traits (as described above) and acoustic traits (Ripmeester & Slabbekoorn, unpublished). We are in the process of testing with playback recordings whether urban songs trigger stronger responses in city birds than in forest birds and vice versa. At the moment, we do not know yet whether congruent habitat-dependent divergence in song and morphology promotes the process of urban speciation. There is also no information available yet about habitat-guided dispersal, although a first study on divergence in neutral markers between the urban and forest birds of the common garden experiment in Germany could not confirm such a

phenomenon (Partecke *et al.* 2006a). It is clear, however, that the aspects of coding and neutral genetic divergence between urban and forest blackbirds warrant further investigation and several complementary studies are on the way.

#### *Considerations on making bird breeding habitat more quiet*

It is possible to make bird breeding habitat close to, or surrounded by, anthropogenic noise sources more quiet. We can build noise barriers, make depressed highways or underground tunnels (e.g. Maekawa 1977), or introduce porous road surfaces, speed limitations and restrictions on allowable noise emissions for road traffic related to engine features, break systems and tire types (e.g. Sandberg 1991). There are many examples of successful implementation of these techniques, typically to reduce noise exposure to humans. This means that the main threshold for applications to the benefit of wildlife will likely be the financial costs. However, when considering expensive mitigating measures, it is very important to realize that birds and humans often benefit from the same, or only slightly modified, measures. Urban birds live and breed near human residences, and birds of more natural areas inhabit space often used for recreational activities. The importance to human health and well-being can be used as additional arguments for installing measures to improve bird-breeding areas. In cases where noise barriers are already in place to the benefit of humans, small cost-effective modifications (e.g. increased height, added absorbent) could be a successful strategy (see Box 2).

Urban planners are increasingly aware of the need to consider noise pollution in constructing cities and residential neighbourhoods from a human perspective (Grimm *et al.* 2000; Yli-Pelkonen & Niemelä 2005; Bucur 2006; Nilsson & Berglund 2006). For example, the idea of urban canyons has received considerable attention: the use of relatively continuous rows of office buildings or apartment flats separating noisy human activities from living space in which noise is not appreciated (de Ruiter 2004). This living space may concern pedestrian areas, urban parks and private gardens, all areas in which urban birds would also benefit from reduced noise levels. The strategy of urban canyons also entails concentration of noise sources: canalization of traffic in a limited number of busy through-roads. This will limit the number of canyons to be constructed and make plans economically more feasible (Thorsson & Ögren 2005). Similarly, it is more realistic to concentrate on a restricted set of specified areas which are shielded from noise, instead of trying to reduce noise levels in all public areas (Kihlman & Kropp 2001; Thorsson *et al.* 2004). Urban canyons and 'quiet zones' provide people living in noisy cities with access to

at least some quiet areas nearby, which may be a last resort for noise-sensitive bird species at the same time. In the best scenario, bird-breeding data and species-conservation values would be incorporated in the process of selecting the areas to be relieved from urban racket.

More and more tools have been developed to assist policy makers to predict and extrapolate noise levels spatially, based on traffic flow, vehicle types and distance to the road (e.g. Horoshenkov *et al.* 1999; Li *et al.* 2002; de Coensel *et al.* 2005). Spatial extrapolation has also been applied to reveal the impact of traffic noise on bird habitat by using road effect-distances based on general dB-threshold values that are just acceptable for birds, and which depend on habitat type and target species (Reijnen *et al.* 1997). For example, roads with 50 000 vehicles a day result in effect-distances from 75 to 930 meters for grassland species and from 60 to 810 meters for woodland species, as was shown by a meta-analysis combining nine studies (Reijnen & Foppen 2006). Highways may negatively affect bird-breeding habitat in a variety of ways, as stated earlier (e.g. collision, chemical pollution). However, visual disturbance and noise are the primary factors that reach furthest in open habitat, while noise is the single most important factor impacting forested habitat beyond 50 meters from the road (Reijnen & Foppen 2006).

#### *The importance of temporal and spectral overlap*

Birds often have a diurnal cycle of vocal activity which matches periods of optimal sound transmission early in the day (Staicer *et al.* 1996; Brown & Handford 2003). Diurnal fluctuations in anthropogenic noise levels are also highly stereotypic with, not surprisingly, noise peaks during the morning and evening rush hour (Jabben *et al.* 2001). Interestingly, traffic jams during these periods may bring down noise levels because of lower driving speeds. Most importantly, however, this means that dawn chorus and rush hour can co-occur at optimal times for sound transmission depending on latitude and season (see Warren *et al.* 2006). Good signalling periods are thus disproportionately affected due to temporal overlap with traffic activity.

The fact that there are often periods during the day in which anthropogenic noise is most detrimental due to concentration of bird singing activity and optimal noise-transmission conditions seems 'bad luck' but also provides the opportunity to ecologically sensible noise control. Reducing traffic flow for short but crucial periods of time, for example, on roads through nature reserves, will raise habitat quality for breeding birds with limited impact on human activities. Similarly, on a slightly larger temporal scale, traffic limitations through sensitive areas during the critical period in spring, when males vocally attract females, could also significantly improve habitat

### Box 2 Noise barriers for birds

Raising a barrier between the noise source and bird breeding habitat can lead to a significant reduction in detrimental noise levels. Vegetation is only of limited use, although the effectiveness will increase with stem and leaf density and width of the zone (e.g. Cook & van Haverbeke 1972; Bucur 2006). A solid barrier as close as possible to the noise source will be most effective (Maekawa 1977; Ishizuka & Fujiwara 2004). Adding an overhang on the road side or increasing the height of a barrier which is already in place to benefit pedestrians at ground level (A), could be a very cost-effective measure to the benefit of flying and tree-dwelling birds at a higher level (B). It is usually also easier to filter out the bird-relevant frequency components of traffic or industrial noise than to block the lower frequencies. Construction details and barrier shape especially can have a big impact in the frequency range between 2.0 and 8.0 kHz. For example, sound-pressure levels at the barrier's edge (= secondary point of radiation) can be significantly decreased by installing a soft, absorbent material on top. This will lead to a decrease in the noise level behind the barrier, especially in the field below the barrier height (A). Specific shapes of the barrier top with multiple diffracting edges may add to this effect. For example, T-shaped noise barriers with soft material on top only have to be three meters high to be as effective

as a 10-metre high rigid-edged plain barrier (Ishizuka & Fujiwara 2004). This effect steadily gets stronger with frequencies above 250 Hz, also for the sound field above barrier height (B), which concerns the habitat layer typically most important for acoustic signalling in many bird species (Slabbekoorn 2004). Noise barriers at both sides of a road shield areas in both directions, but multiple reflections and scattering effects between the barriers will reduce the shielding capacity. Noise levels become higher especially above the barrier compared to a single barrier situation (Maekawa 1977). Buildings by the side of a busy road typically also increase noise levels within the street or urban canyon (Oldham & Radwan 1994; Heutschi 1995). Both inside and outside urban areas, the problem can be brought down by noise abatement schemes using a more absorbent ground surface and intermittent or continuous absorbers on the walls of buildings or noise barriers (Horoshenkov *et al.* 1999). Placing noise barriers at an angle will also reduce the impact of reflections by beaming them more upward into the sky or downward back towards the tarmac. Finally, the choice of construction material or absorbent matter may make noise barriers also bird-friendly in nonacoustic ways. Combination barriers incorporating trees or shrub layers can reduce the negative impact of an artificial, visual barrier in the landscape, and potentially provide nesting and foraging opportunities.

quality. These critical periods can be quite brief, as in some migratory species, for example, where males arrive at the breeding grounds just before the females. For such species, male singing effort peaks upon arrival and may already decline after one or two weeks.

In addition to seasonal and diurnal fluctuations in bird singing activity and noise levels, more short-term fluctuations may also warrant some attention. Fluctuating noise levels in terms of overall amplitude are usually more annoying to humans than relatively continuous noise levels,

especially when areas are relatively quiet overall with sudden unpredictable noise peaks (de Coensel *et al.* 2005). For birds, mean noise levels may similarly not describe the potential for auditory masking or stress levels adequately. Therefore, analyses of sound-level fluctuations in time can add a relevant descriptor capturing more of the dynamics of noise interference.

Traffic-noise fluctuations in terms of frequency are chaotic, but most of the common anthropogenic noise sources show a general decrease in amplitude from low to high frequencies. Bird species in many taxa, such as doves, owls, corvids, woodpeckers, herons and rails use frequencies well below 1.0 kHz. Whether or not species in these groups occur in urban areas or along highways (and some are typically abundant within these habitat types) is probably largely determined by other factors than the impact of noise interference. However, declining signalling efficiency may influence the balance between costs and benefits of city life, especially for those species relying on vocalizations for long-distance communication. Not many noncorvid songbirds use frequencies below 2.0 kHz. The majority of these species uses a bandwidth of 3.0–6.0 kHz, starting at 2.0 or 3.0 kHz and often going up to around 8.0 kHz. The few songbirds that do use very low frequencies down to 1.0 kHz, typically use wideband songs with a bandwidth of about 6.0–9.0 kHz (examples are: European blackbird; nightingale; house sparrow, *Passer domesticus*; European starling, *Sturnus vulgaris*; house martin, *Delichon urbica*), and may therefore be less vulnerable to noise pollution (although we do not know yet whether this is true). Few songbird species rely just on relatively low frequencies, but species that do, like the oriole (*Oriolus oriolus*), the great reed warbler (*Acrocephalus arundinaceus*) and the mistle thrush (*Turdus viscivorus*), may for this reason be relatively sensitive to the masking effect of traffic noise.

A study on distribution and breeding success of great reed warblers in a wetland area in the central part of The Netherlands provides interesting support for the suspected sensitivity to noise in this species (Foppen & Deuzeman 2007). A reed bed in the Vossemeer was known to be inhabited by about 5–10 pairs of reed warblers up until the early 1990s. This reed bed has not changed much since, but it is now situated right beside a road (Vossemeerdijk) with a few thousand cars passing by per day. In the last 15 years, typically only one or two territories each spring have been occupied by singing reed warblers. However, in two years (2003 and 2004) the road was closed to traffic for a substantial time during spring due to road works. The absence of the usual traffic was correlated with an increase from two in 2002 to seven territories in 2003. The return of the noise source was correlated with a decline from five in 2004 back to one territory in 2005. These fluctuations over the course of four seasons consti-

tute only anecdotal evidence, but they do suggest that the vulnerability to a masking of the low-pitched song by traffic noise may have contributed to the overall decline in reed warbler territories in this area since the early 1990s.

Although low-frequency bird songs are most affected by typical anthropogenic noise, it is not true that higher frequencies are free of the impact of anthropogenic noise interference. Masking depends on the amplitude of the acoustic signal relative to the amplitude of the ambient noise within the same frequency range (Lohr *et al.* 2003; Brumm & Slabbekoorn 2005), both measured at the receiver. So, the impact on detection and recognition of acoustic detail can still be serious and deleterious for faint high-pitched notes. Also, high-pitched songs heard at a large distance from the singer, with the receiver potentially being closer to the noise source, may be hampered by the high component of traffic noise which has most energy at low frequencies.

## Conclusions

It is becoming more and more clear that the omnipresence of anthropogenic sounds is not only detrimental to human health and well-being, but can also negatively affect birds. Efforts to bring down anthropogenic noise levels to the benefit of bird-breeding areas will almost certainly encounter financial trade-offs. Mitigating measures are typically expensive or counteract economic values, for instance by slowing down, or putting restrictions on, traffic flow. When considering or arguing for expensive noise-reducing actions, it is very important to realize that birds and humans often benefit from the same or only slightly modified measures.

It is obvious from the remarks above on song spectra that we need a thorough comparative study to assess noise sensitivity of bird communities, or at least of those species of high conservation value. Although it may be true in general that making habitat more quiet will improve breeding conditions for many species, we still lack much essential data to guide conservation efforts with adequate detail. Optimally, such data would come from a comparative study that includes experimental assessment of developmental flexibility, tolerance to spectral range reduction and an assessment of the fitness consequences of masking (cf. Habib *et al.* 2007). Data on urban survivors, such as the great tit (Slabbekoorn & Peet 2003; Slabbekoorn & den Boer-Visser 2006), as well as urban 'losers' will be valuable to generate the insight needed to come up with ecologically solid recommendations.

Behavioural flexibility, such as song plasticity in postdispersal adjustment to neighbours under local noise conditions, may allow some species more time to adapt to human-altered environments. Consequently, thriving urban populations may be diverging from their

forest counterparts in several traits and may be on a track towards becoming even more successful and potentially an independent urban species. However, this may be true for a 'lucky' few, since many species will not be able to go down this fortunate path. Hopefully in the near future, we will be able to explain which species are negatively affected by anthropogenic noise and why. For those situations for which there is the political will and the financial support to reduce detrimental noise exposure, we hope our considerations on making bird breeding habitat more quiet will prove to be useful.

## Acknowledgements

We thank Ruud Foppen, Evert de Ruiter and Machteld Verzijden for helpful comments on earlier drafts of the manuscript. The work on songs of urban great tits was supported by a PULS-grant from the Netherlands Organization for Scientific Research (NWO, ALW-project 831.48.006).

# Top carnivores increase their kill rates on prey as a response to human-induced fear

Justine A. Smith, Yiwei Wang and Christopher C. Wilmers

Center for Integrated Spatial Research, Environmental Studies Department, University of California, 1156 High Street, Santa Cruz, CA 95064, USA

The fear induced by predators on their prey is well known to cause behavioural adjustments by prey that can ripple through food webs. Little is known, however, about the analogous impacts of humans as perceived top predators on the foraging behaviour of carnivores. Here, we investigate the influence of human-induced fear on puma foraging behaviour using location and prey consumption data from 30 tagged individuals living along a gradient of human development. We observed strong behavioural responses by female pumas to human development, whereby their fidelity to kill sites and overall consumption time of prey declined with increasing housing density by 36 and 42%, respectively. Females responded to this decline in prey consumption time by increasing the number of deer they killed in high housing density areas by 36% over what they killed in areas with little residential development. The loss of food from declines in prey consumption time paired with increases in energetic costs associated with killing more prey may have consequences for puma populations, particularly with regard to reproductive success. In addition, greater carcass availability is likely to alter community dynamics by augmenting food resources for scavengers. In light of the extensive and growing impact of habitat modification, our study emphasizes that knowledge of the indirect effects of human activity on animal behaviour is a necessary component in understanding anthropogenic impacts on community dynamics and food web function.

## 1. Introduction

Anthropogenic disturbance can cause shifts in biotic community dynamics, generally through the loss of native species, introduction of novel species or artificially enhanced populations of native generalists [1]. These changes are characterized most often by quantifying the population size or presence of particular species. However, behaviour-mediated interactions are predicted to have equal or greater impacts on animal populations than purely numerical mechanisms [2–4]. Animal behavioural responses to anthropogenic disturbances have the potential to be cryptic but powerful drivers of ecological change in modified habitats [5].

Large carnivores are widely recognized to be sensitive to human disturbances owing to slow life cycles, large space requirements, direct persecution by humans and avoidance of human-dominated areas, often resulting in their decline or extirpation. Reduced large carnivore density and occupancy in some developed areas has resulted in both mesopredator release [6,7] and overpopulation of primary consumers [8,9]. Yet, some large carnivores do persist in modified landscapes, but alter their behaviour to reduce interactions with humans [10,11]. Owing to the strong regulatory influence large carnivores can exert on their competitors and prey, changes in their behaviour are likely to contribute to whole community responses to anthropogenic disturbances [12].

Hunting and foraging are costly behaviours for carnivores, but are often assumed to be optimized so that individuals gain the most energy (or other limiting nutrients) for the least effort [13]. Animals that choose to expend more energy than what is perceived to be optimal may be responding to risks that increase the long-term pay-off of certain energy-expensive behaviours through decreased chance of non-starvation mortality [14]. Hunting in high-risk habitats can therefore create a risk-foraging trade-off in which animals sacrifice efficient foraging to compensate

for increased vigilance and risk avoidance. Giving-up density studies support that an animal's perceived risk is inversely correlated with food intake, suggesting that time spent consuming a food item reflects the fear experienced by forager [15].

Top carnivores generally kill large-bodied prey species, which require a high initial energetic cost during the hunting stage [16], but provide high energy gain during consumption. However, because carnivores are constrained by gut capacity, solitary carnivores can only maximize their caloric yield by repeatedly returning to feed on a prey carcass. In developed habitats, carnivores can be particularly vulnerable to risk-foraging trade-offs because disturbance-induced carcass abandonment can result in food loss owing to scavenging [17] or decomposition [18]. Prey consumption time can therefore be limited by external forces that reduce carnivore access to a carcass. Anthropogenic disturbances can ultimately reduce the net caloric gain carnivores receive from consuming large prey [19] by displacing carnivores from kill sites and decreasing their prey consumption time at kills. If perceived risk increases with human disturbance, the magnitude of human impact should be a predictor of foraging efficiency and consumption time.

We examined puma (*Puma concolor*) behavioural changes associated with perceived risk at kill sites with increasing housing density levels and investigated the relationship between risk-avoidance behaviours and kill rates in disturbed areas. We hypothesized that disturbance would displace pumas more often in highly developed areas, reducing overall prey consumption time and increasing kill rates. In the long term, we anticipate that more frequent risk-avoidance behaviours will increase puma kill rate and subsequently alter interactions with prey, competitors and scavengers.

## 2. Material and methods

Our research was conducted in the Santa Cruz Mountains, which lie in the Central Coast region of California. We captured 30 pumas from 2008 to 2013 and fitted them with GPS/radio telemetry collars (IACUC no. WILMC1011 Model GPS Plus 1 or 2 D, Vectronics Aerospace, Berlin, Germany). Collars were programmed to record locations every 4 h, and location data were downloaded remotely via UHF once a month. We used a custom cluster generation algorithm integrated in the Geographical Information Systems program ARCGIS (v. 10; ESRI, 2010) using the programming languages R (v. 2.1.3.1; R Development Core Team, 2010) and PYTHON (v. 2.6; Python Software Foundation, 2010) to identify groups of locations in which each location was within 100 m of the cluster centre and 6 days of another location in the cluster (for full details on the algorithm, see [10]). We field-investigated clusters in reverse chronological order from their time of formation using the most recently downloaded GPS data. Clusters were investigated within 30 days of their first recorded locations. At investigated clusters, we recorded whether a kill was present, and if so, the species, age and sex of the kill (if identifiable).

We constructed a mixed-effects binomial logistic regression model to predict deer kill sites from all generated clusters. We chose to only use deer kills because deer are the preferred prey in our study area. In addition, small prey cannot be predicted accurately from location data in our study area owing to high variability in puma behaviours at small kill sites. The variables used to fit the model were behavioural characteristics associated with clusters, including number of night locations (NIGHT), a binary variable indicating greater than 1 day duration (BINARY), the harmonic mean distance of locations from the cluster centre within the cluster (HMDIST), the proportion of locations occurring at night (P.NIGHT), site fidelity measured by the proportion of

points occurring within the cluster over the cluster duration (P.ACTIVE) and the farthest distance travelled during a cluster period (DIST). Total duration of a cluster (DUR) was excluded owing to high correlation ( $r > 0.7$ ) with variables already used in the model. We allowed for random slopes and intercepts for individual pumas when fitting the best model. We also constructed a truncated model without behavioural variables that we expected to correlate with housing density in order to allow inference on behavioural influences on kill rates. This model excluded P.NIGHT, P.ACTIVE and DIST. We compared the truncated model and best-fit model to assess if we could confidently use the truncated model. We constructed receiver operating characteristic curves for both full and truncated models and calculated the area under the curve (AUC) to ensure that both models were similar in their predictive abilities. The AUC for the full model (AUC = 0.818) and the truncated model (AUC = 0.820) were nearly identical, and both support good discriminative ability [20]. We assigned each generated cluster as a deer kill or not a deer kill by applying the truncated model to all generated clusters.

We first investigated puma behavioural responses at the population level at four levels of housing density within 150 m of predicted kill sites: no housing, rural (greater than 0.0 and up to 0.062 houses per hectare), exurban (greater than 0.062 and up to 1.236 houses per hectare) and suburban (greater than 1.236 and up to 9.884 houses  $\text{ha}^{-1}$ ; [21]). Owing to the discrete nature of housing count data, each housing class was rounded up to the nearest number of houses, resulting in housing classes within 150 m of a cluster to be defined as 0 houses for no housing, one house for rural, two to nine houses for exurban and greater than nine houses for suburban. We used the 150 m buffer because this is the scale of development found to most impact puma hunting in our study area [10]. We constrained the response variables to only include behaviours we expected to be associated with risk aversion, which were narrowed down to P.NIGHT, P.ACTIVE, DUR, DIST and a final measure of prey consumption time (P.C.TIME) which was calculated as P.ACTIVE  $\times$  DUR. We added the prey consumption time measure because it best reflects the energetic gain an animal receives from a kill. We tested the differences in behaviours at all predicted kill sites in different housing density categories using an ANOVA test and examined pairwise comparisons with Tukey's HSD test for all behaviours found to vary significantly with housing density.

To determine kill rates, we calculated the total number of deer predicted to be killed by each puma from the output of the deer kill prediction model using all generated GPS clusters. We divided the predicted number of kills by the total time each puma was actively collecting GPS data to obtain annual deer kill rates. We investigated sex-specific relationships between kill rates and average values for P.NIGHT, P.ACTIVE, DIST, DUR and P.C.TIME for individual pumas using univariate linear regressions owing to high correlation values ( $r > 0.7$ ) among variables.

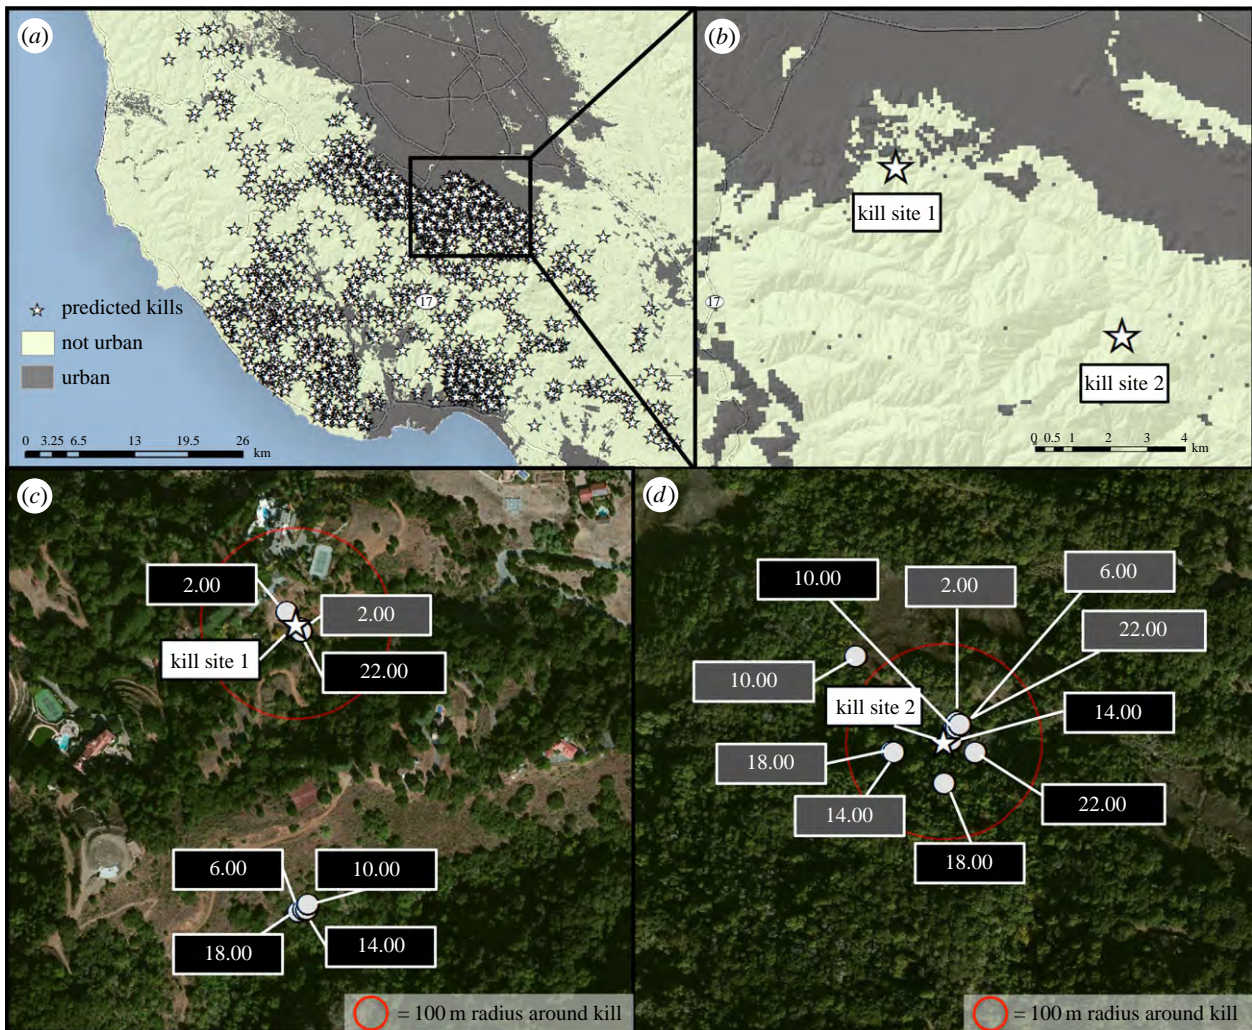

In order to assess the impact of housing on individual pumas, we calculated housing density within each puma home range. Puma home ranges were obtained using a local convex hull (LOCOH) home range estimator, where the 95% isopleth represented the home range boundary [22,23]. All housing points in the Santa Cruz Mountains were manually digitized from high-resolution satellite imagery. We calculated puma home range housing density as the number of houses per  $\text{km}^2$ . We tested for the relationship between individual puma kill rates and home range housing densities using univariate linear regression.

## 3. Results

### (a) Behavioural shifts

Of 703 field-investigated clusters, 208 were classified as deer kill sites. The other remaining clusters included 66 non-deer

**Figure 1.** (a) Study area and predicted kill sites in relation to housing density. Box shows area (b) in which kill site examples (c,d) are shown. Kill site 1 (c) belongs to puma 13F, whose home range is in the top quartile of housing densities among female pumas. Kill site 2 (d) belongs to 28F, whose home range is in the bottom quartile of housing densities among female pumas. Grey labels depict location times during the first day at the kill site and black labels depict location times during the second day. Note that at kill site 1, the puma has made a kill close to development but spends the majority of time away from the kill, whereas at kill site 2, which has no nearby development, the puma stays within the vicinity of the kill. (Online version in colour.)

kills (e.g. raccoons and house cats) and 429 non-kills (often bed sites). Our best-fit binomial logistic regression model to predict deer kills included NIGHT, BINARY, HMDIST, P.NIGHT and P.ACTIVE. The truncated model included NIGHT, BINARY and HMDIST. Neither the random intercept nor a random slope was included in the best-fit full model or the best-fit truncated model. We used the truncated model to predict 1537 deer kills from 8523 generated clusters (figure 1).

At predicted kill sites, females had lower P.ACTIVE ( $F = 67.7, p \ll 0.001$ ), higher DIST ( $F = 16.0, p < 0.001$ ) and shorter P.C.TIME ( $F = 44.2, p \ll 0.001$ ) as housing density increased (figure 2; example shown in figure 1). In suburban habitat, female P.ACTIVE was 36% lower, DIST was 31% higher and P.C.TIME was 42% lower than in no housing areas. Both males ( $F = 19.3, p < 0.001$ ) and females ( $F = 144.4, p \ll 0.001$ ) were more nocturnal (higher P.NIGHT) with increasing housing density at kill sites. Males did not show any responses to housing density concerning time spent at kill sites. Identical analyses using only confirmed kills supported each of the reported trends for predicted kills.

### (b) Deer kill rates

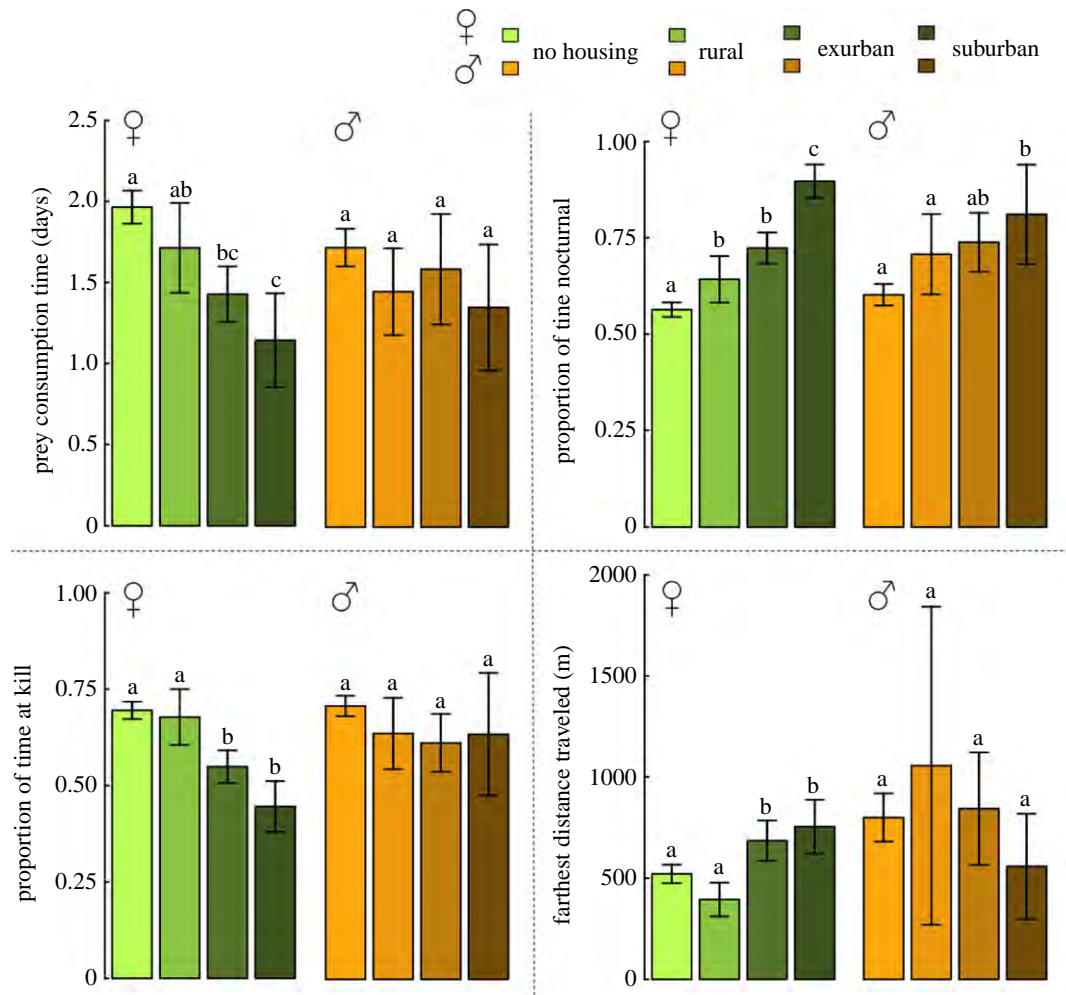

Male average home range size was  $163.0 \pm 7.7$  s.e.  $\text{km}^2$  with  $15.6 \pm 0.8$  s.e. houses  $\text{km}^{-2}$ . Female average home range

size was  $53.8 \pm 2.1$  s.e.  $\text{km}^2$  with  $25.5 \pm 1.3$  s.e. houses  $\text{km}^{-2}$ . Males had an average deer kill rate of  $43.7$  deer  $\text{yr}^{-1}$ , whereas females killed on average  $67.3$  deer  $\text{yr}^{-1}$ . Male deer kill rates were not correlated with any of our variables of interest (P.ACTIVE, P.NIGHT, DIST, DUR or P.C.TIME), nor with home range housing density ( $p = 0.9, r^2 = 0.005$ ; figure 3). Conversely, female deer kill rates showed a strong positive and linear correlation with home range housing density within its observed range ( $p = 0.0003, r^2 = 0.745$ ; figure 3). Females with home ranges in the top quartile of housing density killed 36% more deer per year (81.2) than females in the bottom quartile of housing density (59.7). Female kill rates were also negatively correlated with average fidelity to kill sites (P.ACTIVE;  $p = 0.05, r^2 = 0.322$ ).

## 4. Discussion

Our estimate of average male kill rates ( $43.7$  kills  $\text{yr}^{-1}$ ) stayed constant across housing densities and was comparable to previously reported values described by Knopff *et al.* (35 ungulates  $\text{yr}^{-1}$ , [24]) and Anderson & Lindzey (47 kills  $\text{yr}^{-1}$ , [25]). However, female kill rates increased positively, strongly and linearly with housing density. Although female kill rates in lower housing density areas ( $59.7$  kills  $\text{yr}^{-1}$ ) were

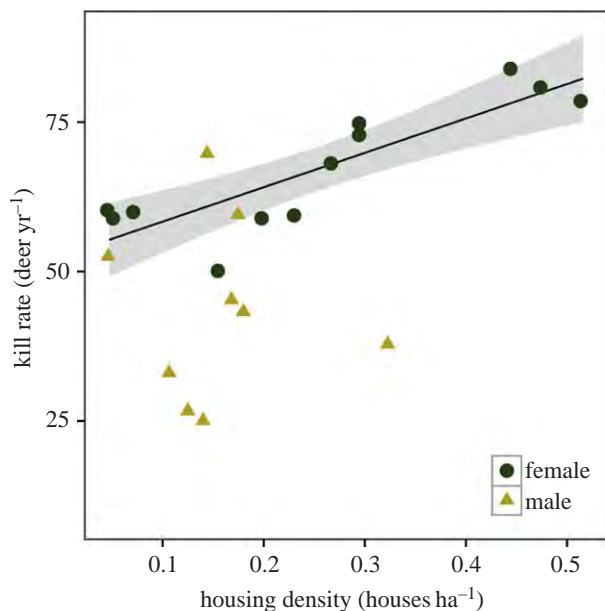

**Figure 2.** Behaviours that vary with housing density at predicted kill sites. Pairwise comparisons from Tukey's HSD tests reported in superscripts, where different letters represent a statistically significant difference. Error bars represent two standard errors from the mean. Sample sizes of housing classes at female kills are: no housing, 719; rural, 83; exurban, 186; suburban, 71. Sample sizes of housing classes at male kill sites are: no housing, 389; rural, 32; exurban, 42; suburban, 15. (Online version in colour.)

comparable to previously estimated mule deer kill rates for solitary adult females (52.5 kills  $\text{yr}^{-1}$ , [25]) and females with kittens (62.4 kills  $\text{yr}^{-1}$ , [26]; 68.1 kills  $\text{yr}^{-1}$ , [25]; 57.2 kills  $\text{yr}^{-1}$ , [24]), female kill rates in the highest quartile of home range housing densities were substantially higher (81.2 kills  $\text{yr}^{-1}$ ). This 36% increase in kill rates between the top and bottom quartiles indicates that development may exert a significant energetic cost associated with hunting behaviour.

Hunting deer requires large energetic investments in the stalking, subduing and killing stages for pumas [16]. We have documented a sizable increase in female kill rates that we expect represents higher energetic costs for females in developed landscapes. Although these costs do not appear to influence adult survival (C. C. Wilmers 2014, unpublished data), impacts on reproductive success possibly make development-interface zones sinks for the puma population. Anecdotally, we have observed that the tagged female living in the most developed habitat in our study area has lost at least three litters in the last 3 years, one of which was confirmed as abandonment (C. C. Wilmers 2014, unpublished data). The three other females living in less developed portions of our study area for which we have also documented at least three dens have had the majority of their litters survive. Although there are many stressors in a developed landscape that might influence kitten survival, we expect that higher energetic costs from increased hunting may contribute to this pattern.

Males did not alter their kill rates or prey consumption time at kills with increasing housing density. Because male life histories are constrained by requirements to defend much larger territories [27], this is perhaps not surprising. We found that male pumas have home ranges that are approximately three times as large as female home ranges on average. Male pumas are also known to spend significantly more time performing scent-marking behaviours than females [28]. We found that males have lower DUR at kills than females by 7.2 h on average (males = 2.86 days  $\pm$  0.06 s.e., females = 2.56 days  $\pm$  0.05 s.e.;  $t = 3.83$ , d.f. = 1000,  $p < 0.001$ ), probably owing to their need to patrol and defend their home range boundaries from encroaching males. Therefore, because males already tend to leave their kills early, they may be less influenced by chronic disturbance. In addition, male home ranges are characterized by much lower overall housing densities, indicating that males may exhibit risk-avoidance behaviours at the landscape scale rather than at the kill site scale.

Higher deer kill rates by females in response to increased housing density appear to be driven by a behavioural shift to a lower proportion of time spent at kill sites over the consumption period. Although females did not alter their total duration spent at clusters, their overall prey consumption times declined owing to a lower proportion of time spent at kills, indicating reduced utilization of carcasses at higher housing densities.

**Figure 3.** Kill rates of individual male and female pumas in response to housing density per hectare within their 95% LOCOH home range. Regression line and 95% CIs for female kill rates in relation to housing density are shown. Housing density coefficient  $\beta_1 = 91.4$ . (Online version in colour.)

Other possible explanations for female increase in deer kill rate are not supported by our understanding of puma energetics and reproduction. Deer in our study have lower detection rates in more developed habitats (C. C. Wilmsers 2014, unpublished data), therefore variation in deer activity or abundance is unlikely to explain these patterns. In addition, it is unlikely that increased kill rate could be a result of greater reproductive activity in high housing density areas because females in our study area avoid anthropogenic development when denning [10]. We conclude that behavioural risk avoidance is a substantial contributor to female prey consumption time and hence hunting patterns, due to our observation that housing density is associated with decreased prey consumption time. Both food loss and increased movement as a result of these behavioural shifts may contribute to observed increased kill rate in human-modified habitats.

An increase in ungulate carcasses left by female pumas may impact the biotic community by providing additional carrion subsidies to scavengers. By leaving their kills for longer periods of time in more developed areas, female pumas might create greater opportunity for scavenging by mesopredators and birds. Subordinate predators often scavenge kills of apex predators when kills are abandoned or not guarded [29], and carrion can form a large proportion of their diets [30]. Pumas are known to be important sources of food subsidies to

mesopredators through carcass abandonment [31]. Our results suggest that mesopredator release may occur not only through the well-documented pathway of apex predator extirpations, but also via behaviour changes in extant apex predators leading to increased food provisioning. The presence of scavengers can exacerbate this pattern by reducing apex predator prey consumption time via food loss [17].

## 5. Conclusion

The results presented here have bearing on human-modified systems globally. Behavioural responses are often overlooked as ecosystem drivers in modified systems, overshadowed by population declines and extirpations. However, many species are able to persist in developing landscapes, but in an altered behavioural state. Our findings suggest a strong, perceivable impact of observed human-induced behavioural change on species interactions instigated by the presence of development. Risk aversion behaviours that result from anthropogenic disturbances are likely to restructure predator–prey interactions in a variety of contexts, given the large effects risk has been shown to have on foraging across taxa. Behaviour-mediated interactions are powerful forces in biotic systems, often playing an even more impactful role than consumptive interactions. A greater focus on behaviour-mediated effects of habitat alteration can further expand our understanding of community-level processes in human-modified systems.

**Ethics statement.** The study was carried out under the IACUC approval no. WILMC1011.

**Data accessibility.** Because pumas are a specially protected species in California, the location data are sensitive and have not been made accessible. However, the data can be available on request by contacting Justine A. Smith at [jsmith5@ucsc.edu](mailto:jsmith5@ucsc.edu).

**Acknowledgements.** We thank the California Department of Fish and Wildlife, Cliff Wylie, Dan Tichenor and Troy Collinsworth for their assistance in helping us capture pumas with hounds. We thank landowners who have allowed us to capture pumas and investigate kills. We thank P. Houghtaling for running our field team and V. Yovovich, Y. Shakeri, C. Fust, S. McCain, J. Kermish-Wells, L. Hibbler and dozens of undergraduate field and laboratory assistants for their contributions to data collection, entry and management.

**Author contributions.** J.A.S. conceived the study, carried out the data analysis and drafted the manuscript. Y.W. assisted in project development and edited the manuscript. C.C.W. conceived and designed the overall study, supervised data collection, advised on data analysis and edited the manuscript.

**Funding statement.** Funding was provided by NSF grant nos. 0963022 and 1255913, as well as by the Gordon and Betty Moore Foundation, The Nature Conservancy, Midpeninsula Regional Open Space District, UC Santa Cruz and the Felidae Conservation Fund.

Large carnivores' fear of the human 'super predator' has the potential to alter their feeding behaviour and result in human-induced trophic cascades. However, it has yet to be experimentally tested if large carnivores perceive humans as predators and react strongly enough to have cascading effects on their prey. We conducted a predator playback experiment exposing pumas to predator (human) and non-predator control (frog) sounds at puma feeding sites to measure immediate fear responses to humans and the subsequent impacts on feeding. We found that pumas fled more frequently, took longer to return, and reduced their overall feeding time by more than half in response to hearing the human 'super predator'. Combined with our previous work showing higher kill rates of deer in more urbanized landscapes, this study reveals that fear is the mechanism driving an ecological cascade from humans to increased puma predation on deer. By demonstrating that the fear of humans can cause a strong reduction in feeding by pumas, our results support that non-consumptive forms of human disturbance may alter the ecological role of large carnivores.

## 1. Introduction

Humans have assumed the role of 'super predator' in animal communities globally, killing terrestrial carnivores at rates as much as nine times higher than their natural predators [1]. In addition to directly killing large carnivores, humans might also elicit fear responses in these species as they do in other wildlife taxa that experience human-caused mortality [2,3]. Indeed, correlative evidence of human-induced changes in large carnivore space use and movement suggests that fear of humans is a common phenomenon among top predators [4–8]. However, it has yet to be experimentally tested if large carnivores perceive humans as predators and whether changes in large carnivore behaviour caused by fear of humans affects ecological communities.

It is increasingly recognized that, even in the absence of direct mortality, fear of predators can itself drive cascading changes across food webs [9,10]. Human-induced fear in large carnivores is likely to have similar cascading effects because of the well-documented top-down effects of large carnivores on their prey and competitors [11–13]. However, different outcomes of human-induced fear in carnivores on prey populations might be expected depending on the nature of the carnivore response. One potential outcome of large carnivore fear of humans is the human shield effect, whereby prey find refuge in human-dominated habitats and are released from top-down forces because carnivores spatially avoid human disturbance [14,15]. However, human disturbance could have the opposite effect on the regulatory role of large carnivores if carnivores persist in human-dominated habitat by instead avoiding humans temporally. This counterintuitive response may actually increase predation pressure on prey by altering carnivore hunting behaviour to accommodate an enhanced risk–foraging trade-off; temporal avoidance could lead to reduced total feeding

time at a kill, which would require increased kill rates to compensate for lost energetic return from each kill. As land is increasingly transformed by anthropogenic development, quantifying how the fear of humans affects interactions between large carnivores and their prey is essential to understanding novel ecological dynamics emerging in human-dominated landscapes [7,11,16].

We previously reported that pumas (*Puma concolor*) in the Santa Cruz Mountains of Central California spent less time at kill sites in more residential areas and increased kill rates of prey [5]. This increased kill rate could potentially be explained by altered prey communities in human-dominated habitats (either from a perceived human shield or access to anthropogenic food subsidies) leading to more vulnerable [17] or available [18] prey. However, if reduced time at kill sites near residential development is fear-induced, it could also result in increased kill rates to compensate for reduced energy gained per individual predation event. Here, we experimentally test whether pumas exhibit fear responses to the human 'super predator' and whether changes in puma feeding behaviour in response to human-induced fear can explain our previously reported differences in puma feeding time and kill rate between areas of high and low human presence in the Santa Cruz Mountains [5]. To our knowledge this is the first direct experimental test of whether large carnivores respond fearfully to human presence, and whether this response has measurable ecological consequences.

To test the relationship between fear of humans and feeding behaviour, we executed a playback experiment on wild pumas. Predator playback experiments have been used to substantiate fundamental ecological relationships [19], including that the fear of predation reduces reproductive success in birds [20], that fear can have cascading impacts on animal communities [10], and that mesocarnivores exhibit heightened fear responses to human 'super predators' relative to non-human predators [3]. However, no study has linked the fear of humans to feeding behaviour in large carnivores. Our study builds on protocols used in over 200 predator playback experiments [19]. Hearing a predator vocalization signals to prey the direct presence of the predator in relatively close proximity, which is why simulating this using audio predator playbacks provides such a powerful means of directly testing fear responses [3,19,21]. Previous experiments have established that prey hunted by the human 'super predator' react to human vocalizations just as prey react to the vocalizations of any other predator [3], demonstrating that assessing responses to human vocalizations provides the means to directly test the prey's perception of humans as predators, rather than humans as simply a source of noise and disturbance (*sensu* [4]). Our experimental approach correspondingly allows us to make direct inferences concerning fear of the human 'super predator' and the resulting consequences of anthropogenic disturbance on risk–foraging trade-offs in a large carnivore. Combined with our previous work [5] our study reveals an ecological cascade from humans to increased predation on deer mediated by fear.

## 2. Methods

Our experiment was part of a long-term study on puma ecology in the Santa Cruz Mountains of Central California, USA [5,6]. The region has a Mediterranean climate characterized by a

rainy season in winter and dry season in summer. Habitat types include mixed hardwood forest, redwood forest, chaparral and grassland. The Santa Cruz Mountains are heavily impacted by human use, particularly residential development and outdoor recreation. Puma exposure to humans here is thus commonplace; all pumas in this study have housing developments in their home range (mean: 21.7 houses km<sup>-2</sup>) and kill and cache prey as close to 5 m from people's homes [5]. Pumas have a good reason to be fearful of humans in this region, as they were bounty hunted in California for decades and even today humans are their primary source of mortality in the Santa Cruz Mountains (Wilmers unpublished data).

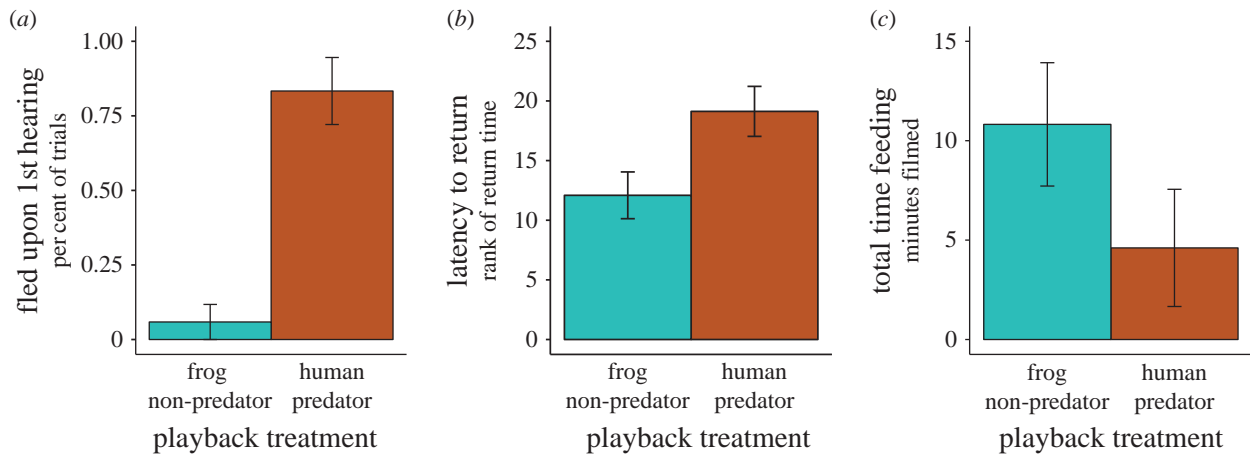

We conducted a playback experiment on pumas at their active kill sites. We first located puma kill sites from recent GPS tracks of collared individuals (IACUC no. WILMC1011). We downloaded recent GPS locations successfully transmitted through GSM or Iridium technologies and identified potential fresh kill sites as clusters of locations within 100 m of one another that occurred between sunset and sunrise. We field-investigated potential kill sites that were no more than 3 days old and at which the puma was present the previous night. If a fresh kill was found, we tied the carcass down so it could not be dragged out of the view of our cameras. Any behavioural effects of tying down the carcass were experienced for both control and experimental playback treatments, therefore baseline disturbance levels should not influence the relative difference in response between treatments.

To test whether pumas fear humans and quantify the cost of this fear, we broadcast predator (human) or non-predator (Pacific tree frog, *Pseudacris regilla*) playbacks at puma kill sites following well-established experimental methods [10,19,20]. Tree frog vocalizations provide an ideal control – like humans, tree frogs occur throughout the study area, but unlike humans they are neither predators, prey, nor competitors of pumas, and thus represent an equally familiar but benign stimulus. Tree frog vocalizations further provide an ideal control because they may naturally be heard both night and day, whenever pumas are active. Controls in other playback studies testing for fear responses in wildlife include running water (study organism: moose; [22]), seals (study organism: raccoon; [10]), sheep (study organism: European badger; [3]) and assorted non-threatening birds (study organism: song sparrow; [20]).

We recorded puma responses to playbacks using an Automated Behavioral Response (ABR) system (i.e. video-enabled camera trap linked to a playback unit triggered by the camera's activation) [21]. We deployed the playback speaker 400–450 cm from the centre of the carcass. Videos were 30 s long, the playback being broadcast for 10 s in the middle of the video. If the puma repeatedly triggered the camera it could hear the playback as often as twice per minute. We used seven exemplars of each playback type [23], the human exemplars all consisting of a single individual speaking conversationally. We edited all exemplars for consistency in amplitude and quality using Audacity® (v. 2.1.0, Audacity Team 2014), and broadcast the playbacks at a consistent peak sound pressure level of 80 dB at 1 m (measured using Radioshack 33-2055 Digital Sound Level Meter set to fast response and C weighting). This volume was chosen to mimic the natural volume of human conversation. Using these exemplars we composed 30 min playlists of each treatment. The playlists alternated between frogs and humans every 30 min; which treatment the puma heard first being determined by when it triggered the camera, and was thus effectively random. An individual puma might be exposed to either or both treatments over 24 h, depending upon its reaction. For pumas that heard both treatments, there was no significant difference in the proportion of each treatment first heard ( $Z = 1.63$ ,  $p = 0.103$ ). Pumas were exposed to each treatment only once over the course of the study.

We tested for the fear response of pumas and its ecological cost as follows: (i) We examined the puma's initial response to

**Figure 1.** Responses of pumas to predator (human) and non-predator (frog) playbacks at puma feeding sites. (a) Proportion of pumas that fled following their first exposure to frog or human playbacks. (b) Latency in time to return (rank) after initial playback exposure. (c) Total time spent feeding during the first 24 h of playback treatment. Bars represent standard error. Although transformation of feeding data was required to meet normalization assumptions for our analysis, here we show mean and standard error of raw feeding time measures for purposes of visualization. (Online version in colour.)

the playbacks by quantifying whether the puma fled (ran away) upon first hearing a treatment. We tested for significant differences in fleeing using Fisher's exact test. (ii) We assessed recovery time following puma initial exposure to each playback as the time difference between their first exposure to a playback treatment and the next video in which they subsequently appeared (hereafter, 'latency to return time'). We ranked the latency to return time for each trial, assigning the highest rank to individuals who did not return. We tested for a treatment effect by applying a Mann–Whitney  $U$  test to the ranked return times. Some pumas were exposed to both treatments enabling us to additionally test these two responses (fleeing and latency) using repeated-measures Wilcoxon matched pairs tests, which provided qualitatively the same answers, reinforcing the robustness of the results. Because there is no qualitative difference, but these repeated-measure tests do necessitate excluding some individuals, we report the results of the between-group comparisons to best reflect the full dataset. (iii) We measured the aggregate effect of hearing a playback treatment on feeding time by calculating the total time a puma was observed feeding during each treatment over the course of 24 h. We Box-Cox transformed these data to meet normality assumptions and tested for differences using ANOVA. Again, because some pumas were exposed to both treatments, we began by including individual identity as a random effect in the feeding analysis (the only parametric test), but because this did not explain any additional variation we removed it from the model and accordingly report results from the univariate (predator versus non-predator) fixed effects model.

### 3. Results

We successfully conducted 29 experimental trials on 17 pumas. All 17 heard non-predator (frog) playbacks and 12 were exposed to both predator (human) and non-predator (frog) playbacks. Pumas fled in the majority of cases (83%) upon first hearing humans and only once upon first hearing frogs (6%; figure 1a; Fisher's exact  $p < 0.001$ ). The latency to return time after pumas first heard a treatment was significantly greater in response to human playbacks (figure 1b; M-W  $U_{12,17} = 151.5$ ,  $p = 0.028$ ) because pumas returned to the carcass less often following their first hearing of a human playback (42% of trials) than following their first hearing of a non-predator (frog) playback (18%), or if they did return, they took longer to do so after first hearing humans

(median = 20 min, range = 0–257) than after first hearing frogs (median = 2 min, range = 0–40). Feeding time was significantly less for the human treatment than the non-predator (frog) treatment ( $F_{1,27} = 5.74$ ,  $p = 0.024$ ; figure 1c). Over the course of 24 h, pumas fed for less than half as long when exposed to humans ( $4.6 \pm 2.9$  SE min; median = 0.03 min) as when exposed to frogs ( $10.4 \pm 3.1$  SE min; median = 4.5 min).

### 4. Discussion

Our results experimentally demonstrate that fear of the human 'super predator' induces substantial behavioural changes in pumas, ultimately leading to significant reductions in time spent feeding. We observed almost unanimous fleeing behaviour in response to the human playback treatment, directly tying a strong fear response to subsequent declines in feeding. Our previous work showed that pumas nearly halve their feeding time of deer in suburban areas compared to areas with less housing [5]. The halving of feeding time during human trials compared to non-predator trials that we observed in this study suggests that this difference in puma behaviour at kills based on nearby housing densities can be fully accounted for by fear, and that this consequently causes pumas to increase their kill rates by 36% [5]. In a previous study we found that deer occupancy was not influenced by housing density, therefore it is unlikely that relative deer availability explains observed changes in kill rate [18]. Our results support the conclusion that increased kill rates in residential areas are driven by a top-down mechanism (fear of humans), rather than a bottom-up mechanism (availability of prey). Thus, non-consumptive forms of human disturbance may alter the ecological role of large carnivores by affecting the link between these top predators and their prey.

Prey generally respond to both direct (e.g. predator vocalizations) and indirect (e.g. moonlight or cover) cues of predation risk, and the strength of their response depends upon both the nature and number of cues. A single direct cue typically induces a stronger response than a single indirect cue, but multiple indirect cues may induce an equivalent or even stronger response than a single direct one [24–26]. Our experiment demonstrates that pumas respond fearfully to a direct cue indicative of the immediate presence of the human 'super predator' (i.e. hearing

human vocalizations). In human-dominated landscapes, pumas are exposed to multiple indirect cues indicative of the presence of the human 'super predator' (e.g. anthropogenic lighting, sounds of vehicles and dogs), and our previous work shows that pumas respond to these indirect cues [5,6,18]. Our purpose in testing the responses of pumas to human vocalizations was to evaluate the perception of humans as predator, as explained above. In the present study, exposure to a single direct cue (hearing human vocalizations) had the same magnitude of effect on feeding time as did cumulative indirect (e.g. lighting, vehicles) and less direct (e.g. hearing humans at a distance) cues [5], as might be expected in the response of any prey to any predator. Fear-induced trophic cascades are not caused by responses to a specific cue, but by prey responding to any and every cue signalling the presence of the predator it fears [9,10,25].

Our results are consistent with theoretical predictions made from other playback experiments that have demonstrated the ability for humans to cause fear responses in wildlife [3] and for fear responses in carnivores to cascade to lower trophic levels [10]. We have combined these concepts in context of large carnivores due to their important regulatory role and susceptibility to disproportionately high mortality rates via the human 'super predator' [1]. Our results show that large carnivores are not exempt from human-induced fear, and that human impacts on their feeding behaviour might have surprising cascading effects.

In this study, we implemented a novel ABR playback experiment [21] to quantify a large carnivore's behavioural response to humans. Such direct testing of human disturbance has not previously been done on a large carnivore due to the challenge of observing these animals in the wild. Our use of recent puma kill sites accompanied by the integrated ABR technology allowed us to make inferences on humans as a driver of risk–foraging trade-offs in a large carnivore.

Similar methods could be executed on other elusive species to investigate a diversity of risk responses to invasive predators, extirpated predators or competing predators.

Overlap between large carnivores and humans is increasing in regions where continued agricultural and residential development coincides with the recovery of large carnivore populations [27,28]. Although the coadaptation of humans and carnivores can lead to coexistence in human-dominated landscapes [29], carnivore behavioural adaptations might result in unintended indirect effects on other species [11]. Our work suggests that fear-induced trophic cascades instigated by the human 'super predator' are likely to contribute to altered ecological dynamics in human-dominated landscapes. As the habitats used by wildlife and humans are increasingly shared, additional work is needed on the extent to which fear in top predators cascades through ecosystems.

**Data accessibility.** Data have been made available in the Dryad data repository: <http://dx.doi.org/10.5061/dryad.6pn0b> [30].

**Authors' contributions.** J.A.S., M.C., C.C.W. and L.Y.Z. conceived of; J.A.S., J.P.S., M.C., C.C.W. and L.Y.Z. designed; and J.A.S., A.C. and C.C.W. conducted the study. J.A.S., M.C., A.C. and D.R. processed and analysed data. J.A.S. wrote the manuscript, with help from J.P.S., M.C., L.Y.Z. and C.C.W. All authors gave final approval for publication.

**Competing interests.** We have no competing interests.

**Funding.** Funding was provided by National Science Foundation grant #1255913, the Gordon and Betty Moore Foundation, and the Natural Sciences and Engineering Research Council of Canada.

**Acknowledgements.** We thank P. Houghtaling, C. Fust, S. McCain and many undergraduate volunteers for assistance with fieldwork. We thank the California Department of Fish and Wildlife, C. Wylie, D. Tichenor, B. Milsap and T. Collinsworth for their assistance capturing pumas, and the many landowners that have allowed us access to their property. We thank Rob Magrath for his helpful comments on the manuscript.

# The Millenium Ark: How Long a Voyage, How Many Staterooms, How Many Passengers?

Michael Soulé, Michael Gilpin, William Conway, and Tom Foose

*School of Natural Resources, University of Michigan, Ann Arbor (M.S.); Department of Biology, University of California, La Jolla (M.G.); New York Zoological Society, Bronx (W.C.); Minnesota Zoological Gardens, Apple Valley (T.F.)*

Barring holocausts, demographic forecasts suggest a "demographic winter" lasting 500-1,000 years and eliminating most habitat for wildlife in the tropics. About 2,000 species of large, terrestrial animals may have to be captively bred if they are to be saved from extinction by the mushrooming human population. Improvements in biotechnology may facilitate the task of protecting these species, but it probably will be decades at least before cryotechnology per se is a viable alternative to captive breeding for most species of endangered wildlife. We suggest that a principle goal of captive breeding be the maintenance of 90% of the genetic variation in the source (wild) population over a period of 200 years. Tables are provided that permit the estimation of the ultimate minimum size of the captive group, given knowledge of the exponential growth rate of the group, and the number of founders. In most cases, founder groups will have to be above 20 (effective) individuals.

**Key words:** zoos, captive breeding, genetic variation, endangered species, heterozygosity, population growth

## INTRODUCTION

According to the models of the UN [United Nations, 1982] and the World Bank [World Bank, 1984], the world population is likely to level off at around 10 to 12 billion about 100 years from now. The implicit assumptions of these forecasts are (1) that agricultural output continues to increase at current rates, (2) that the climatic and agricultural consequences of CO<sub>2</sub> warming, loss of topsoil, and deforestation are insignificant, and (3) that water supplies on a per capita basis can be sustained. These are all unlikely. Thus, famines and other catastrophes may limit the population, especially in Africa, before it approaches these levels. Nevertheless, we can probably expect a near doubling in population size within 100 years.

Received for publication September 17, 1985; accepted October 22, 1985.

Given the rate of habitat destruction today (with only 4.8 billion people), it is likely that the rate will be higher in the year 2100. The reasons are, first, that land and firewood are likely to be in short supply for many decades, especially in the tropical, developing countries. These demands will place additional strains on the remaining 50% of tropical forests. Second, the capacity for regeneration of the renewable resources will be compromised by increased levels of exploitation as it already has been in fisheries owing to overfishing [Nelson and Soulé, in press], in grasslands owing to overgrazing [Eckholm and Brown, 1977], and in forests owing to extraction and erosion [Myers, 1980].

How long will the human population remain at or near the peak level and when will the human usurpation of wildlands end? That is, what is the duration of the "demographic winter?" Ignoring the obligatory disclaimers about extrapolative speculation, our guess is about 500 or 1,000 years. It is obviously impossible to foresee cultural values and public policy in any nation several centuries from now. Nevertheless, we assume that after achieving zero population growth, it will be very difficult

**TABLE 1. A Preliminary Attempt to Predict the Number of Mammalian Species That Will Require Captive Maintenance in the Next 200 Years\***

Order	No. of recognized species	No. of vulnerable species that may require captive breeding
Monotremata	4	
Marsupialia	123	2
Peramelina (bandicoots)	18	
Paucituberculata (shrew-like)	7	
Diprotodontia (herbivores)	101	
Insectivora	409	
Dermoptera (colugos)	2	2
Chiroptera	~ 900	100
Primates	160	160
Edentata (anteaters, sloths)	25	10
Pholidota (pangolins)	7	5
Mysticeta	10	2
Odontoceta (toothed whales)	65	10
Carnivora		
Canidae	35	35
Ursidae	7	2
Felidae	72	60
Others	193	100
Lagomorpha	53	?
Rodentia	~ 1,700	100
Tubulidentata	1	1
Proboscidea	2	2
Hyracoidea	11	5
Sirenia	4	4
Perissodactyla	15	15
Artiodactyla	~ 172	100
<b>Total</b>		<b>815</b>

\*The estimates of "Number of vulnerable species that may require captive breeding" assume the virtual destruction of natural habitats in the tropics, with the exception of northern Australia and scattered nature reserves. It is assumed that none of the nature reserves will be sufficiently large to protect the larger mammals [Frankel and Soulé, 1981].

to bring down the population to an optimum level. Only in very disciplined, regimented cultures is the goal of one child per family likely to be achieved. On the other hand, a resolution of the population explosion might occur much sooner as a consequence of famines, epidemics, or a nuclear holocaust.

Even if we assume that the population drops relatively quickly, say in two or three centuries, we cannot be certain that this will result in the abandonment of the lands that, today, are habitat for wildlife, but that tomorrow will be cities, villages and farms. It is unrealistic to assume that peoples will be easily convinced to abandon villages and farms that have become traditional sites of occupation, unless the land is no longer arable. On the other hand, the reconstruction of quasinatural habitats might become a major social goal in the future. People, especially the young, will leave rural areas if there are real or imagined economic incentives, as evidenced by the exodus to cities now occurring in many tropical nations.

There is another problem, as well. Most of the tropical and temperate lands that still support wildlife today, even the forested lands, are hydrologically and agriculturally marginal. Many of these lands will be seriously degraded if they are settled, and their soils eroded, compacted, or turned to brick. So, even if these lands can be relinquished, centuries may pass before they could provide optimum habitat for wildlife.

This brief futuristic preamble seems to support the pessimistic view that contemporary zoological and botanical gardens must be prepared to be stewards of their charges for many centuries or millenia, barring the development of less space-intensive ways of maintaining viable populations. But even if technological solutions are found for maintaining many species in miniaturized and suspended states, it may be impossible to recapture a true twentieth century ecosystem, with all its complex biotic and functional diversity. The reason is that the large majority of species are smaller plants and animals. These will have been extinct for a long time unless relatively large and well managed fragments of habitat are maintained during the demographic winter [Soulé and Simberloff, 1986].

## HOW MANY KINDS?

How many species will be in the ark? Myers [1984] suggests that we will lose between one-quarter and one-half of all species. Assuming that there are between 10 million and 31 million [Erwin, 1982] species on the planet, we must anticipate losing between 3 million and 16 million species. Of course, the vast majority of these are insects [Raven, 1976; Erwin, 1982].

How many will be vertebrates, especially birds and mammals? A worst case scenario assumes a near total blitzkrieg of national parks and similar reserves in the tropical countries. This is not at all unlikely in the opinion of some [eg, Myers, 1984] with experience in Africa and parts of tropical Asia and Latin America. If this most dreary scenario comes to pass, then we can assume that the larger vertebrates will be the hardest hit. In Table 1 we provide a rough analysis of the number of mammalian species that would be in serious jeopardy. The following groups will all but disappear unless they are captively maintained: primates (160), the large carnivores (ca 100), the perissodactyls (15) and most of the artiodactyls (ca 100). In addition, about 300 species from the other orders will be wiped out. This is about 800 species. We estimate that the same will be true for birds. Locally endemic species in the tropics

[Terborgh and Winter, 1983] and migratory birds are especially vulnerable because they are entirely dependent for their survival on habitats (islands, tropical forests) with dismal prospects. There will probably also be several hundred species of reptiles and amphibians in need of special protection. Therefore, we must consider that at least 2,000 species of large, terrestrial vertebrates will be among the missing unless there is room in the ark.

During the past 2 years, about 19% of the world's mammals and about 9% of all the species of birds have been bred by those zoos reporting to the International Zoo Yearbook (IZY) censuses. The mostly North American collections reporting in the International Species Inventory System (ISIS) contain about 60,000 specimens of mammals and birds (reptiles, amphibians, fishes, and invertebrates are not yet in this system) in 175 reporting collections. Ninety percent of all mammals and almost 75% of all birds added to these collections last year were bred in captivity, and the numbers of many of the endangered species they hold are steadily increasing.

Between 1973 and 1983, for example, there was a doubling of the numbers of snow leopards (130 to 300). Many other species showed similar increases including Siberian tigers (400 to 1,200), golden lion tamarins (85 to about 400), many endangered ungulates such as barasingha (114 to 291), brow-antlered deer (37 to 101), gaur (32 to 83), scimitar-horned oryx (141 to 511), Arabian oryx (75 to 161), addax (142 to 329), and dama gazelle (58 to 178) and many others.

The ability of zoos to breed most mammals and birds is no longer in doubt, but the ultimate carrying capacity of zoos is far from clear. If zoos are to undertake the long-term maintenance of the increasing numbers of refugee species, organized planning should begin now, and on an international scale. Among the difficult questions that need answers: "Is there enough space in the ark?"

Although there are nearly 540,000 mammals, birds, reptiles, and amphibians in zoos reporting to the American Association of Zoological Parks and Aquaria and the IZY, it is unrealistic to assume that more than half of these spaces can be used for long-term propagation. Analysis of present zoo populations suggests that about 330 mammals could be sustained at a population size of 275; 467 birds, 96 reptiles, and 32 amphibians, each at a population of 300; 925 species in all. These sizes (275 and 300) may be larger than necessary for strictly genetic considerations, and might be reduced eventually. Even the number 925, however, may be optimistic given the present logistical and collaborative disarray [Conway, in press]. Such calculations are quite arbitrary (for reasons elaborated below), but they suggest the magnitude of the problem, and the level of commitment required.

Within two or three decades, it may be necessary to devote most of the space in zoos to the captive breeding of endangered species. Such a statement might alarm many in the zoo community, until it is realized that most of the species currently held in zoos will be shifted, one by one, from the nonendangered to the endangered category by virtue of habitat destruction. Nevertheless, the message of the preceding paragraphs is that zoos will need help. Current budgets, facilities, and techniques are no match for the gigantic task of conserving the plant's megafauna.

Is help on the way? The ultimate solution, we believe, must come from research in developmental and reproductive biology focused on the preservation and regeneration of viable organisms from zygotes and embryonic cells. Admittedly, cryogenics, like most technological fixes, is no magic solution. Millions of dollars and decades of research have been invested in the development of the techniques for just a single

species—cattle—and to a lesser extent for horses. So far, the techniques are not transferable to many other species.

On the other hand, there is continuing progress in this field, especially considering where the science was just 20 years ago. Based on the recent successes in bovids, equids, and primates, we consider it likely that traditional captive breeding programs for many species in these groups will be obsolete in a few decades (given reliable refrigeration), and that the vacated space will become available for other taxa. (Even such technological breakthroughs will not obviate the need to maintain some living representatives of most species to serve educational, cultural, recreational and technical-scientific purposes.) In addition, we cannot predict what unforeseen technologies will be developed. We would strongly urge the research community, in and out of zoos, to give high priority to research on cryogenic or other technologies for the long-term preservation of sperm, ova, and embryonic materials, along the lines of the recommendations of the recent FAO/UNEP report on this subject [FAO, 1984].

In the meantime, zoos and similar institutions will have to do their best to maintain relatively large, viable populations of higher vertebrates that are threatened with extinction in their natural habitats. We must therefore determine, as best as we can, the minimum number of individuals in such breeding colonies that will guarantee the maintenance of viability.

#### HOW MANY OF EACH KIND?

As has been described elsewhere [Frankel and Soulé, 1981], the number of individuals required for the maintenance of genetic fitness in a population depends on several variables. These are (1) the definition and the criteria for fitness, (2) the intended duration of the program, and (3) the generation time. We must add a fourth variable, one that is only appropriate for breeding programs with a finite lifetime—the maximum tolerable loss of genetic variation. No loss of additive genetic variation should be tolerated in a program of indefinite length. These four variables will be described briefly.

Fitness in the *immediate*, or short-term, sense concerns individuals. It is the current viability and reproductive success of the individuals in the group. Inbreeding can compromise short-term fitness by producing abnormally high levels of homozygosity for deleterious, recessive genes, the genetic load. There is a large body of evidence [Soulé, 1980; Allendorf and Leary, 1986] suggesting that even very modest decreases in heterozygosity can reduce fitness as estimated by physiological efficiency, growth rates, and developmental (morphological) stability. By trial and error, animal breeders have learned that inbreeding problems (depression) can be avoided if the rate of inbreeding per generation,  $F$ , remains below 2% [Franklin, 1980; Soulé, 1980]. Employing the approximation

$$F = \frac{1}{2N_e} \quad (1)$$

where  $N_e$  is the effective size of the population, the corresponding effective population size is about 25. Franklin [1980], Soulé [1980], and Frankel and Soulé [1981]

recommended a slightly more conservative short-term maximum rate of inbreeding ( $F = 1\%$ ), equivalent to an effective size of about 50. A 1% rate of genetic erosion was considered tolerable by these authors because they were assuming that the groups would be released into the wild within a very short time, say 100 years, an interval that now appears optimistic.

Fitness in the long-term or *ultimate* sense means the capacity of the population to maintain itself indefinitely in its environment. Thus, long-term viability or fitness is variously defined as adaptability (genetic) to environmental change, the maintenance of evolutionary fitness, and population homeostasis. Obviously, the retention of long-term fitness or viability requires the preservation of genetic variation.

How do we go about estimating the time-frame of the ex situ conservation effort for vertebrates? In light of the unpleasant demographic scenario painted above, it would not be unreasonable to plan for a voyage of 1,000 years. An optimist, on the other hand, would argue that applications of molecular biology to the fields of development and reproductive physiology are just entering an “exponential growth phase,” and that technologies for storage and regeneration of embryonic cells that are unimaginable today will be available in less than a century. As these technologies come on line, more species can be moved from the space- and resource-intensive “living zoo” to the miniaturized, “suspended zoo.” If this scenario is correct, our descendants will be able to replace the millenium ark with a “millenium freezer.”

We wish to make it clear that none of us is enamored of the “technological fix” as a solution to major social ills. Technology has never permanently “solved” major human problems such as hunger, poverty, injustice, and warfare. But technology, when applied to specific, technical objectives is very successful, as evidenced by word processors, putting humans in space, and refrigeration.

Regarding the security of frozen or suspended zoos, they are as secure as society itself. There would be redundancy in the holdings, with collections dispersed throughout the world. For those who are nervous about the power failing everywhere at once, the consequences of such a planet-wide catastrophe would be just as serious for zoos as for suspended collections—the pillaging of zoos with all their meat on the hoof, would take no longer than the thawing of all the freezers. In this context, it is not as far-fetched as it sounds to begin planning long-term storage facilities on the back side of the moon.

Another obvious caveat is that a suspended zoo cannot protect the vast majority of smaller organisms that are now threatened with extinction, especially in the tropics. The majority of insect species are undescribed taxonomically [Erwin, 1982] as are a large fraction of neotropical plants [Gentry, 1986]. Whether described or not, most organisms, especially those in the tropics, are small, relatively inconspicuous, and unknown ecologically. Their only human constituency is a handful of biologists; their only refuge is in nature reserves.

Returning to the “how long?” issue, the consensus of the authors is that 200 years is a reasonably conservative temporal horizon. Great works of art have been preserved much longer, even if their collectors and repositories were not. A longer time frame ignores the exponential rate of progress in biological technology. Those who think that 200 years is either too short to too long are free to adjust their programs accordingly. Indeed, conservationists of the 21st Century will have the option to modify their time horizons and to make compensatory changes in effective population sizes, if they conclude that such action is necessary. Fortunately, decisions

made during the initiation phases about effective size are, to some extent, revocable in the first few decades.

Because ultimate or long-term viability or adaptive potential depends on the store of genetic variability, it is desirable to retain as much genetic variability as possible. Ignoring the input of genetic variability from mutation (which in any case will probably be less than the loss when the effective population size is less than a few hundred), we believe that a 90% criterion is reasonable and realistic. That is, the goal should be to preserve at least 90% of the genetic variability that existed in the source population over the next 200 years. Any such criterion is clearly arbitrary. Nevertheless, it was the consensus that the 90% threshold represents, intuitively, the zone between a potentially damaging and a tolerable loss of heterozygosity.

It is prudent to have as many founder individuals as possible. There are two principal reasons for this. First, the more founders, the more genetic variability. Even though a pair of individuals will contain, on average, 75% of the genetic variation or heterozygosity for quantitative traits in the source population (assuming no dominance and epistasis), rare alleles will not survive such a small bottleneck in the number of founders [Allendorf, 1986; Fuerst et al, 1986]. The ratio of genetic variation in the founders compared to the source population approaches 1.0 asymptotically in the range of 25–30 individuals [Gilpin and Soulé, in preparation].

Second, the more founders, the sooner the group will reach the target population size or  $N_K$ . The rate of approach to  $N_K$  depends on the population growth rate [Nei et al, 1975]. When the growth rate is low, the loss of genetic variation from genetic drift can be high in the early generations. The optimum situation, therefore, is to have a large number of founders, say more than 20, and to achieve  $N_K$  very quickly. Parenthetically, the potential for interaction and gene flow between captive groups and wild populations of a species is important. Where survival of a wild population is possible, the benefits of coordinated management should not be dismissed by purists on either side.

Generation time is critical because reproduction is the only point in the life history when there is loss of alleles or genetic variation. Consequently, the longer the generation time, the fewer opportunities there will be for the loss of genetic variation. For example, there will only be eight such opportunities in 200 years when the generation time is 25 years.

Our principal conclusions are summarized in Tables 2–8. The methodology is presented elsewhere [Gilpin and Soulé, in preparation]. Each of the tables was generated by using a unique value for the intrinsic rate of increase per generation (population growth) for the group, from the time of founding until it reached  $N_K$ . These growth rates span the range that is typical of zoo species. The other assumptions used in the calculations include (1) a 200-year program, (2) the retention of 90% of the genetic variation for quantitative traits, and (3) random breeding within the group, as well as (4) non-overlapping generations, (5) an equal sex ratio, and (6) Poisson-distributed family size. The absence of values in the upper parts of some of the tables indicates that more than 10% of the genetic variation is lost even if  $N_K$  is infinite. The value 999 indicates that  $N_K$  lies between 1,000 and 10,000.

Some remarks about these results are in order. First, note that the founder effective size must always be six or above if the 90% criterion is to be met. With fewer than six founders, the group will lose more than 10% or more of the genetic variation existing in the source population as soon as it reproduces.

\*The exponential growth rate per generation is .1.

Second,  $N_K$  is very sensitive to  $N_F$ , the number of founders, although above  $N_F$ s of about 25, the effect diminishes very rapidly. A very great decrease in  $N_K$  can be achieved by doubling  $N_F$ , especially if it is combined with artificially delayed reproduction. As shown in Table 5, for example, a decrease in  $N_K$  from 617 to 124 is achieved by an increase in  $N_F$  from 12 to 24 while increasing the generation time from 6 to 10 years.

Third, the tables contain regions of biological impossibility. For example, Table 7, which corresponds to the intrinsic rate of increase of small rodents that produce several litters of about five offspring per year, shows generation lengths that are unattainable in such species. It should be noted also that the goal of 90% retention of genetic variance for 200 years is virtually unattainable at generation growth rates of

\*The exponential growth rate per generation is .5.

<0.1, unless both generation length and  $N_F$  are >25. For example, Table 8 tabulates the values for slowly reproducing animals (exponential growth rate per generation = 0.05). Very large numbers of founders are required to meet the 90% criterion. Actual growth rates in zoos are often far below those in the wild, for a variety of reasons. Examples of some actual exponential growth rates per year in captive groups might be useful: okapi, 0.1; lion-tailed macaque, 0.05; Siberian tiger, 0.09 (rate is artificially low); Przewalski's horse, 0.10; gaur, 0.11; golden lion tamarin, 0.22.

Figure 1 illustrates a small sample of the tabulated results from Table 5. Curve A was generated with  $N_F = 10$ ; curve B with  $N_F = 20$ ; curve C with  $N_F = N_K$ . The latter assumption is very unrealistic, but note the small effect on  $N_K$  of increasing the founder size above 20.

\*The exponential growth rate per generation is 3.

Our model does not take into account the generation of genetic variation by mutation. Above some theoretical equilibrium size, a population will gain genetic variance by mutation faster than it loses it by genetic drift [Franklin, 1980]. Existing data do not permit an estimate of such an equilibrium. (Actually, there are as many equilibria as there are categories of phenotypic traits for which mutation rates can be measured.) Nevertheless, we are in agreement that the marginal genetic advantage of an effective size of 500 versus 250 is probably insignificant. Because space and facilities will continue to be limiting resources for zoos in the foreseeable future, we believe that the maintenance of more than 200 to 300 effective individuals of a given species is a profligate use of precious resources. For example, one popular species

Fig. 1. Combinations of ultimate effective population sizes and generation lengths in years required to maintain 90% of the genetic variation in the source population. Curve A, founder size of 10; curve B, founder size of 20; curve C, founder size equals ultimate size.

(such as tigers) could monopolize much of the space available for large cats. Parenthetically, it is often pointed out that the census number can be significantly reduced by any manipulations that tend to equalize the reproductive output of families.

A certain amount of subdivision will often be desirable, as discussed by Foose et al [1986]. For large animals, the unit of subdivision may often be all the zoos on a continent. Therefore, the values in the tables could represent the target sizes for either the European or the North American subpopulation, though a strict application of this principle would reduce by half the number of species that could be maintained.

## CONCLUSIONS

We have considered the questions “how long, how many staterooms, and how many passengers?” as a cryptic way of asking

1. How long will it be before habitat for wildlife begins to *increase* rather than decrease?
2. How many species of terrestrial vertebrates will require captive maintenance and propagation?
3. What population sizes are necessary to prevent the decay of fitness and genetic variation in captively bred species?

To the first question, our answer is a millenium, plus or minus 500 years, barring human catastrophes. With regard to captive breeding, however, we qualify this: Assuming that our institutions, and, with them biological technology, survive, a planning horizon of 200 years appears sufficient. By this time, in all likelihood, entirely new technologies for maintaining and regenerating species in miniaturized and suspended states will have been developed.

To the second question, our answer is about 2,000 species of vertebrates (excluding fish), probably plus or minus 500. The captive breeding of so many species will saturate the available space and resources, but, hopefully, advances in cryogenics and similar technologies will obviate the need to maintain all of these at one time as living organisms.

To the third question, the answer is more complex. Our approach is to assume that a reasonable goal is to retain at least 90% of the genetic variance in the founder group for the interval of two centuries. (Considering such a finite period of time permits much more concrete and tailored answers to the question.) The actual target number is found to depend on the effective size of the founder group, the rate of growth of the population in captivity, and the generation time. The results are tabulated for a range of parameter values.

Even with the highest rates of population growth, the effective size of the founder group must be six or more, assuming that 90% of the genetic variation in the source populations is to be conserved. Larger founder sizes allow substantial decreases in  $N_k$ . This should not be construed, however, to mean that hope should be abandoned if such founder sizes are impractical. The goal of 90% retention is arbitrary, but it was the consensus that it intuitively represented the zone between a potentially damaging and a tolerable loss of heterozygosity. With careful manage-

ment, the viability of a captive group should be sustainable, even with fewer founders, and even if the 90% goal is not attainable.

Animals with very long generation times can be maintained with relatively few individuals. For example, an effective size of only about 40 need be kept if the generation time is 25 years. On the other hand, such small populations may be vulnerable to the misfortunes and vagaries of disease, accidents, and occasional breakdowns in curatorial vigilance. Though zoos, to a large extent, are able to buffer the random variation in their environments and in the demographics of their captive groups, formal captive breeding management plans should estimate the frequencies, probabilities, and genetic consequences of such stochastic perturbations.

---

**Abstract:** *Roads are a widespread and increasing feature of most landscapes. We reviewed the scientific literature on the ecological effects of roads and found support for the general conclusion that they are associated with negative effects on biotic integrity in both terrestrial and aquatic ecosystems. Roads of all kinds have seven general effects: mortality from road construction, mortality from collision with vehicles, modification of animal behavior, alteration of the physical environment, alteration of the chemical environment, spread of exotics, and increased use of areas by humans. Road construction kills sessile and slow-moving organisms, injures organisms adjacent to a road, and alters physical conditions beneath a road. Vehicle collisions affect the demography of many species, both vertebrates and invertebrates; mitigation measures to reduce roadkill have been only partly successful. Roads alter animal behavior by causing changes in home ranges, movement, reproductive success, escape response, and physiological state. Roads change soil density, temperature, soil water content, light levels, dust, surface waters, patterns of runoff, and sedimentation, as well as adding heavy metals (especially lead), salts, organic molecules, ozone, and nutrients to roadside environments. Roads promote the dispersal of exotic species by altering habitats, stressing native species, and providing movement corridors. Roads also promote increased hunting, fishing, passive harassment of animals, and landscape modifications. Not all species and ecosystems are equally affected by roads, but overall the presence of roads is highly correlated with changes in species composition, population sizes, and hydrologic and geomorphic processes that shape aquatic and riparian systems. More experimental research is needed to complement post-hoc correlative studies. Our review underscores the importance to conservation of avoiding construction of new roads in roadless or sparsely roaded areas and of removal or restoration of existing roads to benefit both terrestrial and aquatic biota.*

Revisión de los Efectos de Carreteras en Comunidades Terrestres y Acuáticas

**Resumen:** *Las carreteras son una característica predominante y en incremento de la mayoría de los paisajes. Revisamos la literatura científica sobre los efectos ecológicos de las carreteras y encontramos sustento para la conclusión general de que las carreteras están asociadas con efectos negativos en la integridad biótica tanto de ecosistemas terrestres como acuáticos. Las carreteras de cualquier tipo ocasionan siete efectos generales: mortalidad ocasionada por la construcción de la carretera; mortalidad debida a la colisión con vehículos; modificaciones en la conducta animal; alteración del ambiente físico; alteración del ambiente químico; dispersión de especies exóticas e incremento en el uso de áreas por humanos. La construcción de carreteras elimina a organismos sésiles y a organismos de lento movimiento, lesiona a organismos adyacentes a la carretera y altera las condiciones físicas debajo ella misma. Las colisiones con vehículos afectan la demografía de muchas especies tanto de vertebrados como invertebrados; las medidas de mitigación para reducir la pérdida de animales por colisiones con vehículos han sido exitosas solo de manera parcial. Las carreteras alteran la conducta animal al ocasionar cambios en el rango de hogar, movimientos, éxito reproductivo, respuesta de escape y estado fisiológico. Las carreteras cambian la densidad del suelo, temperatura, contenido de agua en el suelo, niveles de luz, polvo, aguas superficiales, patrones de escurrimiento y sedimentación, además de agregar metales pesados (especialmente plomo), sales, moléculas orgánicas, ozono y nutrientes a los ambientes que atraviesan. Las carreteras promueven la dispersión de especies exóticas al alterar los hábi-*

Paper submitted February 8, 1999; revised manuscript accepted July 21, 1999.

*tats, al estresar a las especies nativas y proveer corredores para movimiento. Las carreteras también promueven el incremento de la caza y la pesca, el hostigamiento pasivo de animales y modificaciones del paisaje. No todas las especies ni todos los ecosistemas son afectados por las carreteras de igual forma, pero en general la presencia de carreteras está altamente correlacionada con cambios en la composición de especies, los tamaños poblacionales y los procesos hidrológicos y geomorfológicos que afectan a la estructura de sistemas acuáticos y riparios. Se necesita más investigación experimental para complementar estudios correlativos post-hoc. Nuestra revisión hace énfasis en que en trabajos de conservación es importante evitar la construcción de nuevas carreteras en áreas carentes de ellas o en áreas con pocas carreteras, además de remover o restaurar carreteras existentes con la finalidad de beneficiar tanto a la biota acuática como la terrestre.*

## Introduction

Among the most widespread forms of modification of the natural landscape during the past century has been the construction and maintenance of roads (Diamondback 1990; Bennett 1991; Noss & Cooperrider 1994). As conservation biologists seek to understand the forces that influence the viability of populations and the overall health of ecosystems, it is important that we understand the scope of the ecological effects of roads of all types, especially important as conservation biologists are asked to participate in the development and implementation of strategies to protect or restore elements of biological diversity and integrity.

Roads of all kinds affect terrestrial and aquatic ecosystems in seven general ways: (1) increased mortality from road construction, (2) increased mortality from collision with vehicles, (3) modification of animal behavior, (4) alteration of the physical environment, (5) alteration of the chemical environment, (6) spread of exotic species, and (7) increased alteration and use of habitats by humans. These general effects overlap somewhat. In some cases animals modify their behavior and avoid roads because of concentrated human activity along roads. Roads may facilitate the spread of invasive species by disrupting native communities and changing physical habitats. Roads may fragment populations through roadkill and road avoidance. Despite the difficulty of categorizing discretely the causal basis in every example, these seven categories provide a useful framework for assessing what is known and unknown about the ecological effects of roads.

Selective road removal, relocation, or remediation may provide ecological benefits in certain situations. Yet, although roads are commonly identified as important correlates or indicators of loss of ecological health (e.g., Noss & Cooperrider 1994), the specific mechanisms by which biota are affected are often complicated or uncertain. Therefore, mitigation or treatment of specific effects, whether during road design or in post-construction remediation, can be costly and fraught with uncertainty.

## Mortality from Road Construction

Road construction kills any sessile or slow-moving organism in the path of the road. The extent to which road

construction contributes to direct mortality has not been estimated as has direct mortality from other forms of habitat destruction (e.g., Petranka et al. 1993). The fact that road construction kills individual organisms is obvious, however. The magnitude of such construction is not trivial; the 13,107,812 km of road lanes of all types in the conterminous United States, with an average width of 3.65 m per lane, have destroyed at least 4,784,351 ha of land and water bodies that formerly supported plants, animals, and other organisms (U.S. Department of Transportation 1996). The actual number is likely much higher because this estimate does not include shoulder pavement and land peripheral to the roadbed that is cleared during construction.

Construction may physically injure organisms adjacent to the path of construction. Roads built for extraction of white fir result in damage to trees that is visible up to 30 m from the road (Trafela 1987). Such damage contributes to a decline of up to 30% in forest productivity per rotation, due in part to a decline in growth of damaged trees. Construction also alters the physical conditions of the soil underneath and adjacent to the road. Riley (1984) showed that road construction increases soil compaction up to 200 times relative to undisturbed sites. These changes likely decrease the survival of soil biota that are not killed directly. Direct transfer of sediment and other material to streams and other water bodies at road crossings is an inevitable consequence of road construction (Richardson et al. 1975; Seyedbagheri 1996). High concentrations of suspended sediment may directly kill aquatic organisms and impair aquatic productivity (Newcombe & Jensen 1996).

## Mortality from Collision with Vehicles

Mortality of animals from collision with vehicles is well documented. Many reviews of the taxonomic breadth of the victims of vehicle collision have been published (e.g., Groot Bruinderink & Hazebroek 1996). Few if any terrestrial species of animal are immune. Large mammals ranging in size from moose (*Alces alces*) to armadillos (*Dasypus novemcinctus*) are the best-documented roadkills, probably due to interest in their demography and to their size (Bellis & Graves 1971; Puglisi et al. 1974;

Reilly & Green 1974; Holroyd 1979; Wilkins & Schmidly 1980; Bashore et al. 1985; Davies et al. 1987; Bangs et al. 1989; Palomares & Delibes 1992).

Roadkill among many other species includes American Kestrels (*Falco sparverius*; Varland et al. 1993), Barn Owls (*Tyto alba*; Newton et al. 1991), Northern Saw-whet Owls and Eastern Screech Owls (*Aegolius acadicus* and *Otis asio*; Loos & Kerlinger 1993), tropical forest birds (Novelli et al. 1988), garter snakes (Dalrymple & Reichenbach 1984), granivorous birds (Dhindsa et al. 1988), American crocodile (*Crocodylus acutus*; Kushlan 1988), green iguanas (*Iguana iguana*; Rodda 1990), desert snakes (Rosen & Lowe 1994), toads (van Gelder 1973), plus a wide range of invertebrates, especially insects (H. C. Seibert & Conover 1991).

This form of mortality can have substantial effects on a population's demography. Vehicle collision is the primary cause of death for moose in the Kenai National Wildlife Refuge in Alaska (Bangs et al. 1989) and for Barn Owls in the United Kingdom (Newton et al. 1991), the second highest form of mortality for Iberian lynx (*Felis pardina*) in southwestern Spain (after hunting; Ferreras et al. 1992), and the third highest form for white-tailed deer (*Odocoileus virginianus*) in New York (Sarbello & Jackson 1985) and wolves (*Canis lupus*) in Minnesota (Fuller 1989). Roadkill is a limiting factor in the recovery of the endangered American crocodile in southern Florida (Kushlan 1988) and is contributing to the endangerment of the prairie garter snake (*Thamnophis radix radix*; Dalrymple & Reichenbach 1984). Roadkill is often nonspecific with respect to age, sex, and condition of the individual animal (e.g., Bangs et al. 1989).

Amphibians may be especially vulnerable to roadkill because their life histories often involve migration between wetland and upland habitats, and individuals are inconspicuous and sometimes slow-moving. Roads can be demographic barriers that cause habitat and population fragmentation (Joly & Morand 1997). In the Netherlands, for example, roads with high traffic volume negatively affect occupancy of ponds by moor frogs (*Rana arvalis*; Vos & Chardon 1998). In Ontario, the local abundance of toads and frogs is inversely related to traffic density on adjacent roads, but the incidence of roadkill relative to abundance is higher on highly trafficked roads (Fahrig et al. 1995). Thus, even though populations in high-traffic areas have apparently already been depressed from cumulative road mortality, they continue to suffer higher proportionate rates of roadkill.

Mitigation measures have been employed in different locations with varying degrees of success (e.g., Yanes et al. 1995). For example, underpasses on Interstate 75 have been only partially successful in reducing roadkill of Florida panthers (*Felis concolor coryi*; Foster & Humphrey 1991). Despite mitigation efforts, roads are likely to be a persistent source of mortality for many species.

In general, mortality increases with traffic volume (e.g., Rosen & Lowe 1994; Fahrig et al. 1995). Some species are less likely to be killed on high-speed roads than on medium-speed roads because the former usually have vegetation cleared back further from the road's shoulder, creating less attractive habitat and greater visibility for both animals and drivers. Other species, however, are attracted to the modified habitat alongside and in the meridians of high-speed roads (Cowardin et al. 1985), making them population sinks.

## Modification of Animal Behavior

The presence of a road may modify an animal's behavior either positively or negatively. This can occur through five mechanisms: home range shifts, altered movement patterns, altered reproductive success, altered escape response, and altered physiological state.

Black bears (*Ursus americanus*) in North Carolina shift their home ranges away from areas with high road densities (Brody & Pelton 1989), as do grizzly bears in the Rocky Mountains (*Ursus horribilis*; McLellan & Shackleton 1988). Elk (*Cervus elaphus*) in Montana prefer spring feeding sites away from visible roads (Grover & Thompson 1986), and both elk and mule deer (*Odocoileus hemionus*) in Colorado in winter prefer areas >200 m from roads (Rost & Bailey 1979). Wolves will not establish themselves in areas with road densities greater than a region-specific critical threshold (Jensen et al. 1986; Thurber et al. 1994), probably as a result of a relationship between road density and hunting pressure. Mountain lion (*Felis concolor*) home ranges are situated in areas with lower densities of improved dirt roads and hard-surface roads (Van Dyke et al. 1986), suggesting that either mountain lions avoid these areas or road construction tends to avoid their prime habitat. Elephants (*Loxodonta africana*) in northeastern Gabon preferentially locate in forests away from both roads and villages (Barnes et al. 1991). Both Black Vultures (*Coragyps atratus*) and Turkey Vultures (*Cathartes aura*), on the other hand, preferentially establish home ranges in areas with greater road densities (Coleman & Fraser 1989), probably because of the increase in carrion.

Roads may also alter patterns of animal movement. Caribou (*Rangifer tarandus*) in Alaska preferentially travel along cleared winter roads that lead in the direction of their migration (Banfield 1974). Although the road may enhance caribou movement, it results in increased mortality from vehicle collisions and predation by wolves. After calving, female caribou with calves avoid roads (Klein 1991). The land snail *Arianta arbustorum* avoids crossing roads, even those that are unpaved and as narrow as 3 m (Baur & Baur 1990), and extend their movements along road verges. Reluctance to cross roads is also seen in white-footed mice (*Peromyscus*

*leucopus*; Merriam et al. 1989) and many other rodent species (Oxley et al. 1974), even when the road is narrow and covered only with gravel. Cotton rats (*Sigmodon hispidus*) and prairie voles (*Microtus ochrogaster*) avoid roads as narrow as 3 m (Swihart & Slade 1984). Black bear almost never cross interstate highways in North Carolina (Brody & Pelton 1989) but will cross roads with less traffic volume. Roads act as barriers to gene flow in the common frog (*Rana temporaria*) in Germany, leading to significant genetic differentiation among populations (Reh & Seitz 1990). Other animals that show a reluctance to cross roads include pronghorn antelope (*Antilocapra americana*; Bruns 1977) and mountain lions (Van Dyke et al. 1986).

Some animals seem unaffected by the presence of roads, at least at some spatial scales. Based on a study of 20 wolverines, Hornocker and Hash (1981) concluded that the sizes and shapes of home ranges of wolverines where they are still found in northwestern Montana are independent of the presence of highways. Similarly, the presence of highways explained none of the allelic differentiation among populations of brown hares (*Lepus europaeus*) in Austria (Hartl et al. 1989).

Roads may affect an animal's reproductive success. Productivity of Bald Eagles (*Haliaeetus leucocephalus*) in Oregon (Anthony & Isaacs 1989) and Illinois (Paruk 1987) declines with proximity to roads, and they preferentially nest away from roads. Golden Eagles (*Aquila chrysaetos*) also prefer to nest away from human disturbances, including roads (Fernandez 1993). The reduced nesting success of eagles in proximity to roads may be more a function of the presence of humans than of the road itself; nesting failure by Golden Eagles in Scotland correlates with how easy it is for people to approach but not with proximity to roads themselves (Watson and Dennis 1992). Relative to habitat availability, Sandhill Cranes (*Grus canadensis*) avoid nesting near paved and gravel public roads (Norling et al. 1992); they do not avoid private roads with low-traffic volume (Norling et al. 1992) and can habituate to roads over time (Dwyer & Tanner 1992). Mallards (*Anas platyrhynchos*) in North Dakota, on the other hand, prefer road rights-of-way for nesting (Cowardin et al. 1985), perhaps because of a lower level of predation there.

Roads can also alter escape responses. Pink-footed Geese (*Anser brachyrhynchus*) in Denmark are more easily disturbed when feeding near roads, flying away when humans approach within 500 m, a greater distance than when feeding in areas without roads (Madsen 1985). Both the Lapwing (*Vanellus vanellus*) and Black-tailed Godwit (*Limosa limosa*) are more easily disturbed near roads and have disturbance distances of 480–2000 m depending on traffic volume (Van der Zande et al. 1980). Less well known is the effect of roads and vehicles on an animal's physiological state. MacArthur et al. (1979) showed that heart rate and therefore

metabolic rate and energy expenditure of female big-horn sheep (*Ovis canadensis*) increase near a road independent of any use of the road. Roads contribute to fragmentation of populations through both increased mortality and modification of behavior that makes animals less likely to cross roads. Fragmentation may be accelerated by roads when spatially critical habitat patches (e.g., "stepping stones") become unoccupied as a result of increased local mortality or reduced recolonization.

## Disruption of the Physical Environment

A road transforms the physical conditions on and adjacent to it, creating edge effects with consequences that extend beyond the time of the road's construction. At least eight physical characteristics of the environment are altered by roads: soil density, temperature, soil water content, light, dust, surface-water flow, pattern of runoff, and sedimentation.

Long-term use of roads leads to soil compaction that persists even after use is discontinued. Soil density on closed forest roads continues to increase, particularly during winter months (Helvey & Kochenderfer 1990). Increased soil density can persist for decades: logging skid trails in northeastern California over 40 years old have soil that is 20% more compacted than soil in nearby areas that have not been used as trails (Vora 1988).

The reduction of water vapor transport on a road with a hard surface increases the surface temperature of a road compared to bare soil, an effect that increases with thickness of the road surface (Asaeda & Ca 1993). The heat stored on the road surface is released into the atmosphere at night, creating heat islands around roads. Animals respond to these heat islands: small birds (Whitford 1985) and snakes, for example, preferentially aggregate on or near warm roads, increasing their risk of being hit by cars and, at their northern range limits, reducing energetic demands for breeding.

During the dry season, the moisture content of soils under roads declines even if the roads are not in use (Helvey & Kochenderfer 1990), probably in response to changes in soil porosity. Roads through forests also increase the amount of light incident on the forest floor. The amount of increase depends on how much of the original canopy and lower strata remain, which depends in turn on the width of the road and roadside verge. The increase in light increases the density of species that preferentially grow where light levels are high, such as early-successional, disturbance-adapted species such as the North American orchid *Isotria medeoloides* (Mehrhoff 1989).

Road traffic mobilizes and spreads dust, which when settled on plants can block photosynthesis, respiration, and transpiration and can cause physical injuries to plants (Farmer 1993). These effects are sufficient to alter

plant community structure, especially in communities dominated by lichens and mosses (Auerbach et al. 1997). Although most sediment enters water bodies through overland flow or mass failure, dust from highly trafficked roads can serve as a source of fine sediments, nutrients, and contaminants to aquatic ecosystems (Gjessing et al. 1984).

Roads and bridges can alter the development of shorelines, stream channels, floodplains, and wetlands. Because of the energy associated with moving water, physical effects often propagate long distances from the site of a direct road incursion (Richardson et al. 1975). Alteration of hydrodynamics and sediment deposition can result in changes in channels or shorelines many kilometers away, both down- and up-gradient of the road crossing. The nature of such responses to channel and shoreline alteration is not always predictable; it may depend on the sequence of flood and sedimentation events after the alteration is made. Roads on floodplains can redirect water, sediment, and nutrients between streams and wetlands and their riparian ecosystems, to the detriment of water quality and ecosystem health. Roads are among the many human endeavors that impair natural habitat development and woody debris dynamics in forested floodplain rivers (Piégay & Landon 1997).

Road crossings commonly act as barriers to the movement of fishes and other aquatic animals (Furniss et al. 1991). Although many headwater populations of salmonid fishes are naturally migratory, they often persist today as fragmented headwater isolates, largely because of migration barriers created by road crossings and other human developments that fail to provide for fish passage (Kershner et al. 1997; Rieman et al. 1997). Salmonids and other riverine fishes actively move into seasonal floodplain wetlands and small valley-floor tributaries to escape the stresses of main-channel flood flows (Copp 1989), but valley-bottom roads can destroy or block access to these seasonally important habitats (Brown & Hartman 1988). Persistent barriers may encourage local selection for behaviors that do not include natural migration patterns, potentially reducing both the distribution and productivity of a population.

Roads directly change the hydrology of slopes and stream channels, resulting in alteration of surface-water habitats that are often detrimental to native biota. Roads intercept shallow groundwater flow paths, diverting the water along the roadway and routing it efficiently to surface-water systems at stream crossings (Megahan 1972; Wemple et al. 1996). This can cause or contribute to changes in the timing and routing of runoff (King & Tenyson 1984; Jones & Grant 1996; Ziemer & Lisle 1998), the effects of which may be more evident in smaller streams than in larger rivers (Jones & Grant 1996). Hydrologic effects are likely to persist for as long as the road remains a physical feature altering flow routing—often long after abandonment and revegetation of the

road surface. By altering surface or subsurface flow, roads can destroy and create wetland habitats.

Changes in the routing of shallow groundwater and surface flow may cause unusually high concentrations of runoff on hillslopes that can trigger erosion through channel downcutting, new gully or channel head initiation, or slumping and debris flows (Megahan 1972; Richardson et al. 1975; Wemple et al. 1996; Seyedbagheri 1996). Once such processes occur, they can adversely affect fishes and other biota far downstream for long periods of time (Hagans et al. 1986; Hicks et al. 1991). Roads have been responsible for the majority of hill-slope failures and gully erosion in most steep, forested landscapes subject to logging activity (Furniss et al. 1991; Hagans et al. 1986). Because most of these more catastrophic responses are triggered by the response of roads during infrequent, intense storm events, lag times of many years or decades pass before the full effects of road construction are realized.

Chronic effects also occur, however. The surfaces of unpaved roads can route fine sediments to streams, lakes, and wetlands, increasing the turbidity of the waters (Reid & Dunne 1984), reducing productivity and survival or growth of fishes (Newcombe & Jensen 1996), and otherwise impairing fishing (Buck 1956). Existing problem roads can be remediated to reduce future erosion potential (e.g., Weaver et al. 1987; Harr & Nichols 1993). The consequences of past sediment delivery are long-lasting and cumulative, however, and cannot be effectively mitigated (Hagans et al. 1986).

## Alteration of the Chemical Environment

More has been written about the effects of roads on the chemical environment than on all other effects combined. Maintenance and use of roads contribute at least five different general classes of chemicals to the environment: heavy metals, salt, organic molecules, ozone, and nutrients.

A variety of heavy metals derived from gasoline additives and road deicing salts are put into the roadside environment. The most widely documented is lead, but others include aluminum, iron, cadmium, copper, manganese, titanium, nickel, zinc, and boron (Garcia-Miragaya et al. 1981; Clift et al. 1983; Gjessing et al. 1984; Oberts 1986; Araratyan & Zakharyan 1988).

Heavy metal contamination exhibits five patterns. First, the amount of contamination is related to vehicular traffic (Goldsmith et al. 1976; Dale & Freedman 1982; Lesharne et al. 1992). Second, contamination of soils, plants, and animals decreases exponentially away from the road (Quarles et al. 1974; Dale & Freedman 1982). Most studies indicate that contamination declines within 20 m but that elevated levels of heavy metals often occur 200 m or more from the road. The pattern of decline is influenced

by prevailing wind patterns (Haqus & Hameed 1986). Once metals reach aquatic environments, transport rates and distances increase substantially (Gjessing et al. 1984).

Third, heavy metals can be localized in the soil, either close to the surface if downward transport has not occurred (Indu & Choudhri 1991) or deep below the surface if pollution levels in the past exceeded those in the present (Byrd et al. 1983). Transportation and localization is largely affected by the physical properties of the soil (Yassoglou et al. 1987). Metals and other persistent chemicals fixed to soils may become remobilized once they are inundated or transported to freshwater environments by wind, water, or gravity.

Fourth, heavy metals accumulate in the tissues of plants (Datta & Ghosh 1985; Beslaneev & Kuchmazokova 1991) and animals (Collins 1984; Birdsall et al. 1986; Grue et al. 1986). As with soil, contamination of plant tissue occurs up to at least 200 m from a road and is greatest for individuals along roads with high traffic volume.

Fifth, heavy metal concentrations in soil decline over time where use of leaded gasoline has been stopped and surface-water flow carries the metal ions away (Byrd et al. 1983; Tong 1990). After they leave the terrestrial environment, however, the mobilized metals may cause additional harm to aquatic biota. Also, some of the processes of metal demobilization may be reversed rapidly if environmental conditions, such as acidity of the soils, sediments, or water, change (Nelson et al. 1991).

Deicing salts, particularly NaCl but also CaCl<sub>2</sub>, KCl, and MgCl<sub>2</sub>, contribute ions to the soil, altering pH and the soil's chemical composition (Bogemans et al. 1989). As with lead, discontinuation of the use of deicing salts allows plants damaged by salt stress to recover (Leh 1990). The effects on aquatic biota of temporary surges of salt that often accompany runoff from roads to surface and groundwaters have received little study. Deicing salts on roadways elevate chloride and sodium concentrations in streams (Molles & Gosz 1980; Hoffman et al. 1981; Peters & Turk 1981; Mattson & Godfrey 1994) and in bogs, where road salts can alter patterns of succession in aquatic vegetation (Wilcox 1986). Accumulation of salts from chemicals used for road deicing or dust control can disrupt natural stratification patterns and thus potentially upset the ecological dynamics of meromictic lakes (Hoffman et al. 1981; Kjensmo 1997).

Organic pollutants such as dioxins and polychlorinated biphenyls are present in higher concentrations along roads (Benfenati et al. 1992). Hydrocarbons may accumulate in aquatic ecosystems near roads (Gjessing et al. 1984). In one stream along a British highway, numerous contaminants were present at elevated levels in the water column and sediments, including copper, zinc, and various hydrocarbons, but polycyclic aromatic hydrocarbons associated with stream sediments accounted for most of the observed toxicity to aquatic amphipods

(Maltby et al. 1995). Comparatively little research has focused on the questions of the fate and effects of the organic chemicals associated with roads.

Vehicles produce ozone, which increases the concentration of this harmful molecule in the air, especially in areas where vehicle exhaust accumulates (Flueckiger et al. 1984). Roads are also especially important vectors of nutrients and other materials to aquatic ecosystems, because the buffering role normally played by riparian vegetation (Correll et al. 1992) is circumvented through direct runoff of materials in water and sediment where roads abut or cross water bodies. Water moving on and alongside roadways can be charged with high levels of dissolved nitrogen in various forms, and sediment brings a phosphorus subsidy when it reaches surface waters. Road deicing salts are an additional source of phosphorus (Oberts 1986). The degree to which roads directly contribute to eutrophication problems in aquatic ecosystems has been little investigated. Because roads deliver nutrients that originate in the contributing slope area, the nutrient burden is probably largely controlled by surrounding vegetation and land use. An increased density of road crossings of water bodies can be expected to increase delivery of nutrients.

The alteration of the chemical environment by roads results in a number of consequences for living organisms. First, in the terrestrial environment the chemical composition of some woody plants changes in response to pollution. These changes include increased concentrations of chemicals produced by plants, such as terpenoids, which help them resist the toxic effects of pollution (Akimov et al. 1989) and salts (Bogemans et al. 1989), and decreased production of other chemicals, such as soluble protein and chlorophyll *a*, which are necessary for plant function (Banerjee et al. 1983).

Second, organisms may be killed or otherwise displaced as a result of chemical exposure. Virtually all measures of soil biotic diversity and function decline in contaminated soil, including abundance, number of species, species composition, index of species diversity, index of equability, and bulk soil respiration (Muskett & Jones 1981; Guntner & Wilke 1983; Krzysztofak 1991).

Third, the growth (Petersen et al. 1982) and overall physical health (Flueckiger et al. 1984; Moritz & Breitenstein 1985) of many plants is depressed, even to the point of death (Fleck et al. 1988). The sensitivity of plants to pollutants may change during development; for example, seedlings are more sensitive to salt than are adults (Liem et al. 1984), which influences juvenile recruitment. Pollutants may affect plant health by damaging fine roots, mycorrhizae (Majdi & Persson 1989), and leaves (Simini & Leone 1986) and by changing salt concentrations in plant tissues (Northover 1987). Secondary effects on plant health include decreased resistance to pathogens (Northover 1987), causing further declines. In aquatic environments, plant (and animal) assemblages

may change due to direct and indirect responses to nutrient increases and due to growth suppression or mortality caused by other chemicals introduced by roads.

Fourth, plants (Graham & Kalman 1974; Nasralla & Ali 1985; Dickinson et al. 1987; Guttormsen 1993) and animals (Robel et al. 1981; Collins 1984; Harrison & Dyer 1984; Krzysztofiak 1991; Marino et al. 1992), including those cultivated or raised for agriculture, may accumulate toxins at levels that pose health hazards, including those for humans that consume exposed organisms (Jarosz 1994).

Fifth, increased concentrations near roadsides of some pollutants, particularly salt, attract large mammals, putting them more at risk of being killed by vehicles (Fraser & Thomas 1982). Spills of edible products from trucks and trains also attract wildlife to roadsides. Finally, evolutionary processes may be affected through altered selection pressures that result in local differentiation of populations of both plants (Kiang 1982) and animals (Minoranskii & Kuzina 1984).

### Spread of Exotic Species

Roads provide dispersal of exotic species via three mechanisms: providing habitat by altering conditions, making invasion more likely by stressing or removing native species, and allowing easier movement by wild or human vectors. It is often difficult to distinguish among these factors. Soils modified during road construction can facilitate the spread of exotic plants along roadsides (Greenberg et al. 1997). Some exotic plants establish themselves preferentially along roadsides and in other disturbed habitats (Wester & Juvik 1983; Henderson & Wells 1986; Tyser & Worley 1992; Wein et al. 1992). The spread of exotic diseases (Dawson & Weste 1985; Gad et al. 1986) and insects (Pantaleoni 1989; Schedl 1991) is facilitated by increased density of roads and traffic volume. Road construction that alters the canopy structure of forests promotes invasion by exotic understory plants, which affects animal communities (Gaddy & Kohlsaas 1987). Some roadside verges have been invaded by maritime plants because of their ability to tolerate saline soil (Scott & Davison 1982). Feral fruit trees are found preferentially along roadsides, and some populations are maintained solely by seeds in fruit waste thrown from vehicles (Smith 1986).

Exotic species are sometimes introduced along roadsides for the purpose of erosion control (Niordson 1989). Native species are now more widely preferred for this purpose, but Dunlap (1987) argues that in some cases the need for rapid establishment of plant cover requires the use of exotic species.

In another form of deliberate introduction, roads provide easy access to streams and lakes for fishery man-

agers to stock nonnative hatchery fish (Lee et al. 1997), which adversely affect native biota and disrupt aquatic ecosystems in many ways (Allan & Flecker 1993). Unsanctioned, illegal, and unintentional introductions of fishes, mollusks, plants, and other aquatic organisms also occur frequently (Allan & Flecker 1993), and they are facilitated by public road access to water bodies.

The dispersal of a biological agent such as a pathogen along a roadway can affect both terrestrial and aquatic ecosystems far from the road. In northern California and southwest Oregon, for example, vehicle traffic and roadway drainage along logging and mining roads during the wet season disperse spores of an exotic root disease (*Phytophthora lateralis*) that infects the endemic Port Orford cedar (*Chamaecyparis lawsoniana*; Zobel et al. 1985). Transfer of the water-borne spores from forest roads into headwater stream crossings can result in the infection and nearly complete mortality of Port Orford cedars along a much larger network of downstream channel margins and floodplains, even deep inside otherwise roadless areas. The progressive loss of this important conifer species from riparian ecosystems may engender substantial long-term consequences for the integrity of stream biota, including endangered salmon species, for which the Port Orford cedar provides shade, large and long-lasting coarse woody debris, and stabilization of channels and floodplains.

### Changes in Human Use of Land and Water

Roads facilitate increased use of an area by humans, who themselves often cause diverse and persistent ecological effects. New roads increase ease of access by humans into formerly remote areas. Perhaps more important, roads often increase the efficiency with which natural resources can be exported. At least three different kinds of human use of the landscape, made increasingly possible by roads, can have major ecological effects: hunting and fishing, recreation, and changes in use of land and water.

Roads open up areas to increased poaching and legal hunting. Hunting reduces population sizes of many game species, including brown bear (*Ursus arctos*; Camarra & Parde 1990), Iberian lynx (Ferreras et al. 1992), wolves (Fuller 1989), black bear (Manville 1983), and Egyptian mongooses (*Herpestes ichneumon*; Palomares & Delibes 1992). Roads also increase both legal and illegal fishing in streams and lakes. Native fish populations in previously inaccessible areas are often vulnerable to even small increases in fishing effort. Increased fishing then often gives rise to public demand for fish stocking as an attempt to artificially compensate for the effects of unsustainable harvest, at the further expense of native fishes and other species (e.g., Gresswell & Varley 1988).

Visitors increase when roads make areas more accessible, leading to increased passive harassment of animals—such as elk on Mount St. Helens in Washington State (Czech 1991) and the Oregon Coast Range (Witmer & DeCalesta 1985), brown bear in Europe (Del Campo et al. 1990), and mountain goats (*Oreamnos americanus*) in Montana (Pedevillano & Wright 1987)—and damage to plant communities (Matlack 1993).

Roads are often built into areas to promote logging, agriculture, mining, and development of homes or industrial or commercial projects. Such changes in land cover and land and water use result in major and persistent adverse effects on the native flora and fauna of terrestrial (Van Dyke et al. 1986; Karnefelt & Mattsson 1989; P. Seibert 1993) and freshwater ecosystems (Schlosser 1991; Allan & Flecker 1993; Roth et al. 1996).

Numerous studies have demonstrated declines in stream health associated with roads. Because the nature and extent of land use within a region tend to be highly correlated with road networks, however, it is often difficult or impossible to separate the direct ecological effects of roads from those of the accompanying land-use activities. For example, Eaglin and Hubert (1993) reported that trout biomass and streambed habitat quality in Wyoming streams declined in relation to the number of road crossings and to the proportion of area logged in the contributing catchment. Findlay and Houlihan (1997) found that herpetile species diversity in wetlands declined in relation to the density of roads within 2 km of the perimeter. Among streams in the Pacific Northwest, the status or abundance of bull trout populations has been inversely correlated to road density (Rieman et al. 1997; Baxter et al. 1999); these studies used roads as the best available general proxy of cumulative effects associated with land use and human access. On the other hand, some studies (e.g., Roth et al. 1996) have demonstrated correlations of stream biotic integrity with land-use pat-

terns across large catchments but did not investigate the specific roles that roads might play in mediating the causes and effects.

It appears that roads can serve as useful indicators of the magnitude of land-use changes, but it remains unclear to what degree the associated ecological responses result directly from roads themselves. If roads are largely responsible, effects could be ameliorated through altered road design, placement, remediation, or road removal. Strong interactions between roads and land use are likely, however. Forest roads in Idaho, for example, are less prone to erosion when the surrounding landscape remains in natural forest cover (Seyedbagheri 1996).

## Discussion and Conclusions

Roads have diverse and systemic effects on many aspects of terrestrial and aquatic ecosystems. The ecological effects of roads can resonate substantial distances from the road in terrestrial ecosystems, creating habitat fragmentation and facilitating ensuing fragmentation through support of human exploitative activities (Fig. 1a). Habitat deterioration is not widely appreciated as an aspect of ecological fragmentation in aquatic ecosystems. At the scale of an extensive landscape or stream network, however, roads produce a pattern of aquatic habitat loss that differs from the terrestrial pattern yet nevertheless results in the ecological fragmentation of aquatic ecosystems (Fig. 1b). We coin the term *hyperfragmentation* to describe the multidimensional view of ecological fragmentation and habitat loss that emerges when the consequences of roads or any habitat alteration for terrestrial and aquatic ecosystems are considered simultaneously (Fig. 1c). Hyperfragmentation is the result of a spatial footprint of ecological effect that propagates across the landscape differently in freshwater and

Figure 1. Spatial pattern of direct and indirect habitat alteration caused by human disturbance in a forested watershed: (a) classical forest edge effects contributing to terrestrial habitat fragmentation, (b) downstream-propagating hydrologic and biotic effects leading to large-scale fragmentation of freshwater habitats and populations, (c) combined terrestrial-aquatic view of landscape alteration that we term hyperfragmentation because it considers multiple ecosystem dimensions on the same landscape. Arrows indicate pre-dominant spatial vector of effects.

aquatic ecosystems than in terrestrial systems. Even where only a small percentage of the land's surface is directly occupied by roads, few corners of the landscape remain untouched by their off-site ecological effects. The breadth of these effects cannot be appreciated unless one takes a broadly transdisciplinary view of ecosystems and biological communities.

Road design, management, and restoration need to be more carefully tailored to address the full range of ecological processes and terrestrial and aquatic species that may be affected. Deliberate monitoring is necessary to ensure that projects have robust ecological benefits and minimal adverse effects and that they are cost-efficient relative to their actual benefits (e.g., Weaver et al. 1987). Of course, such assessments require time and money that are usually unavailable. Most funds used to remediate problem roads are earmarked for actual field operations and are not available to support such assessment and monitoring. Few of the experts building roads or "restoring" them are trained to recognize and address the full spectrum of ecological issues that we have identified. Moreover, by their nature roads have systemic ecological effects that, even if recognized, cannot be overcome.

If a broad view of the ecological effects of roads reveals a multiplicity of effects, it also suggests that it is unlikely that the consequences of roads will ever be completely mitigated or remediated. Thus, it is critical to retain remaining roadless or near-roadless portions of the landscape in their natural state. Because of the increasing rarity of roadless areas, especially roadless watersheds, conservation efforts cannot rely entirely on protection of existing natural areas. But neither can conservation efforts depend entirely on tenuous and unexamined assumptions about the capability of site- and species-specific mitigation and remediation measures to reduce the ecological consequences of existing and proposed roads.

## Acknowledgments

We thank M. Hourdequin for organizing the symposium at the 1997 annual meeting of the Society for Conservation Biology at which we originally presented much of this material and for her patience during the preparation of this manuscript. We also thank R. Noss and an anonymous reviewer for improvement of the paper. The second author's contribution to this paper and his participation in the symposium were supported by The Pacific Rivers Council.

Guest Editorial, part of a Special Feature on [Effects of Roads and Traffic on Wildlife Populations and Landscape Function](#)

## Effects of Roads and Traffic on Wildlife Populations and Landscape Function: Road Ecology is Moving toward Larger Scales

[Rodney van der Ree](#)<sup>1</sup>, [Jochen A. G. Jaeger](#)<sup>2</sup>, [Edgar A. van der Grift](#)<sup>3</sup>, and [Anthony P. Clevenger](#)<sup>4</sup>

**ABSTRACT.** Road ecology has developed into a significant branch of ecology with steady growth in the number of refereed journal articles, books, conferences, symposia, and “best practice” guidelines being produced each year. The main objective of this special issue of *Ecology and Society* is to highlight the need for studies that document the population, community, and ecosystem-level effects of roads and traffic by publishing studies that document these effects. It became apparent when compiling this special issue that there is a paucity of studies that explicitly examined higher order effects of roads and traffic. No papers on landscape function or ecosystem-level effects were submitted, despite being highlighted as a priority for publication. The 17 papers in this issue, from Australia, Canada, the Netherlands, and USA, all deal to some extent with either population or community-level effects of roads and traffic. Nevertheless, many higher order effects remain unquantified, and must become the focus of future studies because the complexity and interactions among the effects of roads and traffic are large and potentially unexpected. An analysis of these complex interrelations requires systematic research, and it is necessary to further establish collaborative links between ecologists and transportation agencies. Many road agencies have “environmental sustainability” as one of their goals and the only way to achieve such goals is for them to support and foster long-term and credible scientific research. The current situation, with numerous small-scale projects being undertaken independently of each other, cannot provide the information required to quantify and mitigate the negative effects of roads and traffic on higher levels. The future of road ecology research will be best enhanced when multiple road projects in different states or countries are combined and studied as part of integrated, well-replicated research projects.

**Key Words:** *animal movement; animal-vehicle collisions; barrier effect; ecological threshold; gene flow; habitat fragmentation; mitigation; population viability analysis; road ecology; road-effect zone; traffic mortality; traffic noise; traffic volume; transportation planning*

### INTRODUCTION

Humans are responsible for the current unprecedented rate of biodiversity loss across the globe with climate change, pollution, and the loss, fragmentation, and degradation of habitat being the major drivers of extinction (Vitousek et al. 1997). Roads and other linear infrastructure are a major cause of habitat loss, fragmentation, and degradation and are ubiquitous in most landscapes around the world. Worldwide, there are already an estimated 750 million vehicles travelling on approximately 50 million km of public road (T. Langton, *personal communication*), and the road

network and traffic volumes are still increasing, particularly in eastern Europe, China, India, and Latin America.

Linear infrastructure is important for society because it provides connectivity for people. However, linear infrastructure also exerts significant negative effects on adjacent habitats, wildlife populations, communities, and ecosystems. Research about the ecological effects of roads and traffic on the natural environment began in 1925 when Dayton Stoner documented the 225 traffic-killed vertebrates from 29 species that he observed during a 632 mile trip in Iowa, USA (Stoner 1925).

<sup>1</sup>University of Melbourne, <sup>2</sup>Concordia University Montréal, Department of Geography, Planning and Environment, Quebec, Canada, <sup>3</sup>Alterra, Wageningen UR, Netherlands, <sup>4</sup>Western Transportation Institute, Montana State University, USA

The term “road ecology” was first used in German (“Straßenökologie”) in 1981 (Ellenberg et al.), and was later translated into English by Forman et al. (2003) for their book *Road Ecology: Science and Solutions*. Since the mid 1990s, there has been a rapid increase in the number of studies, publications, and symposia, particularly from Europe, North America, and Australia. These include major national and international reports and best practice guidelines (Iuell et al. 2003, Trocmé et al. 2003, National Research Council 2005, Clevenger and Huijser 2009), regular dedicated conferences such as the biennial International Conference on Ecology and Transportation (ICOET), Infra-Eco Network of Europe (IENE), and symposia and special issues of peer-reviewed journals, e.g., *Biological Conservation* (Mader 1990), *Conservation Biology* (Hourdequin 2000), *GAIA* (Jaeger et al. 2005), and *Naturschutz and Landschaftsplanung* (Roedenbeck and Jaeger 2006).

The overall aim of road ecology research is to quantify the ecological effects of roads, with the ultimate aim of avoiding, minimizing, and compensating for their negative impacts on individuals, populations, communities, and ecosystems. This research has demonstrated the numerous and diverse effects of roads and traffic on plants and animals, with most studies focusing at the level of the individual animal. These effects include the loss and fragmentation of habitat, increased rates of wildlife mortality because of collision with vehicles, alterations to light, moisture and wind regimes due to the creation of edges, pollution from traffic, e.g., light, noise, and chemical, and facilitating the spread and dispersal of weeds and feral animals. Roads also affect the aesthetic and recreational quality of landscapes for humans (Di Giulio and Holderegger 2009). Consequently, roads have been described as the single most destructive element in the process of habitat fragmentation (Noss 1993) and their ecological effects are considered “the sleeping giant of biological conservation” (Forman 2002:viii).

Understanding the impacts of roads and traffic at higher levels is necessary for a number of good reasons. Most governments have agreed that conservation of biodiversity is important and therefore road agencies must endeavor to ensure that they are contributing to achieving this goal. Counting the number of dead animals on the side of the road or measuring the size of the ecological road-

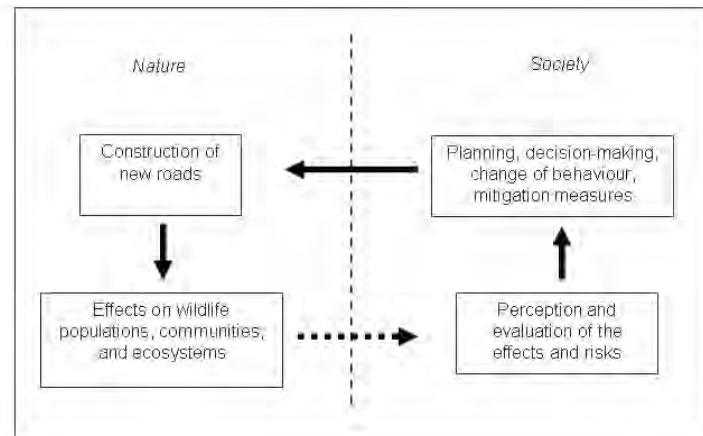

effect zone will not, by itself, inform whether roads and vehicles are endangering the existence of populations or species. The important parameter must be the long-term viability of adjacent populations, and this requires data on the sizes of the populations, vital rates, and level of connectivity among subpopulations. Similarly, a critical question when evaluating mitigation works is the extent to which populations have become more viable, and whether they are now sufficiently viable, not simply how many animals pass through an underpass (van der Ree et al. 2007). The extent to which the results from the numerous local studies can be extrapolated to larger spatial and temporal scales is unknown. Therefore, an important next step is to evaluate how the density and configuration of entire road networks affect the functional relationships within and among ecosystems at the landscape scale. Answers to this question will inform cumulative environmental assessments and transportation planning (Roedenbeck et al. 2007). Roads also affect humans in a range of ways but little research on this topic has been completed (Di Giulio and Holderegger 2009).

Reducing the negative effects of roads and traffic will only be possible if more dialogue is achieved between the scientific community and the planners and political decision makers (Fig. 1). The majority of people in the world live in cities and increasingly, their encounters with wildlife involve animals that have died after collision with vehicles. Novel approaches to engage the public, and hence, governments, are required. A recent example was an award-winning exhibition in the Whyte Museum in Banff, Alberta, Canada in 2006 of images of wildlife using the now famous overpasses and underpasses in Banff National Park. A second example was a creative arts competition as part of the IENE 2010 conference for Hungarian school children to portray the conflict, and solutions, between roads and wildlife (Fig. 2).

#### **ABOUT THIS ISSUE: THE EFFECTS OF ROADS AND TRAFFIC ON POPULATIONS, COMMUNITIES, AND ECOSYSTEMS**

The two main objectives of this special issue of *Ecology and Society* were to (1) highlight the need for studies that document the population, community, and ecosystem-level effects of roads and traffic, and (2) publish studies that document

**Fig. 1.** Society's ability to address the negative effects of road networks on wildlife populations and ecosystems depends on the perception of the ecological effects and risks. As the perception of the effects by society has been severely limited (as indicated by the dotted line), alternative approaches may be required that would be based on more indirect indicators of ecological risk and on the precautionary principle.

these effects. The special issue consists of 17 papers from four countries, i.e., Australia, Canada, the Netherlands, and U.S.A., that all deal to some extent with either population or community-level effects of roads and traffic. It became apparent when compiling the special issue that there is a paucity of road ecology studies that explicitly examined higher order effects of roads. No papers on landscape function or ecosystem-level effects were submitted, despite being highlighted as a priority for publication.

The special issue begins with a synthesis paper (Fahrig and Rytwinski 2009) and ends with an insight paper (Simmons et al. 2010). The synthesis is an appropriate first paper because it assesses the widely held assertion that “there are very few studies that assess the population-level effects of roads and traffic.” The assertion was found to be partly true and partly false; the authors located 79 studies that provide data on population-level effects (abundance and density) but found that in most cases, the population-level effect was ‘hidden’ in many of the papers reviewed. Nevertheless, Fahrig and Rytwinski (2009) found that overwhelmingly, roads and traffic had a negative effect on animal abundance, with negative effects outnumbering positive effects by a factor of five. The final paper in the special issue reviews some of the genetic methods used in road ecology and provides an

insight into how conservation genetics can be better utilized in future studies. Simmons et al. (2010) argue that conservation genetics is a rapidly evolving field and that many of the widely perceived limitations to the use of genetics are either misconceptions or no longer apply. They conclude with strong recommendations that genetic approaches be combined with field studies to increase the inferential strength of whichever study design is adopted (sensu Roedenbeck et al. 2007).

The road-effect zone is the distance from the edge of the road over which significant ecological effects can be detected (Forman and Alexander 1998). Eigenbrod et al. (2009) quantified threshold effects of a motorway on anuran populations in Canada, and Bissonette and Rosa (2009) investigated the effects of a motorway on the composition and abundance of a small-mammal community in the deserts of Utah, USA. Eigenbrod et al. (2009) were the first to quantify the road-effect zone on the species richness and relative abundance of anurans, and found strong negative effects for four of seven species, extending 250–1000 m from the road edge. They conclude that although most anurans are likely to have reduced abundances near motorways, the extent and cause of this relationship will vary among species (Eigenbrod et al. 2009). In contrast, Bissonette and Rosa (2009) found that roadside vegetation in desert environments often provides

**Fig. 2.** Runner up of the "On Dangerous Roads" Competition organized by Varangy Akciócsoport Egyesület for the 2010 Infra-Eco Network of Europe Conference showing an overpass used by wildlife. An ongoing project in the Netherlands is studying the effectiveness of an overpass for amphibians, in combination with fences along the road. This overpass is equipped with a cascading series of small ponds fed with water pumped into the highest pond in the center of the overpass.

suitable habitat for small mammals. Only 2 of 13 species of small mammals were never captured near roads, and the remaining 11 species' numbers were either similar or more abundant near the road than further away.

Vegetation adjacent to roads often provides habitat (e.g., Bissonette and Rosa 2009), and in some landscapes, even the majority of habitat (van der Ree and Bennett 2003). Wildlife that use this habitat will experience traffic noise and may be affected by it. Anthropogenic noise has the potential to severely disrupt the communication of species by acoustic interference or masking. Three studies in this special issue investigate this effect on frogs and birds. Parris and Schneider (2008) found that the Grey Shrike-thrush (*Colluricincla harmonica*) sang at a higher frequency in areas with traffic noise than the Grey Fantail (*Rhipidura fuliginosa*) and that the probability of detecting either species declined substantially with increasing traffic noise and traffic volume. The effects of traffic noise on frogs were assessed by Parris et al. (2009) in an urban landscape

in southeast Australia and by Hoskin and Goosem (2010) in tropical rainforest in northeastern Australia. One species of urban frog in and around Melbourne called at a higher pitch in traffic noise, while the second species studied may also call at a higher pitch, but more data is required to be sure (Parris et al. 2009). *Litoria rheocola* in tropical rainforest also called at a higher pitch when closer to the road, as well as calling at a higher rate when near roads (Hoskin and Goosem 2010). The abundance of some species of rainforest frogs was also lower near roads.

A significant proportion of the road ecology literature is focused on evaluating the use and effectiveness of mitigation measures that aim to restore connectivity for wildlife or reduce rates of animal-vehicle collisions. A review presented at the ICOET conference in 2007 concluded that most studies in the scientific and grey literature had focused almost exclusively on documenting rates of use of wildlife passages, and that few had explicitly evaluated the effectiveness of mitigation measures

at enhancing population viability (van der Ree et al. 2007). In this special issue, five papers have addressed the topic of mitigation of road effects on wildlife in differing perspectives. Thorne et al. (2009) highlight the importance of landscape-scale planning to better integrate the needs of wildlife into regional transportation plans. Using two examples from California, USA, they show how road projects can benefit financially and ecologically when road agencies and conservation groups collaborate early in the planning stages. Approximately 1 – 2 million mammal-vehicle collisions occur annually in North America, causing in excess of 200 human fatalities and over one billion U.S. dollars in property damage each year (references in Huijser et al. 2009). Huijser et al. (2009) reviewed the effectiveness and cost of 13 measures considered effective at reducing collisions with large ungulates and found that for many sections of road, the effectiveness, measured as money saved, exceeds the costs to install the mitigation. The results of their cost-benefit model suggests that there must be many locations in North America where the mitigation measures are cost-effective, and thereby would save society money and improve road safety for humans and wildlife if implemented more often. At a smaller spatial scale, Grosman et al. (2009) combined real data on the movement of moose (*Alces alces*) with agent-based computer simulations to investigate if the removal of salt pools or their relocation from adjacent to the highway to 100 – 1500 m away from the road would result in fewer moose-vehicle collisions. Their model predicted that the removal of salt pools from near the edge of the highway would result in an almost 50% reduction in moose-vehicle collisions (Grosman et al. 2009).

The viability of populations adjacent to wildlife crossing structures is one of the fundamental measures of success of mitigation (van der Ree et al. 2007). Two papers in this special issue explicitly investigated the increase in the viability of a population of wildlife after mitigation (Taylor and Goldingay 2009, van der Ree et al. 2009). Taylor and Goldingay (2009) used population modeling to assess the viability of the Greater Glider (*Petauroides volans*) in Brisbane, a rapidly urbanizing area of Australia. They concluded that even a relatively low rate of dispersal across the road was sufficient to substantially reduce the risk of extinction of the smaller subpopulation isolated by the road. Similarly, van der Ree et al. (2009) used population viability modeling to assess the effectiveness of under-road tunnels installed in 1985

to restore connectivity for the critically endangered Mountain Pygmy-possum (*Burramys parvus*; Mansergh and Scotts 1989). They found that the tunnels reduced, but did not completely eliminate the negative effect of the road, with the density of the population affected by the road still 15% lower than a comparable undivided population nearby (van der Ree et al. 2009).

The majority of studies that assess the use of wildlife crossing structures have utilized two primary methods to detect and record wildlife passage, namely remotely triggered cameras, and/or the detection of tracks in a suitable substrate (van der Ree et al. 2007). Clevenger and Sawaya (2010) have used the suggestions of Simmons et al. (2010) and tested the feasibility of a noninvasive genetic sampling approach to identify the species as well as the sex, individual, and relatedness of different individuals using the crossing structure. The technique, if successful, would be applied at a larger scale to determine the level of genetic fragmentation and natural and anthropogenic factors influencing gene flow. They tested their approach on Black Bears (*Ursus americanus*) and Grizzly Bears (*U. arctos*) at two underpasses in Banff National Park. Hair was collected from 90% of crossing events (determined from cameras), and 70% of hair samples had sufficient DNA for extraction, resulting in the identification of five individual bears at each underpass, and highlighting the potential of this method for population-level analysis of the efficacy of wildlife crossing structures (Clevenger and Sawaya 2010).

There is still a paucity of data on the behavior and movement of animals near roads. Bouchard et al. (2009) evaluated the behavioral response of the Northern Leopard Frog (*Rana pipiens*), a species known to be negatively affected by roads and traffic. They studied the movement of frogs during their spring migration and also undertook short distance translocations of migrating frogs and found frogs near roads with more traffic took longer to move and tended to deviate more from straight-line movements when released near roads (Bouchard et al. 2009). The combination of the Northern Leopard Frog's apparent inability to avoid roads and their slow rate of movement make them highly vulnerable to road mortality. The second study in this special issue on the movement behavior of wildlife near roads was for the Squirrel Glider (*Petaurus norfolcensis*) in southeast Australia (van der Ree et al. 2010). The authors found that the size

of the gap in the canopy was the primary determinant of the rate of crossing in their study, with similar rates of crossing across the dual-roadway with tall trees in the median and across single-lane roads. In this study, traffic volume, i.e., approximately 5000 vehicles per day per roadway of which about 25% occurs at night when the gliders are active, did not appear to greatly influence crossing rates.

The traffic volume on minor roads is expected to continue to increase in areas with high human population densities because existing motorways are nearing capacity and the minor roads are expected to accommodate the excess flows (references in van Langevelde and Jaarsma 2009). Traffic calming is a regional planning approach to concentrate these flows onto a few roads, and ensure low-volume and low-speed roads are maintained. The conclusions of population viability modeling suggest that the results are species specific and depend upon the size of the traffic-calmed area as well as the area and quality of habitat (van Langevelde and Jaarsma 2009).

## **ROAD ECOLOGY: THE ROAD AHEAD**

The research presented in this special feature shows that road ecology is moving toward larger scales. However, it also became evident while compiling this special issue that many higher order, e.g., population, community, ecosystem, or landscape-level, effects remain unquantified. These higher order effects must become the focus of future studies because the complexity and interactions among the effects of roads and traffic are large and potentially unexpected. An analysis of these complex interrelations requires systematic research. Therefore, a promising avenue to further develop the field of road ecology is to establish collaborative links with road and transportation agencies. Experience shows that the level of engagement with each local, state, or national road agency depends largely on the presence of interested people, rather than an institutionalized approach to environmental matters. However, institutional mandates are important as they are often a precondition for interested people to spend their efforts during work hours on these issues. Many road agencies have “environmental sustainability” as one of their goals and the only way to achieve such goals is for them to support and foster long-term and credible scientific research. Every road project is essentially

an experiment and when combined with other road projects, they become replicated. The challenge we face as researchers is to (1) use good scientific approaches to design studies that are scientifically robust and maximize the individual value of each road project within a larger experimental scope; (2) ensure our research is applied and has tangible value for road agencies and for ecological outcomes; (3) address the higher order effects of roads, traffic, and mitigation measures.

This special feature demonstrates that the emerging field of road ecology is confronted with many important unanswered questions. Research needs to address large spatial and temporal scales that are not compatible within most postgraduate programs, i.e., single MSc or PhD theses, or short-term research contracts. The synergistic effects of roads and other factors that operate simultaneously, e.g., agricultural intensification and increased urbanization, have rarely been investigated. However, empirical studies are limited by the delayed response of wildlife to many environmental changes, i.e., there is an extinction debt such that wildlife populations will continue to decline for many years, in the order of decades, before they will reach a new equilibrium (Tilman et al. 1994, Findlay and Bourdages 2000). This lack of knowledge is often used as a justification to build more roads by arguing that not enough is known and more research is needed before road construction may slow down. This constitutes a “fragmentation spiral” (Jaeger 2002), because research has been unable to catch up with the ecological effects of the rapid increase in road densities. This situation is contrary to the precautionary principle and flies in the face of the principles of sustainability. The use of computer models may help overcome these limitations. For example, simulation models have demonstrated that there are thresholds in the effects of road density on the viability of wildlife populations above which populations are prone to extinction (Jaeger and Holderegger 2005, Frair et al. 2008). In addition, a research approach is required that will address the remaining uncertainties that to a large degree are irreducible, e.g., through building on the precautionary principle (e.g., Jaeger 2002). This would open up promising new lines of action for landscape management. For example, the German Federal Environment Agency recently suggested that region-specific limits to control landscape fragmentation should be introduced (Penn-Bressel 2005).

With this issue, we hope to contribute to the field of road ecology and to highlight both its appealing theoretical insights and its high practical relevance. Most importantly, we hope that this special issue will inspire further research in road ecology at the scale of populations, communities, and ecosystems. We are looking forward to these exciting research studies to come.

## Abstract

Wide-ranging large carnivores pose myriad challenges for conservation, especially in highly fragmented landscapes. Over a 13-year period, we combined monitoring of radio collared pumas (*Puma concolor*) with complementary multi-generational genetic analyses to inform puma conservation in southern California, USA. Our goals were to generate survivorship estimates, determine causes of mortality, identify barriers to movement, and determine the genetic and demographic challenges to puma persistence among >20,000,000 people and extensive urban, suburban, and exurban development. Despite protection from hunting, annual survival for radio collared pumas was surprisingly low (55.8%), and humans caused the majority of puma deaths. The most common sources of mortality were vehicle collisions (28% of deaths), and mortalities resulting from depredation permits issued after pumas killed domestic animals (17% of deaths). Other human-caused mortalities included illegal shootings, public safety removals, and human-caused wildfire. An interstate highway (I-15) bisecting this study area, and associated development, have created a nearly impermeable barrier to puma movements, resulting in severe genetic restriction and demographic isolation of the small puma population (n ~ 17–27 adults) in the Santa Ana Mountains west of I-15. Highways that bisect habitat or divide remaining “conserved” habitat, and associated ongoing development, threaten to further subdivide this already fragmented puma population and increase threats to survival. This study highlights the importance of combining demographic and genetic analyses, and illustrates that in the absence of effective measures to reduce mortality and enhance safe movement across highways, translocation of pumas, such as was done with the endangered Florida panther (*P. c. coryi*), may ultimately be necessary to prevent further genetic decline and ensure persistence of the Santa Ana Mountains population.

## Introduction

Many large carnivores have been extirpated from substantial portions of their historic range, and extant populations are threatened by habitat loss and fragmentation, and conflict with humans [1]. Human population growth expected over the next century exacerbates these threats [2–5], and exurban development will have substantial impacts on habitat that today is still relatively intact [6]. Because large carnivores pose myriad challenges for conservation in urbanizing landscapes, we began a long-term study of pumas (*Puma concolor*) in 2001 in southern California, USA, to provide quantitative insights and guidance for conservation of pumas and other large carnivores in human-dominated habitats.

Pumas, also known as mountain lions, cougars, or panthers, are wide-ranging carnivores that historically occurred throughout the Americas. Humans have extirpated or greatly reduced puma numbers in much of their former range in the past 200 years [2]. The only documented breeding population of pumas remaining in the eastern United States is in Florida, where a small population of federally endangered pumas (Florida panthers—*Puma concolor coryi*) persists, largely because their endangered status spurred intensive management including translocation and genetic introgression [7, 8]. In the western United States, pumas are hunted for sport in several states, but there is considerable controversy and uncertainty about the long-term consequences of hunting on population persistence. For example, a recent study of heavily-hunted and semi-protected puma populations in Utah [9] did not detect a compensatory decrease in natural mortality in response to heavy hunting pressure, and concluded that uncertainties in the functional relationship between natural and anthropogenic mortality could lead to biased conclusions and mismanagement.

In California, pumas are considered a “specially protected mammal” and hunting is prohibited [10]. Despite these protections, recent genetic studies of pumas in southern California show that the genetic viability and long-term persistence of some populations are in jeopardy [11, 12]. The threats facing pumas in southern California—habitat loss, increased conflict with humans, demographic isolation, and genetic restriction [11–15]—mirror the challenges facing large carnivores in urbanizing landscapes around the world [3], and long-term studies intended to guide conservation and management in these settings are difficult and expensive to conduct. We addressed this information gap by conducting a 13-year study of pumas in the California south coast ecoregion, USA, a biodiversity hotspot [16, 17] with a growing population of >20,000,000 people [18].

Sandwiched between the sprawling metropolitan areas of greater Los Angeles and San Diego, much of the available puma habitat in our study area is not protected from new highways and development, and is subject to ongoing habitat loss and fragmentation [15]. Our goals for this study were to generate survivorship estimates and cause-specific mortality data for pumas in this region, and identify options for improving survivorship and facilitating movement within and among conserved and non-conserved areas. This demographic study builds upon and complements our recent genetic analysis [11], and provides the essential ecological context for understanding the causes and potential solutions to the genetic restriction we found in pumas in the Santa Ana Mountains.

## Materials and Methods

### Statement

We operated under Protocol 10950/PHS, Animal Welfare Assurance number A3433-01, with capture and sampling procedures approved in Protocol number 17233 by the Animal Care and Use Committee at the University of California, Davis, and Memoranda of Understanding and

Scientific Collecting Permits from the California Department of Fish and Wildlife (CDFW). Permits and permissions for access to conserved lands where captures and monitoring were conducted were obtained from CDFW, California Department of Parks and Recreation, The Nature Conservancy, United States (U.S.) Fish and Wildlife Service, U.S. Forest Service, U.S. Bureau of Land Management, U.S. Navy / Marine Corps, U. S. Fish and Wildlife Service, Orange County Parks Department, San Diego County Parks Department, Riverside County Parks Department, San Diego State University, University of California—Riverside, Audubon Starr Ranch, Vista Irrigation District, Rancho Mission Viejo / San Juan Company, Sweetwater Authority, California Department of Transportation, the City of San Diego Water Department and Parks Department, and the Irvine Ranch Conservancy. Anesthetic drug combinations used in capture procedures were either teletamine / zolazepam (Telazol) or medetomidine / ketamine at dosages prescribed in the scientific literature.

### Study Area and Population

The study area encompassed the Santa Ana Mountains (a portion of the Peninsular Ranges) and the remainder of the Peninsular Mountain Ranges and surrounding foothills to the east (hereafter referred to as the eastern Peninsular Range). These areas constitute the majority of occupied puma habitat in southern California south of greater Los Angeles (Fig 1). Pumas are the primary large carnivore remaining in the study area since grizzly bears (*Ursus arctos californicus*) were extirpated in the early 1900s [19, 20].

**Fig 1. Puma study area in southern California, USA, and regional context.** The focal area of this study includes the Santa Ana Mountains and the eastern Peninsular Range. Inset shows location within California.

doi:10.1371/journal.pone.0131490.g001

An extensive and growing network of roads, some carrying more than 250,000 vehicles per day, encircles and fragments the study area [21] (Fig 1). Interstate highway 15 (I-15) connects the greater Los Angeles, Riverside, and San Diego metropolitan areas, and the highway and associated development have been hypothesized to be a barrier to puma movement between the Santa Ana Mountains in the west and the eastern Peninsular Ranges [11, 13, 22, 23]. Therefore, we assigned pumas that were captured or found dead west of I-15 to a putative “Santa Ana Mountains” source population, and those east of I-15 to a putative “eastern Peninsular Range” source population.

Land use varies considerably across the study area, with the eastern Peninsular Ranges generally having less intensive development and more rural, undeveloped, and protected lands. Burdett et al. [15] classified land use and urbanization in the study area into five categories: protected public lands (55% of the study area), private undeveloped (9.5%), rural (14.4%; >16.18 ha per housing unit), exurban (15.7%; 0.68–16.18 ha per housing unit), and suburban/urban (5.4%; <0.68 ha per housing unit). The Santa Ana Mountains have substantial protected public lands, but new highway construction, development, and land use practices tend to be much more intensive immediately adjacent to remaining high quality puma habitat [15].

## Capture and Monitoring Methods

We captured, marked, and monitored radio collared pumas from 2001 through 2013. Pumas were captured primarily using baited cage traps [24], and to a lesser extent using hounds or foot-hold snares [25, 26]. Each captured animal was tattooed in one ear with a unique numerical identifier (“marked”) and a numbered tag was placed in the opposite ear. Age was determined from dental characteristics and body morphometrics as described in Ashman et al. [27] and Laundre et al. [28, 29]. We classified pumas <18 months as kittens, 18–30 months as subadults, and >30 months as adults [30]. We applied Very High Frequency (“VHF”; MOD500 Telonics, Mesa, AZ), and/or Global Positioning System (“GPS”; Simplex P-1D, Televilt, Lindesberg, Sweden; TGW 3580, Telonics, Mesa, AZ; GPS4400S, GPS3300S, and GlobalstarTrack S, Lotek, Ontario, Canada) radio collars to pumas if their body weight exceeded 22.7 kg. GPS locations were collected at varying time intervals from every 5 minutes to every 6 hours depending on specific study objectives.

## Puma Movements

We hypothesized that the Pacific Ocean, Sonoran Desert, major highways, and urban centers would form barriers that constrained pumas in our study area into one or more discrete populations. To test this hypothesis, we examined movements of radio collared pumas from 2001–2013 to determine the degree of interchange within and between the Santa Ana Mountains and eastern Peninsular Range populations, and whether monitored pumas emigrated out of the entire study area. We were particularly interested in determining if ongoing habitat fragmentation had created or hardened existing barriers, and in evaluating puma movements relative to corridors or linkages identified through previous modeling efforts. These included: 1) the east-west “Santa Ana—Palomar Mountains Linkage” across I-15 that connects the Santa Ana Mountains and eastern Peninsular Range puma populations [31]; 2) the “Coal Canyon Corridor” under California State Route 91 (SR-91) linking the Santa Ana Mountains and the Chino Hills to the north [17, 32]; and 3) the “Parque-to-Park Linkage” connecting California and Baja California, Mexico to the south [33].

## Mortality and Survival Analyses

The distribution of radio collared pumas in the populations west and east of the I-15 freeway were compared using the Fisher exact test to determine if they differed by sex or age class,

and a two-sample t-test was used to determine if they differed by average age at entry or exit to the study (in months), or the average number of days monitored (STATA IC 13.0, STATA-Corp, College Station, Texas, USA). A P value of  $\leq 0.05$  was used as the cutoff for significance for all analyses.

Deaths of radio collared pumas from 2001–2013 were detected when VHF or GPS data indicated a lack of movement, and the cause of death was determined by field investigation and necropsy. In addition, we combined mortality data for our marked ( $n = 36$ ) pumas with “unmarked” ( $n = 218$ ) pumas that were confirmed to have died in the study area from 1981–2013 based on CDFW records. Age determination was less precise for unmarked animals due to conditions of carcasses at discovery or variable experience of reporting parties in the aging of pumas. Therefore, we classified unmarked pumas as either subadults ( $\leq 30$  months) or adults ( $>30$  months) [30].

We compared long-term trends in the number of pumas being killed under depredation permits in our dataset to the total number of puma mortalities across all of California during the same time period, as reported by CDFW [34], by plotting 5-year simple moving averages for each dataset. For each calendar year, the number of puma mortalities was averaged for the current year and previous 4 years. This allowed us to smooth short-term fluctuations and visualize long-term trends in the data.

Radio collared pumas entered the study on the date they were first captured, and exited on the date of mortality or the last date of detection by radiotelemetry. The number of days each animal was monitored was calculated as the time between entry and exit dates. Cause of death was determined at necropsy for both marked and unmarked animals unless the state of carcass decomposition precluded definitive diagnosis. In those cases, cause of death was classified as “unknown”. Because numbers of at-risk individuals varied across the course of the study, a formal cause-specific mortality analysis was not possible [35]. However, source population, sex, and age class (at time of mortality) were evaluated in both marked and unmarked populations for associations with the various causes of mortality using the Fisher exact test (STATA IC 13.0, STATA Corp, College Station, Texas, USA).

We estimated survival using the known-fate model in Program MARK (Version 7.1) [36]. We chose a set of 8 models a priori for analysis that included combinations of population, sex, and age class (at the time of collaring) as parameters. Support for each model was assessed using Akaike’s Information Criterion (AIC), corrected for small sample size ( $AIC_c$ ). The *sin* link function was used to run all models. If no model was clearly superior to all others ( $AIC_c$  weight  $>90\%$  and  $\Delta AIC > 2$ ) [36–38], we performed model averaging to reduce the uncertainty in our parameter estimates.

We used a Cox proportional hazards model (STATA IC 13.0) to evaluate the relationship of biologically important covariates (source population, sex, age, and year of mortality) to the length of time pumas survived during the study. Adult age class ( $>30$  months old) and mortality years 2007 and 2008 were used as reference categories in the models. Staggered entry into the study was addressed by including the Andersen-Gill formulation [39, 40]. The Breslow approximation method was used to address tied failure times [41], and Schoenfeld residuals were used to test the proportional hazards assumption that relative risk for each variable of interest was the same for the duration of the study.

## Results

### Puma Monitoring and Movements

Our analyses included 74 pumas that were captured, marked, and radio collared between March 2001 and December 2013 (Table 1). The distribution of these marked pumas in the

**Table 1. Demographic characteristics of radio collared pumas in southern California, USA from 2001–2013.**

Variable	Number of pumas		
	Total	Santa Ana Mountains	Eastern Peninsular Ranges
<b>Sex</b>

eastern Peninsular Range ( $n = 43$ ) and Santa Ana Mountains ( $n = 31$ ) did not differ significantly by sex, age class, average age at entry or exit to the study, or the average number of days monitored.

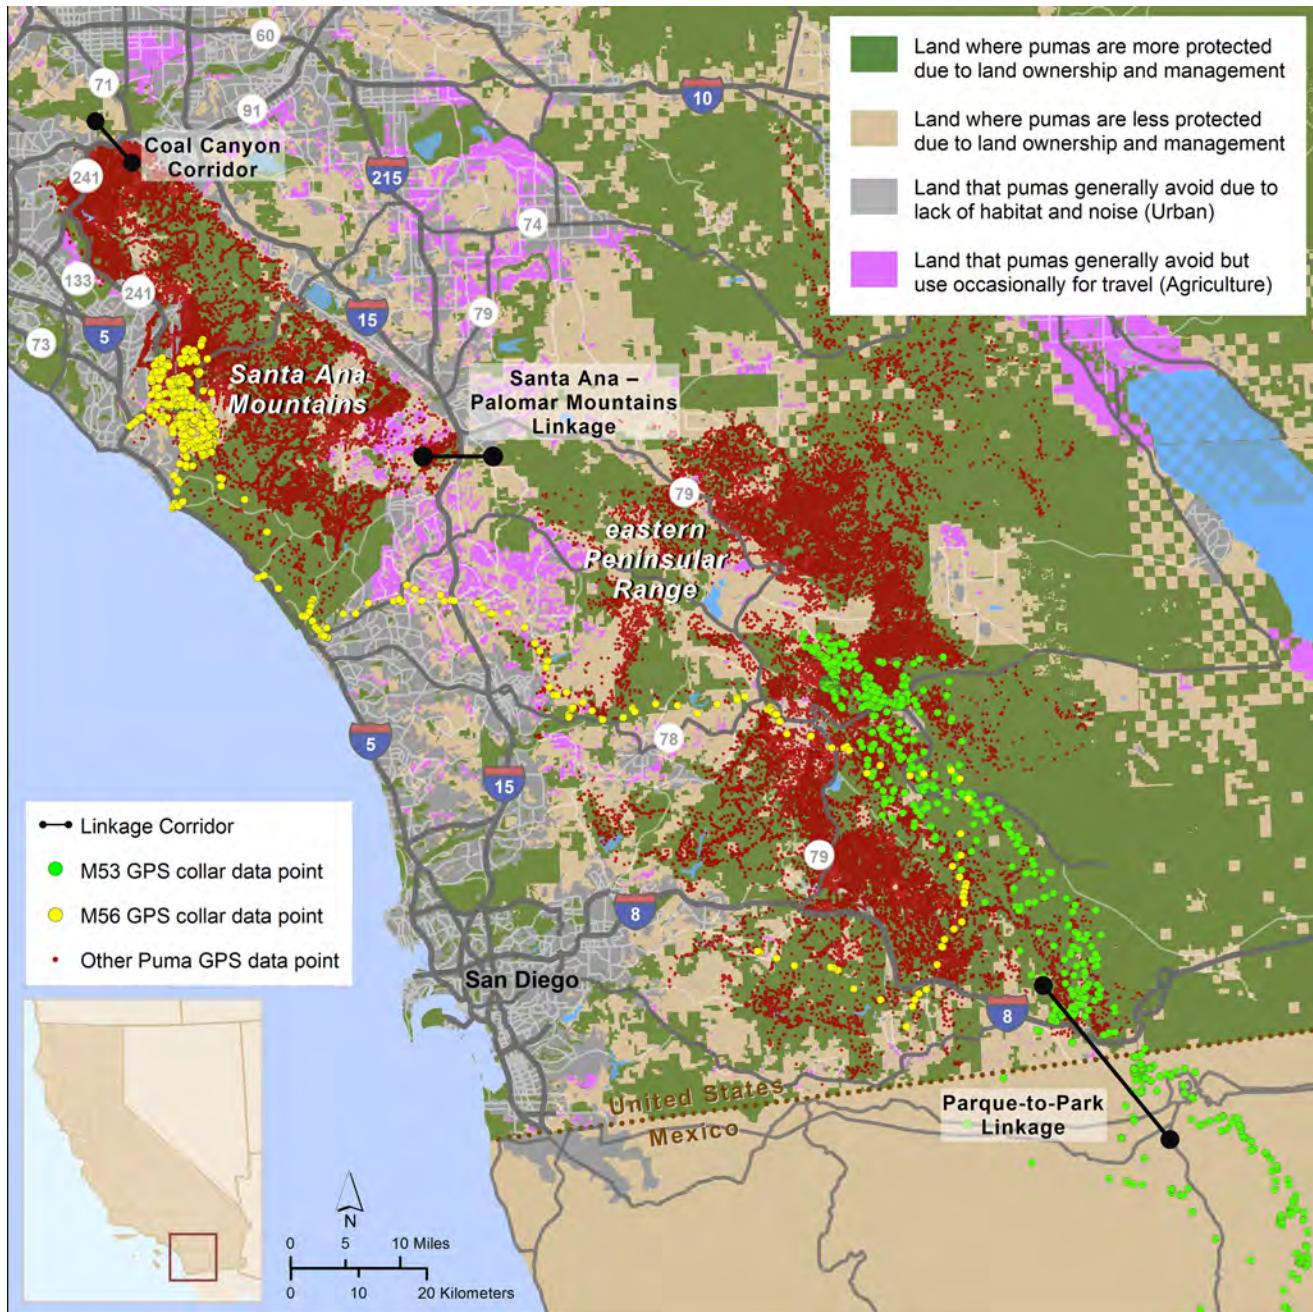

We detected numerous long distance ( $>80$  km) movements by radio collared pumas from 2001–2013, but only one radio collared puma moved out of the overall study area. In 2009, a young adult male (M53) traveled approximately 150 km south from his capture site in the eastern Peninsular Range, utilizing the Parque-to-Park Linkage to cross the U.S.-Mexico border (Fig 2). He reached a point 70 km south of the border before returning to his original location in the U.S. Several other radio collared pumas were detected near, but not across, the U.S.-Mexico border (Fig 2).

Radio collared puma movements between the eastern Peninsular Range and Santa Ana Mountains were limited, indicating the pumas in these regions formed relatively discrete populations. In 2010, a dispersing sub-adult male (M56) crossed I-15 from west to east several miles south of the proposed Santa Ana Mountains—Palomar Mountains Linkage (Fig 2), but he was killed 25 days later for depredating domestic sheep.

None of the radio collared pumas used the Coal Canyon undercrossing beneath SR-91 at the northern tip of the Santa Ana Mountains to move into the Chino Hills to the north (Fig 2). However, two unmarked pumas were killed from 2001–2013 while attempting to cross this major freeway within 3 km of the Coal Canyon undercrossing.

### Puma Mortality

The number of pumas alive ( $n = 38$ ) vs. dead ( $n = 36$ ) by the end of the study did not differ between source populations, sexes, or age class at entrance or exit (Table 1). Though time-at-risk and sample size constraints prevented a formal cause-specific mortality analysis, we report here proportional mortality of both marked and unmarked pumas over the entire study period. Over the course of the entire study period, proportional mortality due to vehicle collisions and depredation permits was greater than for all other causes of mortality. Other known sources of mortality included disease, illegal shooting, arson-caused wildfire, public safety removal, and intraspecific aggression (Table 2). Proportional mortality due to vehicle strikes and

**Fig 2. Puma GPS collar data points collected from 2001–2013 in southern California, USA.** GPS collar data points are overlaid on lands classified (by color) based on their relative levels of puma protection and typical usage. Primary linkages within the study area are noted and GPS collar data points from pumas M53 and M56 are highlighted. Inset shows location within California.

doi:10.1371/journal.pone.0131490.g002

degradation permits differed between pumas from the eastern Peninsular Range and Santa Ana Mountains populations ( $P = 0.034$ ), but did not differ by sex or age class. In fact, all mortalities of marked pumas due to degradation permits occurred in the eastern Peninsular Range, while 60% of mortalities due to vehicle collisions were in the Santa Ana Mountains (Table 2; Figs 3 and 4). With the exception of vehicle strikes and degradation, the data were too sparse to evaluate relationships between specific causes of mortality and various risk factors.

**Table 2. Proportions and numbers of radio collared pumas that died from different causes in Southern California study areas from 2001–2013.**

Cause of mortality	Total	Santa Ana Mountains	Eastern Peninsular Ranges
Vehicle Strike <sup>a</sup>	0.28 (10)	0.46 (6)	0.17 (4)

<sup>a</sup> Mortalities secondary to depredation permits and vehicle strikes differed between the two populations ( $P = 0.034$ ; Fisher’s exact test).

doi:10.1371/journal.pone.0131490.t002

In the combined dataset (marked and unmarked pumas;  $n = 254$ ), proportional mortality due to depredation permits was approximately 3.4 times higher for males than females (54M:16F;  $P = 0.001$ ), while proportional mortality due to vehicle collisions was equal for both sexes (45M:45F). In the combined dataset, proportional mortality varied between the eastern Peninsular Range and Santa Ana Mountains populations ( $P < 0.001$ ). There were more mortalities due to depredation permits in the eastern Peninsular Range ( $n = 62$ , compared to  $n = 11$  in the Santa Ana Mountains), and almost equal numbers of mortalities due to vehicle collisions in the two populations ( $n = 46$  in the eastern Peninsular Range, compared to  $n = 50$  in the Santa Ana Mountains; Fig 5). Mortality varied substantially year by year in the combined dataset, but the trend for mortalities due to depredation permits tended to increase from 1981 to 2004 and then began to decline, before trending upward again through 2013 (Fig 6), a pattern generally similar to that seen in CDFW’s graph of statewide depredation data (<http://www.dfg.ca.gov/wildlife/lion/depredation.html>). In contrast, the trend for deaths due to vehicle collisions increased steadily through 2013, with no decline or downward trend detected after 2004 (Fig 6). Vehicle mortalities occurred throughout the study area (Figs 3 and 4), however the majority of vehicle-related mortalities in the Santa Ana Mountains occurred on California State Highway 241 (SR-241) and SR-74, two highways that traverse puma habitat, and I-15 in the Santa Ana Mountains to Palomar Mountains Linkage area (Fig 3).

### Puma Survival

Survival estimates were calculated using data from the 74 radio collared pumas that were monitored from 2001–2013 for a total of 29,578 puma days (mean = 400, SE = 38 days per animal). Using the known-fate model within Program MARK, the estimated mean annual survival rate was 55.8%, (95% CI = 44.5–65.6%). In the most parsimonious model survival was constant across populations, sexes, and ages (“S(.)”; Table 3). Two models had  $\Delta AIC$  values  $< 2$ : model “S(Sex)” which included sex as a parameter (model likelihood = 0.43), and model “S(Population)” which included population as a parameter (model likelihood = 0.37; Table 3). These models yielded annual survival estimates of 58.6% for females and 52.5% for males across the entire study area, and 56.5% for the Santa Ana Mountains population and 55.4% for the eastern Peninsular Range population across all sexes and age groups (Table 3). Due to the distribution of AICc weights among the top models (Table 3), we performed model averaging of similarly

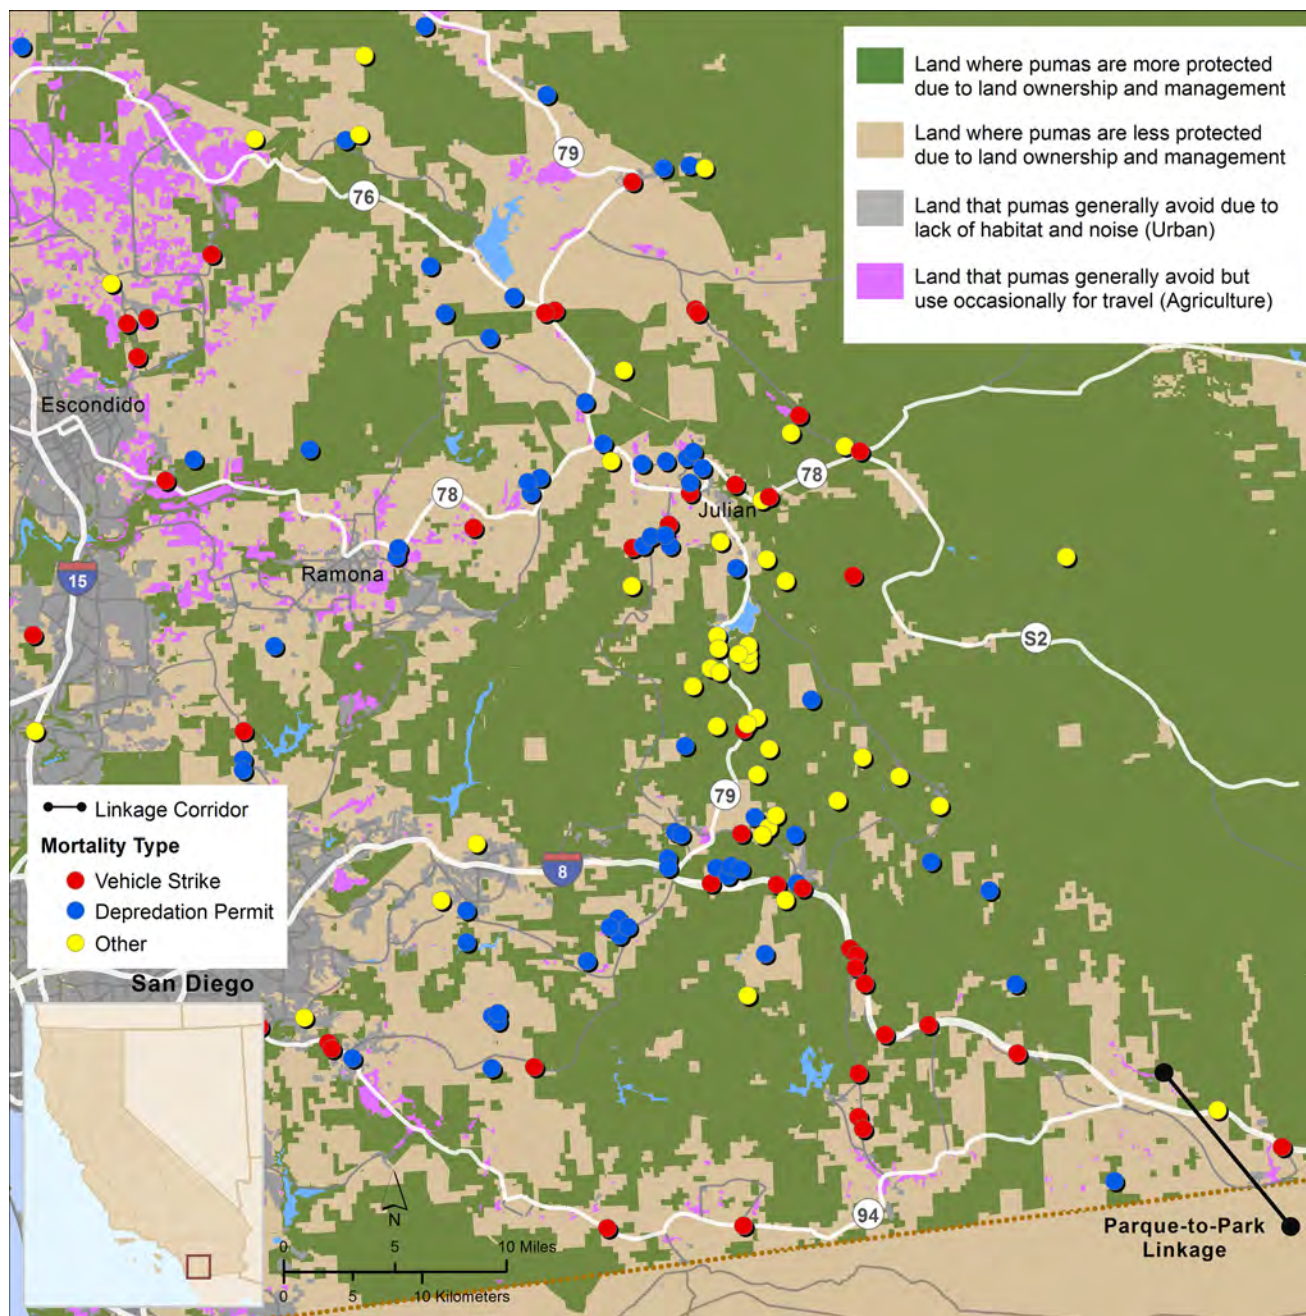

**Fig 3. Sites and causes of puma mortalities in the Santa Ana Mountains, 1981–2013.** The Coal Canyon Corridor and Santa Ana—Palomar Mountains Linkage are noted, as well as the limits of a wildlife fencing project on SR 241. Inset shows location within California.

doi:10.1371/journal.pone.0131490.g003

parameterized models but did not detect any differences among groups (95% CI of survival estimates overlapped).

Survival rates varied widely among years, and the Cox proportional hazards model identified calendar years 2001, 2003, 2005, 2006, and 2009 as having significantly higher hazard ratios compared to years 2007 and 2008 (Table 4). All other covariates, including source population, sex, and age at entry were not significantly associated with time to death. Evaluation of the proportional hazards assumption for the final model based on a test of Schoenfeld residuals

**Fig 4. Sites and causes of puma mortalities in the eastern Peninsular Range, 1981–2013.** Area depicted is generally east of Interstate 15, with the Parque to Park linkage noted. Inset shows location within California.

doi:10.1371/journal.pone.0131490.g004

indicated that the relative risk for each variable of interest, after including year as a variable in the model, did not differ for the duration of the study ( $P = 0.99$ ).

### Discussion

This 13-year study demonstrates the high risk of mortality for pumas associated with fragmentation and urbanization, and coupled with our genetic analyses [12], we conclude that puma

**Fig 5. Percentages of pumas dying from different causes of mortality in southern California, USA.** Mortalities of radiocollared (n = 36; 2001–2013) and unmarked (n = 212; 1981–2013) pumas were assigned to the Santa Ana Mountains or the eastern Peninsular Ranges subpopulation. Six unmarked pumas were not included in this figure because they were found on the I-15 freeway and could not be assigned to a population.

doi:10.1371/journal.pone.0131490.g005

persistence in this human-dominated landscape is threatened [42–46]. Annual puma survival rates for radio collared pumas in the Santa Ana Mountains (56.5%) and eastern Peninsular Range (55.4%) were very low from 2001–2013, and were similar to those in heavily hunted populations [2, 9, 43]. Indeed, annual survival rates for our study population were lower than rates for pumas in the peri-urban Santa Monica Mountains population northwest of Los Angeles (>75%) [12], and are within the range that is considered a threat to persistence of puma populations [13].

Our movement data (this paper) and our genetic findings [11] support the hypothesis that pumas in the Santa Ana Mountains and eastern Peninsular Range effectively form two subpopulations, bisected by an interstate highway and neighboring development. Our data demonstrate that both subpopulations had low survival; and though proportional mortality is a crude measure of causes of death in a population, the major causes of puma proportional mortality

**Fig 6. Pumas killed secondary to vehicle collisions or depredation permits from 1981–2013 in southern California, USA.** Five year moving average of pumas killed secondary to vehicle collisions or depredation permits (n = 174) in the Santa Ana Mountains and eastern Peninsular Ranges.

doi:10.1371/journal.pone.0131490.g006

differed between these areas. Depredation permits were the most common proportional mortality factor in the eastern Peninsular Range and primarily affected males, whereas vehicle strikes were the main source of proportional mortality in the Santa Ana Mountains, affecting males and females equally. Conservation biologists have long expressed concern about demographic and genetic isolation of pumas in the Santa Ana Mountains [11, 13], and this study, coupled with our companion genetic study [11], provides a comprehensive view of the fractured demographic and genetic connectivity among pumas in this region.

Ernest et al. [11] concluded that Santa Ana Mountains pumas monitored in this study “had high average pairwise relatedness, high individual internal relatedness, a low estimated effective population size, and strong evidence of a bottleneck and isolation from other populations in California.” Genetic restriction and isolation were pronounced even though limited gene flow

did occur from the eastern Peninsular Ranges into the Santa Ana Mountains. Genetic analysis showed that a male puma (M86) captured in the Santa Ana Mountains was likely born in the eastern Peninsular Ranges, and successfully migrated into the Santa Ana Mountains during our study. This male, and two females (F61 and F89) captured in the Santa Ana Mountains, were the likely parents of four pumas born in the Santa Ana Mountains in 2010–2011 (M91, F92, M93, and M97) [11]. However, this is the only evidence of successful genetic interchange between the two populations during the study period other than an 8 month old kitten (F102) [11] killed by a car in the Santa Ana Mountains in August 2003. In 13 years, none of the pumas radio collared in the eastern Peninsular Range were observed to move west into the Santa Ana Mountains, and the single radio collared male that did move from the Santa Ana Mountains into the eastern Peninsular Range was killed for depredating domestic sheep within weeks of crossing I-15. This suggests that the estimated 17–27 adult pumas in the Santa Ana Mountains [13] have become an insular population, much like the small population of pumas located in the Santa Monica Mountains [12]. The combination of small population size, limited potential for immigration of new individuals (male and female) into the area, female mortality rates that are similar to males, and negative effects of genetic restriction [11], collectively put the Santa Ana Mountains population at risk for demographic collapse [13, 22, 47].

Southern California has been the focus of multiple regional-scale conservation planning efforts aimed at protecting a network of natural habitats, among extensive urban, suburban, and exurban development and a burgeoning population of >20,000,000 people [48]. Pumas have been a focal species for these efforts because of their ecological value, their inherent value to humans, and their utility as surrogates for other wide-ranging taxa in conservation planning [13, 22, 42, 49–52]. Despite some concerted conservation efforts (e.g. [14]), this study shows that pumas are currently subject to high levels of human-caused mortality, and that wildlife corridors that facilitate safe movement through the landscape are lacking or insufficient. These

threats will only grow worse without further action. For example, additional urban development is underway or proposed on both the east and west sides of I-15 in the Santa Ana–Palomar Mountains Linkage (Figs 2 and 3) [53, 54], and 14,000 new homes and associated highways will be constructed at the south end of SR-241 in the center of puma habitat in the Santa Ana Mountains [55].

Conserving core habitat areas and functional wildlife corridors has been the main focus of conservation efforts for pumas in southern California [15, 31, 32, 56, 57] and coordinated regional action in the form of targeted investment in habitat protection is especially urgent to maintain viability of the Santa Ana Mountains population. However, our analysis highlights that land protection alone will not be sufficient to ensure puma persistence in the region. Also important will be directed focus on improving road infrastructure to facilitate safe wildlife crossings, and reducing depredation conflicts that precipitate puma deaths. Options for enhancing movements across I-15 and other highways include protection of additional lands on both sides of the highway, improving or adding large culverts, adding exclusionary fencing [58] such as that currently being constructed on SR 241 (Fig 3) [59], and possibly constructing vegetated overpasses for wildlife use [60, 61]. Strategies to reduce mortalities stemming from depredation permits include education activities to promote wider use of predator-proof enclosures for their domestic animals during the crepuscular periods and at night [62–65]. A focus on land protection, roadway and wildlife crossing design, and landowner outreach will be critical for persistence of puma in southern California, and may well be a formula for conserving large carnivores in highly populated and fragmented landscapes generally.

The combination of long term field monitoring of radio collared animals coupled with genetic analyses was critical for understanding puma biology and providing directions for conservation efforts in southern California. The movement of puma M86 across I-15 from the eastern Peninsular Ranges may aid in the genetic rescue of the Santa Ana population, but only if his offspring survive and reproduce. To date, only one of his four known offspring are still alive in the wild—a female with two dispersal-age offspring, and evidence points towards pumas being less likely to successfully navigate this human-dominated landscape in the future. In the absence of effective measures to reduce mortality and enhance safe movement across highways, translocation of pumas, such as was done with the Florida panther [66], may ultimately be necessary to prevent further genetic decline and assure persistence of the Santa Ana Mountains population.

## Acknowledgments

We thank the following for their technical and administrative assistance: G. Lee, M. Plancarte, L. Hull, and L. Stockbridge. Field work assistance was provided by J. Bauer, C. Bell, P. Bryant, K. Davis, D. Dawn, M. Ehlbroch, K. Krause, D. Krucki, K. Logan, B. Martin, J. Messin, B. Mill-sap, M. Puzzo, T. Ryan, D. Sforza, L. Sweanor, P. Taylor, T. Walden, C. Wallace, T. Watkins, S. Weldy, C. Wiley, S. Winston, E. York, and numerous volunteers, as well as rangers, biologists, wardens, and animal control officers from multiple agencies. Thanks to E. Boydston, K. Crooks, R. Fisher, and L. Lyren for assistance coordinating field projects and data. We appreciate advice and / or assistance received from C. Basilevec, A. Bridges, J. Burger, S. Clemenza, D. Clifford, L. Coley-Eisenberg, L. Correa, J. Dice, S. DeSimone, P. DeSimone, J. Embery, D. Fere-menga, J. Gannaway, J. Gump, K. Greer, B. Hillis, B. Hudgens, M. Jennings, M. Jorgensen, P. Jorgensen, M. Kenyon, N. Martinez, V. McFall, M. Mitrovich, K. Preston, Z. Principe, J. Randall, R. Rempel, S. Riley, D. Steele, P. Swift, B. Tippetts, S. Torres, and S. Vandewoude. We are appreciative of necropsy and pathology services provided by multiple veterinary pathologists at the California Animal Health and Food Safety Laboratory System of the University of

California, Davis, and cooperation provided by the University of California South Coast Research and Extension Center, the California Department of Transportation, and all of the land owners and managers who allowed field activities on their properties.

This paper is dedicated to the memory of deceased biologists Eric York, Deana Dawn, and Donna Krucki, whose hard work and devotion to the well-being and long-term persistence of pumas were critical to the success of this project.

## Author Contributions

Conceived and designed the experiments: TWV WMB RB SAM PRH TS HBE. Performed the experiments: TWV WMB RB HBE JNS. Analyzed the data: TWV WMB JNS CKJ BSC HBE PRH RB. Contributed reagents/materials/analysis tools: JNS CKJ HBE SAM BSC. Wrote the paper: TWV JNS CKJ SAM RB TS BSC PRH HBE WMB.

DEPARTMENT OF TRANSPORTATION  
Federal Highway Administration  
Environmental Impact Statement: San Diego and Orange Counties,  
California  
AGENCY: Federal Highway Administration, U.S. Department of  
Transportation.  
ACTION: Notice of Intent.

-----

SUMMARY: The Federal Highway Administration (FHWA), on behalf of the California Department of Transportation (Caltrans), is issuing this notice to advise the public that a Draft Environmental Impact Statement (Draft EIS) will be prepared for a proposed highway project in Orange County and San Diego County, California.

January 8, 2020

To Whom It May Concern

Please accept this letter as comment on the Draft Environmental Impact Statement that will be prepared in relation to the proposed highway project as presented in this publication in the Federal Register. I would request that my comments be considered during the development of the project Draft EIS.

Comments:

As a wildlife veterinarian and researcher who has conducted scientific studies for over a decade in the south Orange County region where the proposed project is planned, I have significant concerns with the negative impacts that several of the proposed alternatives may have on mountain lion (*Puma concolor*) and other wildlife movement and connectivity. My special expertise and knowledge relates to mountain lions in that area, but their movement patterns can illuminate the patterns of numerous other wild species as well.

It is well established by multiple peer reviewed studies and published reports to government agencies (1-4) that mountain lions in the Santa Ana Mountain Range are seriously genetically restricted and have unusually low annual survival rates, with the number one source of mortality being collisions with cars (5). This has resulted in a population under serious threat of extirpation within less than two decades if inbreeding depression begins to reduce reproductive success in the population (3). As a result of the aforementioned studies, the Santa Anas mountain lion population has been petitioned for listing under the California Endangered Species Act, and its status is currently being studied intensively by our research group at the University of California–Davis, as well as by the California Department of Fish and Wildlife. Connectivity across highways has emerged as the most important factor in restriction of

connectivity, and extensive study has been done and is ongoing by our group and collaborators that is related to this issue across the region (4, 6-7, Vickers unpublished data).

The majority of the mountain lion deaths from vehicle collisions in the last two decades have been on the SR 241 Toll Road, but SR 74 and other regional highways that are less busy have also been sites of mountain lion mortalities. The toll road agency has built additional fencing on SR 241 in one 6 mile section to reduce the rate of vehicle collisions, and that has been quite successful in that goal, but other sections of both SR 241, as well as sections of SR 74, remain a danger to mountain lions and other wildlife.

In the area of the proposed project, movement of mountain lions between habitat patches is already compromised in both the north-south and east-west directions by existing housing and roads, with more approved and under construction in Rancho Mission Viejo. Connections between Chiquita Canyon and Bell Canyon habitat areas north of SR 74, and habitat areas to the south of SR 74 are already affected negatively by increasing traffic on SR 74 itself and expanding development in Ranch Mission Viejo, including Los Patrones Parkway. Though passageway structures for wildlife and fencing are present on Los Patrones Parkway, to my knowledge movement studies have not been done with GPS collars to determine if that roadway is having any barrier effect on east-west movement.

Mountain lions must move north and south in the region of the proposed project in order to utilize habitat specifically set aside for conservation. Increasing restriction of access to those habitats is anathema to the effort and expense of conserving those habitat areas originally and maintaining their function for wildlife. Thus any project that is built in that region should be extremely sensitive to negative impacts on mountain lions and other wildlife. Our studies of the impacts of SR's 241, 74, 78, 79, 76, and 67, and large freeways such as SR 91 and I-15, all confirm that essentially any significant highway can be both a barrier and a mortality source. Preliminary results from studies underway by our research team and other UC Davis and University of Southern California researchers, as well as those by other researchers, suggest that the light, noise, and other aspects of highways can have negative impacts on wildlife numbers and diversity near the highways. Thus highways can exert negative effects at some level even when adequate wildlife passageways and fencing are well designed. This should be kept in mind when considering the different alternatives in the Environmental Impact Statement.

As such, all of the Alternatives should be closely evaluated to ascertain that they would not further fragment the mountain lion population in the Santa Ana Mountains and put it at further risk via increased road mortality, or worsen its genetic connectivity.

The Alternatives listed in the Federal Register notice are:

**Alternative 1/No Build Alternative; taking no action.**

**Alternative 13; connect SR 241 to I-5 via a connection from Los Patrones Parkway to La Novia Avenue, I-5 widening and improvements, and the addition of HOT lanes in each direction on I-5**

**Alternative 17; connect SR 241 to I-5 via a connection from Los Patrones Parkway to Avenida Vaquero, I-5 widening and improvements,**

and the addition of HOT lanes in each direction on I-5  
Alternative 14; connect SR 241 to I-5 via a connection from  
Los Patrones Parkway to Avenida Pico, I-5 widening and improvements,  
and the addition of HOT lanes in each direction on I-5  
Alternative 11; add I-5 general purpose lanes from I-405 to  
San Diego County  
Alternative 12; add I-5 HOT/toll lanes from I-405 to San Diego  
County  
Alternative 9; connect Ortega Highway and Antonio Parkway to  
Avery Parkway and SR 73  
Alternative 18; connect SR-241 to SR-73 and extend Crown  
Valley Parkway to SR 241  
Alternative 21; extend Los Patrones Parkway to Avenida La Pata  
and add HOT lanes in each direction on I-5  
Alternative 22; extend Los Patrones Parkway to Avenida La Pata  
Alternative 23; extend I-5 managed lanes from SR 73 to  
Basilone Road or from Avenida Pico to Basilone Road (depending on the  
design option)

In my view, several of the alternatives would have minimal negative impact on the Santa Ana Mountains mountain lion population. These include Alternatives 1, 11, 12, and 23c and 23d.

In my view, Alternatives 9, 13, 14, 17, 18, 21, and 22 all would potentially disrupt some mountain lion movement through this already fragmented landscape, and further disrupt local gene flow in this imperiled species unless structural plans are such that permeability is assured. All of these alternatives place the highway footprint in lands that currently host many wildlife species including mountain lions and others. Some of the named alternatives would potentially have a negative effect on subsequent major north-south or east-west movement. Alternative 18 for instance would cut a major habitat block (Chiquita Canyon) into 3 pieces, and Alternatives 14, 17, 21, and 22 would all erect another barrier to north-south movement.

In my view, Alternative 21's hot lanes could be added to I-5 without mountain lion habitat disruption, but Alternative 21's extension of Los Patrones Parkway to Avenida La Pata would likely have some detrimental impact on the local mountain lion population.

In my view, of the Alternatives that involve construction of new wide highway segments south of SR 74, Alternative 13 would appear to be least disruptive of large wildlife habitat patches, but like the other Alternatives south of SR 74, some barrier effect on north-south movement of mountain lions may occur unless extraordinary design elements are included that maximize safe travel potential and eliminate mortality potential, but that also eliminate other negative impacts of sound, light, etc from vehicles and infrastructure along the highway. These can include freeway light shielding and design, berms and walls to reflect sound and light away from the habitat, and other measures.

I feel that it is critical that any Alternative that is accepted by the various agencies involved, and the public, keep the interests of wildlife on an even par with transportation improvement in the list of goals of any project.

Thank you,

## Abstract

Human development strongly influences large carnivore survival and persistence globally. Behavior changes are often the first measurable responses to human disturbances, and can have ramifications on animal populations and ecological communities. We investigated how a large carnivore responds to anthropogenic disturbances by measuring activity, movement behavior, and energetics in pumas along a housing density gradient. We used log-linear analyses to examine how habitat, time of day, and proximity to housing influenced the activity patterns of both male and female pumas in the Santa Cruz Mountains. We used spatial GPS location data in combination with Overall Dynamic Body Acceleration measurements recorded by onboard accelerometers to quantify how development density affected the average distances traveled and energy expended by pumas. Pumas responded to development differently depending on the time of day; at night, they were generally more active and moved further when they were in developed areas, but these relationships were not consistent during the day. Higher nighttime activity in developed areas increased daily caloric expenditure by 10.1% for females and 11.6% for males, resulting in increases of 3.4 and 4.0 deer prey required annually by females and males respectively. Our results support that pumas have higher energetic costs and resource requirements in human-dominated habitats due to human-induced behavioral change. Increased energetic costs for pumas are likely to have ramifications on prey species and exacerbate human-wildlife conflict, especially as exurban growth continues. Future conservation work should consider the consequences of behavioral shifts on animal energetics, individual fitness, and population viability.

## Introduction

Habitat conversion is a primary driver of species extinctions and increases exposure of wildlife to anthropogenic disturbances [1]. These disturbances influence many integral animal behaviors (e.g., foraging, mating, and movement) [2] and transform species interactions [3±4].

Conversion to low-density development at the wildland-urban interface is the fastest growing type of land use change in the continental United States [5] and is expected to continue expanding in the coming decades [6]. Although many species, including mammalian apex predators, continue to live at the wildland-urban interface [7], these regions may prove to be population sinks due to the increased risk of human-caused mortality or from the costs of adopting behavioral adaptations in response to human disturbances [8].

Behavioral changes by animals often provide the first measurable indication that individuals are responding to anthropogenic disturbance [9±11]. These behavioral responses can alter energetic budgets with important effects on individual fitness that may lead to population and community level changes. Movement behavior in particular carries rich information about where, when, and how an animal interacts with its surroundings, providing insight into the relationship between internal state and environmental factors [12]. Technological advances with GPS and accelerometer tracking devices now allow scientists to link animal movement behavior to caloric expenditure, which greatly increases our understanding of how animal energetics are impacted by human development at the landscape level. With the integration of accelerometers and traditional biologgers, we can monitor how natural and anthropogenic landscape structures change behavioral patterns and energy allocation in wild animals [13], with far ranging conservation implications for species living at the wildland-urban interface.

Large carnivores are frequently the first species to be lost from ecosystems as humans transform and develop landscapes [14]. Despite this, comparatively little is known about the behavioral and energetic responses of predators to development that could eventually lead to their local extirpation [15]. Large carnivores often respond to human disturbance and persecution through behavioral modifications much like prey species respond to predators [10]. Pumas (*Puma concolor*) have demonstrated behavioral responses to human developments by avoiding roads, moving quickly through developed areas, and changing temporal feeding patterns [8,16]. As human development continues to fragment previously intact landscapes, it becomes increasingly vital to understand how large carnivores adjust their behavior and energetic responses to anthropogenic perturbations. Only by better understanding these relationships can we implement protective policies that reduce human-wildlife conflict and promote their continued co-existence with humans [17].

Here we examined how human development alters daily behavior and energetics of pumas in the Santa Cruz Mountains of central California. We investigated the extent to which proximity to houses affected puma movements and daily activity budgets. These behavioral differences translate into differential energetic costs that progressively accumulate over time, which may have lasting repercussions on individual fitness [18]. We also investigated whether habitat type and time of day influenced how pumas responded to human development. In order to link behavior change to energetic impacts, we evaluated how human development affected the daily movement patterns and caloric expenditures of pumas using GPS tracks, which we calibrated using accelerometer data from a much finer temporal scale. Lastly, we explored the extent to which puma prey demands are altered in human-modified habitats and discuss potential consequences for recruitment of future generations.

## Methods

### Study species and area

Pumas are territorial, apex predators which live throughout diverse habitats in the Americas [19]. Individuals are primarily nocturnal and solitary, although females will typically raise and accompany cubs for up to 15±21 months after birth. In our study area in the Santa Cruz Mountains of California, pumas predominantly feed on black-tailed deer (*Odocoileus*

*hemionus columbianus*, 90% by biomass), but occasionally on other species, including wild boars (*Sus scrofa*), raccoons (*Procyon lotor*) and house cats (*Felis catus*) [20].

Our 1,700 km<sup>2</sup> study area encompasses a diverse landscape ranging from dense, urban development to large tracts of intact and relatively undisturbed native vegetation. Puma home ranges contain both protected and developed lands, with an average home range housing density of  $21.7 \pm 3.0$  SE houses/km<sup>2</sup> (range  $4.6 \pm 51.5$ ) [8]. Even pumas that regularly move through or near residential areas also use nearby protected areas, allowing for comparison of movement behavior across a disturbance gradient within individual pumas. The vegetation is primarily forested (e.g., woodlands, hardwood and conifer forests) and shrubland (e.g., scrub and chaparral) habitats. It is bisected by a large freeway and further crisscrossed by numerous other smaller roads providing access to rural houses and developments. The climate is Mediterranean, with precipitation concentrated between November and April, and elevation ranges from sea level to 1155m.

## Data collection

We captured 22 wild pumas (11 males, 11 females) from June 2010–March 2013 using trailing hounds, cage traps, or leg hold snares. Each animal was tranquilized using Telazol at a concentration of 100mg/mL ( $3.3 \pm 6.0$  mg/kg estimated body weight) and outfitted with a GPS/VHF collar (3.7 kg; Model GPS Plus 1D, Vectronics Aerospace, Berlin, Germany). Six of the 22 animals were also equipped with a custom-built archival 3-axis accelerometer sampling continuously at 64Hz when activated [21]. The tri-axial accelerometer was mounted such that the x-axis was parallel to the anterior-posterior plane of the animal, the y-axis to the transverse plane, and the z-axis to the dorsal-ventral plane.

Accelerometers on pumas were programmed to record at a duty-cycle of 2 days on and five days off to maximize battery life. The GPS was programmed to acquire locations every 15 minutes during a 24-hour intense sampling period starting from noon one day each week. The Animal Care and Use Committee at UC Santa Cruz approved all animal-handling procedures (Protocols Wilmc0709 and Wilmc1101).

## Data processing

During each 15-minute GPS sampling interval, we assigned one behavioral state (active or inactive) to each collared individual and considered these states to be mutually exclusive. We considered any distance greater than 70m between successive 15 minute GPS fixes to be an active period, and a distance smaller than 70m to be an inactive period. We used accelerometer measurements to determine the distance cutoff between activity states as follows. We used a random forest algorithm described in Wang et al. [22] to categorize 2-second increments of accelerometer measurements into mobile or non-mobile behaviors. These were then aggregated into 15-minute observation periods to match the GPS sampling periods. After inspecting the data visually, we identified 10% activity (i.e., 10% of accelerometer measurements categorized as mobile out of 15 minutes) as the cutoff between active and inactive periods. Because of the strong linear relationship ( $r = 0.89$ ) between accelerometer defined activity and the distance traveled between GPS fixes, 10% activity recorded by accelerometers corresponded to 70 meters between GPS fixes.

## Environmental and anthropogenic measurements

Our study animals inhabit a landscape primarily comprised of forested or shrubland habitats interspersed with developed areas. To examine how human development and habitat type affected puma behavior, we collected spatial information on buildings and habitat types

surrounding each puma GPS location. Using the Geographic Information Systems program ArcGIS (v.10, ESRI, 2010), we digitized house and building locations manually from high-resolution ESRI World Imagery basemaps for rural areas and with a street address layer provided by the local counties for urban areas. For each puma GPS position recorded, we calculated the distance in meters to the nearest house. We placed circular buffers with 150m radii around each GPS location and used the California GAP analysis data [23] to categorize the local habitat as either predominantly forested or shrubland. We chose a buffer size of 150m based on a previous analysis of puma movement responses to development [24]. We also classified the time each GPS location was recorded as diurnal or nocturnal based on sunset and sunrise times.

## Markov chains

We modeled puma behavior sequences as discrete-time Markov chains, which are used to describe activity states that depend on previous ones [25]. Here, we used first-order Markov chains to model a dependent relationship between the succeeding behavior and the preceding behavior. First-order Markov chains have been successfully used to describe animal behavioral states in a variety of systems, including sex differences in beaver behavior [26], behavioral responses to predators by dugongs [27], and impacts of tourism on cetacean behavior [28+29]. Because we were modeling behavior transitions with respect to spatial characteristics, we recorded the states of the puma (active or inactive) in the 15 minutes prior to and succeeding each GPS acquisition. We populated a transition matrix using these preceding and succeeding behaviors and examined whether proximity to houses influenced the transition frequencies between preceding and succeeding behavior states. Transition matrices are the probabilities that pumas remain in a behavioral state (active or inactive) or transition from one behavior state to another.

We built multi-way contingency tables to evaluate how sex ( $S$ ), time of day ( $T$ ), proximity to house ( $H$ ), and habitat type ( $L$ ) affected the transition frequency between preceding ( $B$ ) and succeeding behaviors ( $A$ ). Because high-dimensional contingency tables become increasingly difficult to interpret, we first used log linear analyses to evaluate whether sex and habitat type influenced puma behavior patterns using two three-way contingency tables (Before  $\times$  After  $\times$  Sex, abbreviated as BAS). Log linear analyses specifically test how the response variable is influenced by independent variables (e.g., sex and habitat) by using Likelihood Ratio Tests to compare hierarchical models with and without the independent variable [25]. We found that there were strong sex differences in activity patterns because adding  $S$  to the model greatly increased the goodness-of-fit ( $G^2$ ) compared to the null model ( $\Delta G^2 = 159.8$ , d.f. = 1,  $P < 0.0001$ ), which assumed that succeeding behaviors only depend on preceding ones. Therefore, we evaluated data from male pumas separately from those of female pumas.

We then used another three-way contingency table for each sex to evaluate whether behavior patterns differed between habitats ( $L$ ). We found that including habitat type significantly improved model fit for male ( $\Delta G^2 = 7.9$ , df = 1,  $P < 0.005$ ) but not female pumas ( $\Delta G^2 = 3.18$ , df = 1,  $P = 0.0744$ ). Thus we evaluated three sets of data: all females, males in forests, and males in shrublands. For each dataset, we created four-way contingency tables (Before  $\times$  After  $\times$  House  $\times$  Time) to evaluate how development and time of day affected behavioral transitions using the likelihood ratio methods described above.

Our null model ( $BA$ ,  $BHT$ ) is built such that succeeding behaviors ( $A$ ) are only affected by behaviors in the previous time steps ( $B$ ) and independent of proximity to houses and time of day. We tested whether including additional factors (proximity to house and time of day) improved model fit by comparing the null model with hierarchically more complex models. For example, the effects of proximity to housing on succeeding behaviors are evaluated by

comparing the goodness-of-fit ( $G^2$ ) values for the null model and the model containing an interaction between succeeding behaviors and houses (*BAH*, *BHL*). We also tested the interaction between proximity to houses and time of day by comparing the saturated model (*BAHT*), which fits the data fully, to a less complex model without the interaction term (*BAH*, *BAT*, *BHT*). Finally, we selected the best fitting model by minimizing the Akaike Information Criterion (AIC) estimate.

### Behavioral budgets

We tested whether transition matrices differed when pumas were close to houses or roads using the Z test for proportions [30]. We also estimated the amount of time pumas spent in each behavioral state by conducting an eigenanalysis on the transition matrix. Because Markov chains are ergodic matrices, we used the left eigenvector of the transition matrix to estimate the proportion of time pumas spent in each state [25]. We compared these values using a Z test of proportions and calculated 95% confidence intervals using the Wilson's score test [31].

### Puma travel and energetic costs

For each puma, we identified all 24-hour intensive sampling periods during which GPS points were recorded every 15 minutes. At a fix rate of 4 times an hour, up to 96 GPS points are recorded throughout the day, equating to a total of 95 travel segments (straight lines between consecutive points). We removed any days from analyses that were missing more than 10% (i.e., 9 points) of potential GPS fixes. We determined the linear length of all travel segments and calculated the total daily distance ( $D$ ) in km traveled by pumas by summing all travel segments and correcting for any missing GPS fixes using the formula:

$$D_{total} = D_{summed} \times 95/n \tag{1}$$

in which  $n$  represents number of actual recorded segments. Next, we calculated the minimum cost of transport ( $COT$ , W/kg) expended daily for each puma by adapting the equation developed by Taylor et al. [32]:

$$COT = \sum_i^n 10.7(wt)^{-0.316} \times v_i + 6.03(wt)^{-0.303} \tag{2}$$

in which  $wt$  is the weight (kg) of the animal when captured and  $v_i$  is the velocity of travel (m/s) between consecutive GPS points.  $COT$  has the units Watts/kg, which we converted to kcal/kg by applying the conversion factor 4.1868 Watt = 1 cal/s.

Lastly, we estimated the minimum number of black-tailed deer, the primary prey of pumas in our area, needed to sustain each puma given their daily minimum  $COT$ . We calculated the daily deer biomass ( $DB$ ) needed to fulfill each puma's prey requirements using Eq 3 [33]:

$$DB \left( \frac{kg}{day} \right) = \frac{COT (kcal)}{1890 \left( \frac{kcal}{kg} \right) \times 0.86 \times 0.88} \tag{3}$$

in which 1890 kcal represents the caloric content in each kg of wet deer tissue [34], and this value is then modified by multiplying it by the conversion efficiency (0.86) and the proportion of deer in a puma's diet there estimated as 88% [20]. Finally, we used Eq 4 to convert the daily deer biomass into an estimate of the yearly deer requirements [33]:

$$\frac{Deer}{year} = \frac{DB \left( \frac{kg}{day} \right) \times 365 \text{ days}}{36.5 \text{ kg} \times 0.79} \tag{4}$$

in which 36.5 kg is the average weight of a black-tailed deer doe [35] and 0.79 is the edible proportion of the deer [34].

It is broadly understood that the energetic estimates generated using the equation developed by Taylor et al. [32] are the minimum estimates for *COT*. Even at 15-minute GPS sampling intervals, animals can deviate greatly from straight-line travel paths, thus expending many more kcals than estimated. In contrast, Overall Dynamic Body Acceleration (ODBA) measurements recorded by accelerometer collars, which sums the dynamic acceleration of the subject across three dimensions, provide a more precise measurement of energetic expenditure because it takes measurements at a rate of 64Hz [36]. Not all pumas were outfitted with accelerometer collars and we were unable to use ODBA alone to estimate energetic budgets. Instead we recorded ODBA values from two wild pumas whose accelerometers were active concurrent to the GPS intensive sampling periods. Using those values, we calculated the correlation between *COT* estimates from ODBA measurements and those estimated using velocities generated from intensive GPS sampling by Eq 2. This resulted in a correction factor that we applied to the energetic estimates of each puma in the study.

## Development influences on puma movement

To quantify puma exposure to human development, we used ArcGIS (v. 10.1, ESRI, 2012) to create buffers of 150m around all GPS points within each 24-hour intensive GPS sampling period. We then calculated the number of houses encompassed within each buffer polygon and also recorded the time of day. For each day, we recorded the average housing density individual pumas were exposed to and the average distance pumas traveled between successive GPS locations during both nocturnal and diel periods. We hypothesized that pumas would use more calories by moving faster and further through areas with more houses in order to minimize their exposure to development [24,37]. However we also predicted that this relationship might be affected by time of day because pumas may prefer to stay hidden if they are in more developed areas during the day.

We used linear mixed effects models using restricted maximum likelihood estimation with the average diurnal and nocturnal calories burned between successive GPS points as the dependent variable. To select the best model, we used a top-down model selection approach to compare models with no random terms, with random intercepts, and with both random intercepts and slopes [38]. We started by fitting a linear model that included the full complement of fixed effects terms: sex of the puma (male coded as 1 and female as 0), time of day (day coded as 1 and night as 0), the average number of houses (log-transformed to account for all distributions being bound at zero), the interactions between sex and time of day, and the interaction between time of day and housing. In a second model, puma identity was included as a factor in the model to allow for random intercepts. For the third model, we also tested whether individual pumas responded to time of day, the log average number of houses, and their interaction differently by including random slopes for those terms. We used AIC to compare the three models to determine the optimal model structure. We examined the residuals for our final model visually to identify any obvious deviations from normality.

To quantify the difference in puma energetic expenditure between areas with low and high housing density, we calculated the average caloric expenditure by individual pumas in the top and bottom housing density quartiles of their home range for both days and nights. To maximize statistical power, only pumas with a minimum of 20 day and 20 night measurements were included in this analysis. We added day and night averages to get total daily difference in caloric expenditure. We calculated the percentage increase in calories used as the total daily difference between caloric expenditure for high and low housing density divided by the

average daily caloric expenditure for the individual puma. In order to conceptualize variation of human disturbances for individual pumas, we classified average housing density in the top and bottom quartiles into the following categories described by Theobald [5]: rural (greater than 0.0 and up to 0.062 houses per hectare), exurban (greater than 0.062 and up to 1.236 houses per hectare), suburban (greater than 1.236 and up to 9.884 houses/hectare), or no housing. We used the package *nlme* [39] in R (v. 3.0.2, R Core Team, 2013) for all analyses.

## Results

### Log linear analyses

We recorded 78,242 GPS locations for 22 pumas, comprised of 6,967 behavioral transitions (e.g. active to inactive) for males in shrubland habitats, 11,379 transitions for males in forested habitats, and 21,977 transitions for females in all habitats. Log linear analyses revealed that both proximity to houses and time of day influenced puma activity levels, but this effect differed by sex, and by habitat type for males. Proximity to houses and time of day had a significant positive effect on the number of behavior transitions of male pumas in forests (Table 1). However, for males in forests, support for the interaction term (proximity to houses × time of day) was ambiguous because the two models had a ΔAIC of less than 0.2, indicating that they were statistically indistinguishable [40]. AIC comparison revealed that the best models for all female pumas and males in shrublands included the proximity to houses, time of day, and an interaction between the two (Table 1). This indicates that the time of day determined how pumas altered their movement patterns near development, which we discuss next.

**Table 1. Results of log-linear analysis for all puma behavioral transition models.**

Study Group	Model <sup>ab</sup>	ΔAIC <sup>c</sup>	Components added <sup>a</sup>	ΔG <sup>2</sup> , df, P-value

## Behavioral budgets

All puma behavioral transitions showed contrasting responses to housing depending on the time of day (Fig 1). At night, all pumas regardless of sex or habitat were less likely to remain inactive, more likely to remain active, and more likely to transition between behavioral states near houses. In contrast, male and female pumas were more likely to stay inactive near houses during the daytime. However, male pumas in forests were also less likely to remain active near houses in the forest during the day whereas male pumas in shrublands were unaffected.

Both male and female pumas were generally more active at night than during the day. Male pumas near houses at night were active 26.9% and 21.1% of the time in forested and shrubland habitats, respectively, compared with 17.2% and 13.2% when they weren't close to human structures (Fig 2). Females were active 13.3% of the time when near houses at night, compared with only 7.5% when further away (Fig 2). In the daytime, puma activity was generally low, with females and males in forests exhibiting no difference in activity level in relation to proximity to houses (Fig 2). However, males in shrubland habitats were less likely to be active near houses (2.8%) than when far from houses (8%) during the day.

## Energetic costs

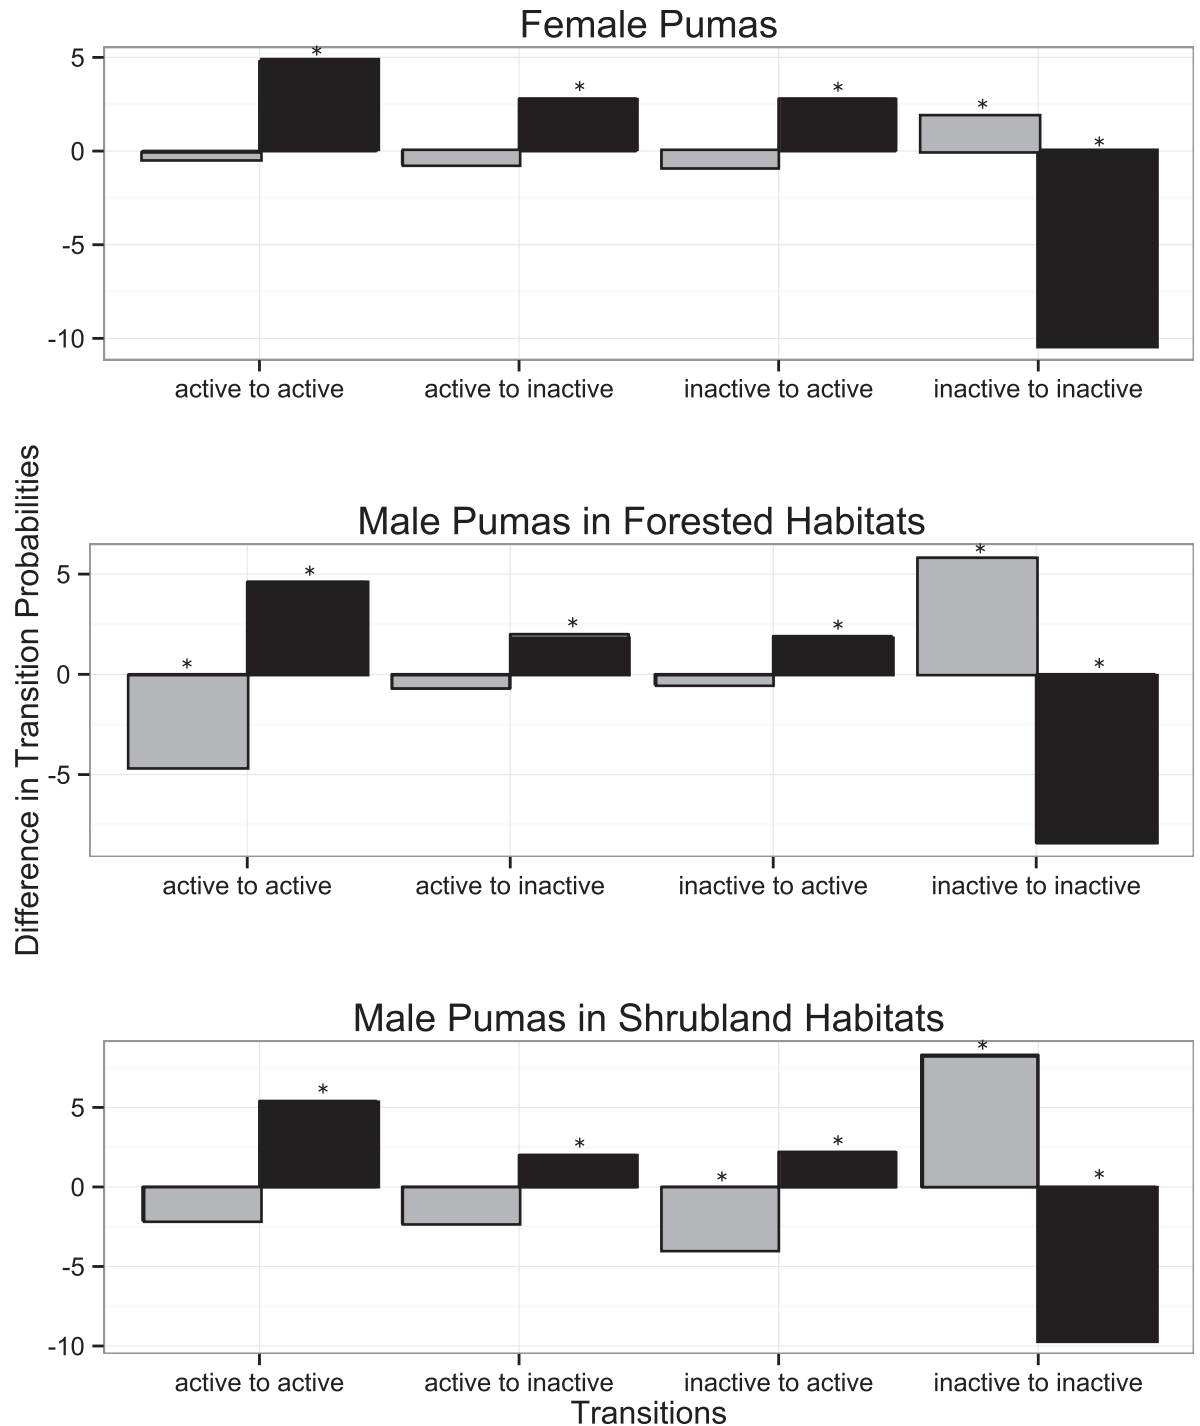

Our COT estimates based on ODBA measurements from accelerometers for pumas 16M and 28F showed that our energetic expenditure estimates from GPS movement data greatly underestimated caloric intake. Applying the COT formula from Taylor et al. [32] to the intensive GPS sampling period, we estimated that 16M expended 2,492 and 2,296 kcals over two days and that 28F expended 1,793 kcals. In contrast, our COT estimates from ODBA for the same three days were about  $2 \pm 2.5$  times higher at 6,079 and 5,492 kcals, and 3,608 kcal, respectively. We used the results from a linear regression between the COT values calculated using 15 min GPS and ODBA measurements (intercept = 8.21, slope = 1.88;  $r = 0.75$ ) to apply corrections factor to all puma energetic calculations.

We used 19 pumas (10 males and 9 females) to evaluate movement activities and energetics over 369 24-hour intense sampling periods (216 for females and 153 for males) (Table 2). Male pumas, averaging  $53.3 \text{ kg} \pm 7.82 \text{ kg}$  (SD), traveled a mean of  $7.43 \text{ km} \pm 2.2 \text{ km}$  daily and expended  $5,145 \text{ kcal} \pm 542 \text{ kcal}$  (after factoring the correction factor). Females, averaging  $39.8 \text{ kg} \pm 2.73 \text{ kg}$ , were more sedentary and traveled a mean of  $4.12 \text{ km} \pm 0.5 \text{ km}$  daily and expended  $4,760 \text{ kcal} \pm 555 \text{ kcal}$ . If a puma only subsisted on a diet of black-tailed deer, we calculated that a male puma would need to kill a minimum average of 45.5 doe equivalents/year and that a female puma would need to kill 42 doe equivalents/year.

## Development influences on puma energetics

We found that the model structure that included random intercepts and slopes for Puma ID minimized AIC values and fit the data better compared to a fixed-effects model ( $\Delta\text{AIC} = 632$ ) and the model with random intercepts only ( $\Delta\text{AIC} = 23.4$ ). The final model included all original fixed effects terms for sex, time, the log-transformed number of houses, the interaction between sex and time, and the interaction between time and number of houses (Table 3). As expected, males burned more calories than females during both nocturnal and diurnal hours (Fig 3). However, the influence of increased housing density on puma energetic expenditures differed depending on time of day, with pumas burning more calories between GPS points in more developed areas during nocturnal hours but not during diurnal hours.

Average daily caloric expenditure for individual pumas was consistently higher on days when pumas were in high housing density areas than in low housing density areas, constituting a  $434.3 \pm 130.3 \text{ SE kcal}$  increase for females and a  $513.3 \pm 83.1 \text{ SE kcal}$  increase for males

**Fig 1. The effect of proximity to houses on the daytime (gray) and nighttime (black) transition probabilities between activity states for female pumas, male pumas in forested areas, and male pumas in shrubland habitats.** Difference in transition probabilities is calculated as probability of transitioning between states when pumas are  $\leq 150\text{m}$  from buildings subtracted by the probability of transitioning between states when pumas are  $> 150\text{m}$  from buildings. A positive value means pumas are more likely to engage in those transitions when close to buildings than when further away. Asterisks above columns represent significant differences between transition probabilities close and far from houses ( $P < 0.05$ ).

<https://doi.org/10.1371/journal.pone.0184687.g001>

**Fig 2. Proportion of time spent active for female pumas, male pumas in forests, and male pumas in shrublands  $\leq 150\text{m}$  from buildings during the day (light gray) or night (black bars) and  $>150\text{m}$  from buildings during the day (white) or night (dark grey bars).** Asterisks between paired columns represent significant differences between activity levels near houses and far from houses ( $P < 0.05$ ). Error bars represent 95% confidence intervals.

<https://doi.org/10.1371/journal.pone.0184687.g002>

(Table 4). These differences in average daily caloric expenditure were equivalent to a mean total percentage increase of  $10.1 \pm 3.1$  SE% of daily kcals used by individual females and  $11.6 \pm 1.8$  SE% of daily kcals used by males. When the increase in daily calories is converted to the extra number of deer required annually by each puma, females would need to kill an additional 3.4 deer annually to meet higher energetic requirements, and males would need to kill 4.0 more deer.

## Discussion

This study explores how housing development influences puma behavior and energetics in a fragmented landscape. Our results suggest a clear relationship between proximity to houses and puma movement activity. This effect was modulated by the time of day, whereby pumas were more likely to be active and remain active when within 150m of development at night. We also found that pumas were more likely to transition between behavioral states when close to houses. These activity shifts may reflect discomfort with being in close proximity to humans and domestic animals or reaction to other abiotic disturbances from these sources, such as light pollution or human-associated sounds [41].

As we predicted, there was a significant positive relationship between distance traveled and the number of houses surrounding each puma's travel path. This pattern resulted in greater metabolic demand associated with higher densities of residential development. Both male and female pumas moved further and expended more calories in developed areas at night but not during the day, providing evidence that puma response to development was strongly influenced by the time of day. Although pumas only increased their movement activity near houses at night, we found that this still resulted in increased net energetic expenditure. Increases in distance traveled are unlikely to be influenced by deer availability, as occupancy of deer is ubiquitous across our study site in both developed and protected areas [20].

The increases in caloric expenditure we observed could in part explain observed increases in puma kill rate in developed areas [8]. To compensate for the higher energetic costs of living in developed areas alone, we found that pumas would need to kill on average a minimum of 3.4 and 4.0 more deer annually for female and male pumas, respectively. This estimated increase is likely conservative, as we have previously found that pumas in the most developed parts of our study area kill over 20 more deer per year than pumas in less disturbed areas [8]. Higher kill requirements based on increased movement may exacerbate other behavioral influences on energetics, including changes in feeding rates and handling time of prey [8] and altered diet composition [20].

Although pumas in our study area are not legally harvested, human-caused mortality is the leading cause of death for collared pumas. Hence, even in the absence of puma hunting, which is illegal in California, high human-induced mortality rates due to depredations give pumas strong incentive to alter their behaviors to minimize contact with people. Pumas fear humans in this human-dominated ecosystem, demonstrated by immediate responses to human stimuli [41], altered feeding behavior [8,24,41], reduced occupancy of developed areas [7], and strong avoidance of development when engaged in reproductive behaviors [24]. As large tracts of land increasingly transition from undeveloped to exurban development, non-lethal human disturbances will likely continue to alter puma behavior. As demonstrated here, changes in puma movement behavior has energetic consequences. The cumulative energetic cost of all behavior change in human-dominated systems is likely to exceed even the substantial estimated energetic requirements reported here.

**Fig 3. Predicted curves bounded by 95% confidence intervals relating the average calories expended between 15-minute GPS points and the average number of houses in a 150m radius around locations in nighttime and daytime.** Predictions for males are indicated by the solid line and females are indicated by the dashed line.

<https://doi.org/10.1371/journal.pone.0184687.g003>

Increased energetic requirements are likely to disproportionately impact females with kittens, given their higher energetic demands [34]. Kittens older than 6 months follow their mothers to kill sites to feed [42]; if these locations are close to development, their feeding times

may decline in response to disturbances [8]. Additionally, females may choose daytime resting locations further away from kill sites in developed areas, thus reducing the energetic gains kittens receive from carcasses. Although we could not track kitten survival during our study, most female pumas we tracked had kittens and lived in home ranges that encompassed developed areas. Future studies that measure kitten recruitment will shed light on the added energetic and survival costs of raising kittens in human-modified landscapes.

Our approach of using GPS and accelerometer data allowed us to obtain more accurate estimates of energetic use and requirements, which were likely underestimated in previous studies using GPS or telemetry data alone. The average activity levels of our study animals (20.8%) was relatively low compared to Beier et al.'s [37] estimates of 25% diel activity for pumas in southern California. This discrepancy may be due to methodological differences; Beier et al. [37] used the radio-telemetry to estimate the locations of animals, which is characterized by lower precision and sampling in comparison to GPS data. Pumas tracked in our study have some of the lowest travel distances (4±7 km/day) of any pumas studied, traveling less than half as far as those monitored by other studies [34,43]. However, despite their relatively short travel distances, our corrected estimates of puma energetic expenditures (average of 4,760 kcal for females and 5,145 kcal for males) was nearly twice as high as those of Laundré [34] (average of 2,420 kcal for females and 3,144 kcal for males), which suggests that previous estimates of puma energetics from GPS or radio-tracked animals have considerably underestimated true field energetics. Metabolic costs derived solely from minimum COT equations or telemetry-only tracking studies may woefully underestimate true large predator hunting costs due to their inability to account for additional energy demand associated with topographic complexity, substrate type, intermittent locomotion, maneuvering, feeding and weather [13,44,45].

Incorporating calibrated accelerometer datasets alongside GPS locations, as demonstrated here for pumas, allows for significantly finer-scale reconstruction of behavioral and energy budgets. Our accelerometer-corrected estimates for minimum annual deer consumption (42

deer/yr for females without kittens and 45.5 deer/yr for males) are likewise much higher than those predicted by Laundré [34] (14.9 deer/yr for females and 19.4 deer/yr for males). Instead, our estimates are similar to the field-estimated kill rates of  $25 \pm 84$  deer/yr for pumas in our population [8].

Our study provides evidence that behavioral responses to human disturbance have energetic consequences to individuals. While previous research had focused primarily on how urbanization and development affect the persistence or declines in wildlife populations, more studies now examine the behavioral responses of these species as they adapt to increased human presence [8,46]. Understanding how animal motivations and behaviors are altered by human influences can shed light on why some species can continue to persist in human dominated landscapes while others become extirpated [47,48]. New technologies such as accelerometers can reveal much more than whether or not an animal is in an area, but elucidate how successfully the individual is able to move, feed, and reproduce [49]. Increasing awareness of the consequences of human-induced behavioral change in wildlife can contribute to more robust wildland-urban interface planning and reductions in human-wildlife conflict.

Currently, exurban or low density development is the fastest growing type of land-use change in the United States [50]. As low density development fragments previously intact landscapes, it could pose significant challenges to survival for wildlife due to cumulative effects of increased non-lethal human disturbance. By incorporating energetic measurements from accelerometers, we showed the substantial consequences of these changes in behavior on energetic costs and requirements. Changes in movement activity and behavior can provide the first indications of predator energetic responses to development. Large carnivores such as pumas occupy pivotal roles in ecosystems, and changes to their behaviors can lead to demographic effects that reverberate throughout the ecological community. In addition, as energetic needs increase with development, large carnivores may switch to domestic or synanthropic prey sources, exacerbating conflict with humans and threatening carnivore survival and population persistence. For all large carnivores, accounting for human-induced behavioral change should play a larger role in any conservation management strategy.

## Acknowledgments

We thank P. Houghtaling, Y. Shakeri, C. Fust, S. McCain and dozens of undergraduate volunteers for collecting field data, as well as the California Department of Fish and Wildlife, C. Wylie and D. Tichenor for their significant support in helping to capture pumas with hounds. We thank T. Williams and C. Bryce with help on calculating puma energetics and B. Nickel and A. Cole for spatial analysis assistance. C. Bryce also helped edit and improve the manuscript.

## Notice of Petition

For action pursuant to Section 670.1, Title 14, California Code of Regulations (CCR) and Division 3, Chapter 1.5, Article 2 of the California Fish and Game Code (Sections 2070 *et seq.*) relating to listing and delisting endangered and threatened species of plants and animals.

### I. SPECIES BEING PETITIONED:

Species Name: Mountain Lion (*Puma concolor*). Southern California/Central Coast Evolutionarily Significant Unit (ESU)

### II. RECOMMENDED ACTION: Listing as Threatened or Endangered

The Center for Biological Diversity and the Mountain Lion Foundation submit this petition to list mountain lions (*Puma concolor*) in Southern and Central California as Threatened or Endangered pursuant to the California Endangered Species Act (California Fish and Game Code §§ 2050 *et seq.*, “CESA”). This petition demonstrates that Southern and Central California mountain lions are eligible for and warrant listing under CESA based on the factors specified in the statute and implementing regulations. Specifically, petitioners request listing as Threatened an Evolutionarily Significant Unit (ESU) comprised of the following recognized mountain lion subpopulations:

1. Santa Ana Mountains
2. Eastern Peninsular Range
3. San Gabriel/San Bernardino Mountains
4. Central Coast South (Santa Monica Mountains)
5. Central Coast North (Santa Cruz Mountains)
6. Central Coast Central

Alternatively, as detailed in the petition, in the event the Commission determines that these six populations collectively either do not comprise a single Southern California/Central Coast ESU or otherwise do not meet the criteria for listing as Threatened, petitioners request the Commission consider whether any of these populations, singularly or in combination, comprise one or more ESUs and meet the criteria for listing as Threatened or Endangered pursuant to CESA.

III. AUTHORS OF PETITION:

Tiffany Yap, D.Env/PhD  
Brendan Cummings

## Executive Summary

The Center for Biological Diversity and the Mountain Lion Foundation submit this petition to list mountain lions (*Puma concolor*; cougar, puma) in Southern and Central Coastal California as “threatened” or “endangered” pursuant to the California Endangered Species Act (CESA) (California Fish and Game Code §§ 2050 et seq.). Following Section 670.1, Title 14, California Code of Regulations, petitioners present scientific information regarding life history, population trend, range, distribution, abundance, kind of habitat necessary for survival, factors affecting the ability to survive and reproduce, degree and immediacy of threat, impact of existing management efforts, suggestions for future management, availability of sources and information, and a detailed distribution map.

Specifically, petitioners request listing as a “threatened species” an evolutionarily significant unit (ESU) comprised of the following recognized mountain lion subpopulations:

1. Santa Ana Mountains
2. Eastern Peninsular Range
3. San Gabriel/San Bernardino Mountains
4. Central Coast South (Santa Monica Mountains)
5. Central Coast North (Santa Cruz Mountains)
6. Central Coast Central

As demonstrated in this petition, mountain lions in these areas comprise an ESU (referred to as the “Southern California/Central Coast ESU”) and meet the statutory definition of a “threatened species.”

The California Fish and Game Commission has long recognized that ESUs can be designated and listed under CESA, and this interpretation of CESA has been upheld by the courts. *See California Forestry Assn. v. California Fish & Game Com.* (2007) 156 Cal.App.4th 1535, 1540 (“Consistent with the policy of the CESA, we will hold that the term ‘species or subspecies’ includes evolutionarily significant units”); *Central Coast Forest Assn. v. Fish & Game Com.* (2018) 18 Cal.App.5th 1191, 1197, fn. 4 [“CCFA IP”] (“An ESU is included within the term ‘species or subspecies’ in sections 2062 and 2067.”). While the ESU concept has primarily been applied to fish, the Commission recently listed an ESU of a mammal, the Pacific Fisher, as a “threatened species.” *See* 14 C.C.R. 670.5(b)(6)(J) (“Fisher (*Pekania pennant*) Southern Sierra Nevada Evolutionarily Significant Unit”).

Under CESA, a “threatened species” is “a native species or subspecies of a ... mammal... that, although not presently threatened with extinction, is likely to become an endangered species in the foreseeable future in the absence of the special protection and management efforts . . . .” Cal. Fish & Game Code § 2067. An animal is an “endangered species” when it is “in serious danger of becoming extinct throughout all, or a significant portion, of its range due to one or more causes, including loss of habitat, change in habitat, overexploitation, predation, competition, or disease.” Cal. Fish & Game § 2062.

Certain populations of the Southern California/Central Coast mountain lion ESU are already “in serious danger of becoming extinct” (e.g. Santa Ana and Santa Monica mountains), and if assessed separately, would individually meet the definition of an “endangered species.” When considered as a whole, the Southern California/Central Coast ESU is not at imminent risk of extinction but still faces significant and growing threats that ultimately threaten the viability of the entire ESU; it consequently meets the definition of a “threatened species.”

Currently, there is no reliable estimate of mountain lion abundance in California. In 1984 the California Department of Fish and Wildlife (CDFW) estimated between 4,000-6,000 adult mountain lions in the state (Mansfield and Weaver 1984). However, CDFW acknowledges that this estimate is outdated and likely overestimates mountain lion abundance. CDFW is currently undertaking a large-scale research effort to estimate mountain lion numbers throughout California.

While reliable absolute abundance estimates are unavailable, recent genetic research has led to estimates of effective population size for California mountain lion populations.<sup>1</sup> These estimates highlight the genetic isolation among California mountain lion populations and raise significant concerns for the continued viability of mountain lions in Southern California and along the Central Coast.

Researchers have recently identified 10 genetically distinct mountain lion populations in California (Figure ES-1) (derived from Gustafson et al. 2018). Nine of these populations occur almost exclusively in California, while one is centered in Nevada but extends into the northeastern corner of California.

The abundance of mountain lions in the North Coast and inland populations (Western Sierra Nevada, Eastern Sierra Nevada, and the genetic cluster centered in the state of Nevada) is not well established; however, these populations are better connected than Southern California and Central Coast mountain lions, and they show relatively high levels of genetic diversity. Gustafson et al. (2018) suggest that these four populations may comprise an ESU. While these populations should be monitored and managed to ensure their continued viability, petitioners do not seek protection of these populations as an ESU under CESA at this time.

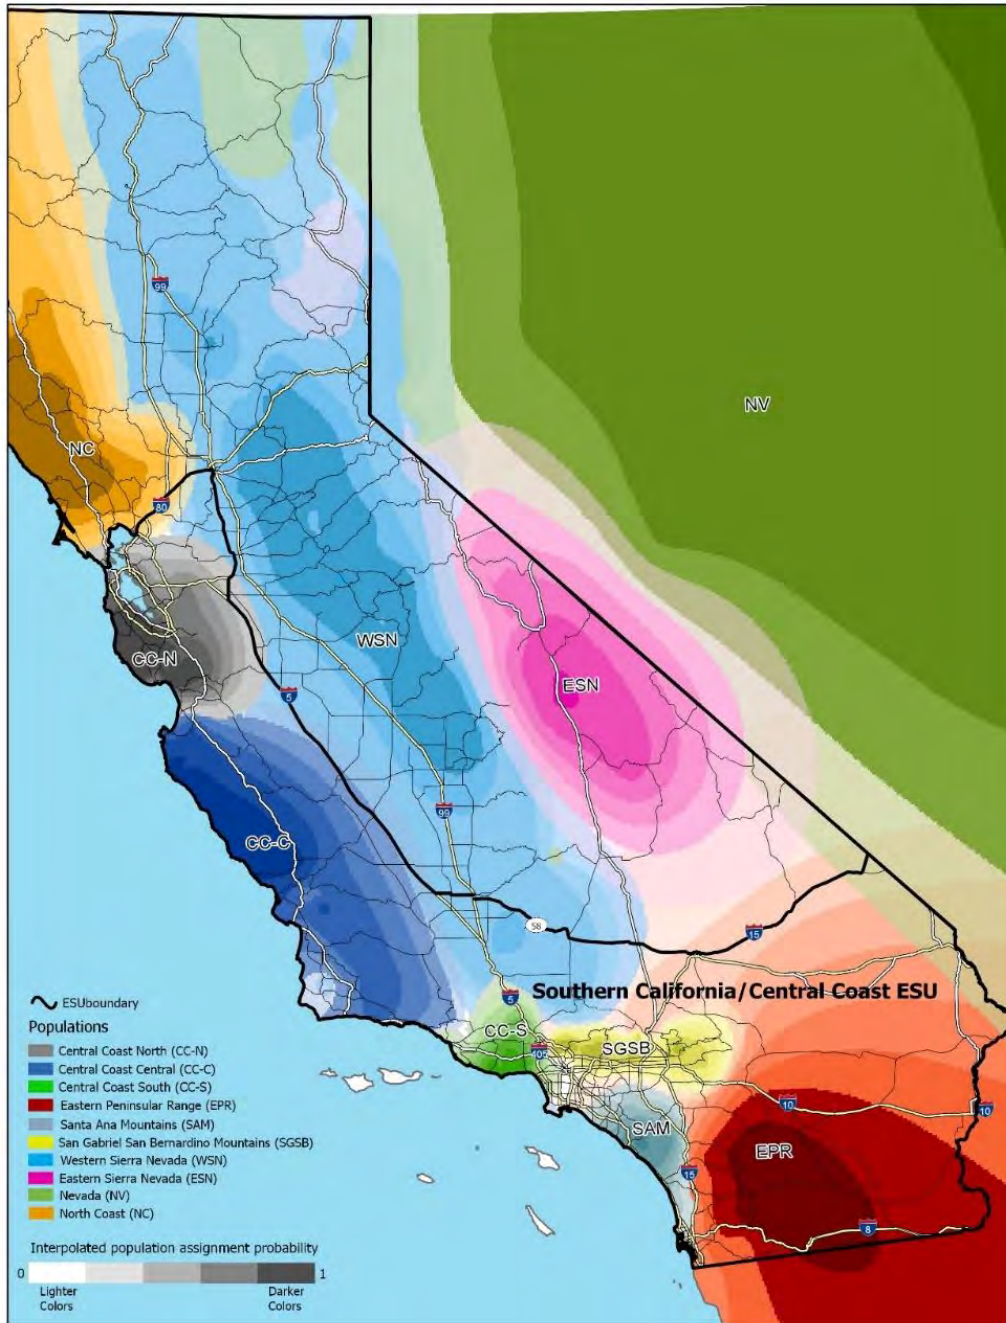

Considering the genetic source-sink dynamics among the remaining six populations, petitioners demonstrate that the populations along the Central Coast and in Southern California collectively comprise an ESU that warrants protection under CESA.<sup>2</sup> The Southern California/Central Coast ESU is comprised of six genetically distinct mountain lion populations: Central Coast North (CC-N, which includes mountain lions in the Santa Cruz Mountains and East Bay), Central Coast

---

<sup>1</sup> At its simplest, effective population size is the number of animals contributing offspring to the next generation. It is an important measure of the genetic health of a population.

<sup>2</sup> As explained *infra* at Section 3.0, these remaining populations can be grouped into one or several potential ESUs. Petitioners believe that for purposes of listing under CESA, treating them as a single ESU is supported by the best available science. Moreover, a single ESU also is the most pragmatic from a management perspective, as recovery of the individual populations ultimately depends upon maintaining and/or reestablishing connectivity between them. *See CCFA II*, 18 Cal.App.5th 1191, 1237 (“[T]he nature of the ESU designation is such that genetics alone are not determinative: One must look beyond genetics to questions of policy to determine which populations to include in an ESU.”)(quotations omitted).

Central (CC-C), Central Coast South (CC-S, which includes the mountain lions in the Santa Monica Mountains), San Gabriel/San Bernardino Mountains (SGSB), Santa Ana Mountains (SAM), and Eastern Peninsular Range (EPR) (Gustafson et al. 2018).

**Figure ES-1.** Map of genetically distinct mountain lion populations and major roadways in California based on data collected from 1992-2016 (the division and status of these populations could change over time and with further research). The black lines show the proposed Southern California/Central Coast ESU boundary. Derived from Gustafson et al. (2018). Genetics data source: Kyle Gustafson, PhD, Department of Biology and Environmental Health, Missouri Southern State University, and Holly Ernest, DVM, PhD, Department of Veterinary Sciences, Program in Ecology, University of Wyoming, Laramie. Roads data source: ESRI.

The boundary of the Southern California/Central Coast ESU is proposed in Figure ES-1, and includes mountain lions that occur south of the San Francisco Bay and I-80, west of I-5 to the intersection of I-5 and SR-58, south of SR-58 to I-15, south of the I-15 from the SR-58 intersection to the California-Nevada border, and, for the purposes of CESA, as far south as the California-Mexico border. These boundaries are recommended as they include virtually all mountain lions associated with the six populations comprising the ESU and are also unambiguous and readily discernable for purposes of management. We recommend including mountain lions in the Tehachapi and Sierra Pelona Mountains south of SR-58 in this ESU. While most mountain lions sampled from this region share some genetic affinities with Western Sierra Nevada (WSN) animals, many also show genetic connections with CC-S, SAM, EPR and SGSB mountain lions. This area serves not just as a connecting link between mountain lion populations comprising the Southern California/Central Coast ESU, but also between this ESU and all other California mountain lions and is therefore essential for the overall genetic health of mountain lions in the state.

While Southern California and Central Coast mountain lions face a multitude of threats, the greatest challenges stem from habitat loss and fragmentation and the consequent impact on their genetic health. Most of the populations comprising the ESU have low genetic diversity and effective population sizes, which puts them at increased risk of extinction (Ernest et al. 2003; Ernest et al. 2014; Riley et al. 2014; Vickers et al. 2015; Benson et al. 2016; Gustafson et al. 2018; Benson et al. 2019). The populations most at risk are the SAM, CC-S, SGSB, and CC-N populations. Due to extreme isolation caused by roads and development, the SAM and CC-S, populations exhibit high levels of inbreeding, and, with the exception of the endangered Florida panther, have the lowest genetic diversity observed for the species globally (Ernest et al. 2014; Riley et al. 2014; Gustafson et al. 2018; Benson et al. 2019). The SGSB and CC-N similarly have low observed genetic diversity and effective population sizes, and they reside in areas of significant isolation and habitat fragmentation, which also puts them at increased risk (Gustafson et al. 2018). And although the CC-C and EPR populations have slightly higher levels of genetic diversity and effective population sizes, high rates of development, habitat loss and fragmentation, and human-caused mortalities in both areas could lead to a similar fate of isolation, genetic drift, low effective population size, and increased risk of extinction in the foreseeable future.

Although minimum viable effective population size has been found to vary depending on the species (Frankham 1995; Traill et al. 2010), general conservation management practice over the past few decades has followed a 50/500 rule, under which an effective population size of 50 is assumed sufficient to prevent inbreeding depression in the short term (over the duration of five generations) and an effective population size of 500 is sufficient to retain evolutionary potential in perpetuity (Traill et al. 2010; Frankham et al. 2014). It is clear that Central Coast and Southern California mountain lion populations are genetically compromised and face significant risk of extinction in both the short- and long-term. Five of the six populations have effective population sizes well below 50 (from lowest to highest: CC-S, SGSB, SAM, CC-N, EPR), and one population (CC-C) is just barely above that threshold at  $N_e = 56.6$  (Table ES-1) (Gustafson et al. 2018).

**Table ES-1.** Effective population size from Gustafson et al. (2018) and estimated total adult population of Central Coast and Southern California Mountain Lion Populations.

<b>Population</b>	<b>Effective Population Size (<math>N_e</math>)</b>	<b>Estimated Total (Adult) Population (<math>N</math>)<sup>1</sup></b>
Central Coast North (CC-N)	16.6	33-66
Central Coast Central (CC-C)	56.6	113-226
Central Coast South (CC-S)	2.7 <sup>2</sup>	5-10
Santa Ana Mountains (SAM)	15.6 <sup>3</sup>	31-62
San Gabriel/ San Bernardino Mountains (SGSB)	5	10-20
Eastern Peninsular Range (EPR)	31.6	63-126
<b>Total</b>		<b>255-510</b>

<sup>1</sup>Calculations are based on the estimated ratio of effective to total adult population size ( $N_e/N$ ) of Florida panthers being 0.25 to 0.5 (Ballou et al. 1989). This ratio was used in the USFWS Florida Panther Recovery Plan (USFWS 2008). Petitioners recognize that these derived population estimates, while informative, are not definitive and will likely be superseded by new population estimates being developed by CDFW.

<sup>2</sup>Benson et al. (2019) calculated an  $N_e$  of 4 for the Santa Monica Mountains population within the CC-S. Applying the Ballou et al. (1989) factors would lead to an estimate of 8-16 mountain lions in this area, which is roughly consistent with current estimates of this well-monitored population.

<sup>3</sup>Several studies provide  $N_e$  calculation for the SAM population. Ernest et al. (2014) calculated an  $N_e$  of 5.1 and Benson et al. (2019) calculated an  $N_e$  of 6. Applying the Ballou et al. (1989) factors to the most recent calculation would lead to an estimate of 12-24 mountain lions in the SAM, which is roughly consistent with current estimates.

Although low effective population sizes standing alone are cause for conservation concern for Southern California and Central Coast mountain lion populations, there are other human-caused factors that further limit their long-term persistence. Habitat loss and fragmentation due to roads and development have led to extreme levels of isolation and high mortality rates. With low genetic diversity and high risk of inbreeding depression due to genetic isolation, vehicle strikes on roads, increased conflicts with humans that lead to depredation kills, high levels of intraspecific strife likely due to limited space and lack of connectivity, rodenticide and other environmental toxicant poisoning, and impacts of more frequent human-caused wildfires and climate change, the small isolated mountain lion populations of Southern California and the Central Coast will likely not persist without the restoration and enhancement of functional connectivity between populations and large blocks of heterogeneous habitats.

Loss of mountain lions in Southern California and the Central Coast would be devastating not just for the mountain lions themselves but also the many species that directly and indirectly rely on them. These top predators are important ecosystem engineers that facilitate healthy ecosystems and allow biodiversity to thrive (Ripple and Beschta 2006; Ripple and Beschta 2008;

Ripple et al. 2014; Ruth and Elbroch 2014; Barry et al. 2019; Elbroch and Quigley 2019). As keystone species mountain lions help support plant recruitment in riparian areas, stabilize stream banks, and sustain healthy habitats for a myriad of aquatic and terrestrial species, including plants, invertebrates, fish, amphibians, reptiles, birds, and mammals (Ripple and Beschta 2006; Ripple and Beschta 2008; Ripple et al. 2014). Their kills are also an important source of food for multiple terrestrial and avian scavengers (Ruth and Elbroch 2014; Barry et al. 2019; Elbroch and Quigley 2019).

Existing laws and regulations have proven to be inadequate to protect Southern California and Central Coast mountain lions. Although the California Wildlife Protection Act of 1990 (Proposition 117) prohibits hunting of mountain lions and has funded the acquisition of important habitat for preservation, the Act alone does not ensure that core habitats and connectivity are protected from development, highways, or other threats. Moreover, numerous mountain lions are killed each year pursuant to depredation authorizations issued under this regime, and there is no limit to the number of depredation permits a property owner can request or any limit to the number of depredation permits which can be issued for any population. And while CDFW has proactively issued a bulletin detailing a new depredation policy for mountain lions in the CC-S and SAM that requires property owners to first implement non-lethal measures prior to being issued a kill permit, this policy does not apply to other vulnerable populations.

Other environmental laws also are insufficient. State and local agencies continue to interpret the California Environmental Quality Act (CEQA) as allowing for the construction of highways and other development in mountain lion habitat and essential corridor areas without adequate mitigation despite severe impacts of such projects on mountain lions. Agencies likewise have generally interpreted CEQA and the federal National Environmental Policy Act as not requiring implementation of connectivity measures when projects fragment or destroy mountain lion habitat. And perhaps most importantly, Caltrans lacks a clear affirmative mandate to design, build, or improve crossings for mountain lions on existing highways, despite the undisputed role of transportation infrastructure in preventing connectivity and gene flow.

Future human population growth and associated development will further diminish and fragment remaining mountain lion habitat, driving Southern California and Central Coast mountain lions closer to extinction and undermining any chance of recovery. Should state and local agencies continue to build and expand roads and highways and permit construction in wildlife habitat and corridors without ensuring adequate habitat connectivity, the genetic health of mountain lion populations will continue to decline while the number of mountain lions killed by vehicle strikes and other human activity will increase.

Ultimately, without a reversal of these trends, mountain lions will disappear from Southern and Central Coastal California in the coming decades, representing a loss of the species from a significant portion of its range in the state. Nevertheless, most of the threats facing mountain lions can be halted or sufficiently reduced if CDFW is provided with adequate resources and all relevant state and local agencies sufficiently prioritize mountain lion conservation in their decision-making. Legal protection of mountain lions under CESA, along with the attention and resources that such listing will generate, can help ensure the long-term survival of this iconic and ecologically significant species in Southern and Central Coastal California.

# The Southern California/Central Coast Evolutionarily Significant Unit (ESU) of Mountain Lions Warrants Listing as Threatened under the California Endangered Species Act (CESA)

## 1 Introduction

This petition summarizes available scientific information regarding the natural history of mountain lions, their distribution and abundance in California, population trends and threats, describes the proposed ESU, and discusses the limitations of existing management measures in protecting the species. As demonstrated below, mountain lions in Southern California and along the Central Coast meet the criteria for protection as a threatened species under the California Endangered Species Act (CESA), and would benefit greatly from such protection.

## 2 Life History

### 2.1 Species Description

Adult female mountain lion (left) and kittens (right). Photos: NPS.

The mountain lion (*Puma concolor*) is also commonly called a puma (from the Inca language Quechua) or cougar (corrupted from *cuguacuarana* from the indigenous Guarani people in Paraguay, Argentina, Bolivia, and Brazil). Adults are large, slender cats with short, muscular limbs and a long tail that is about one third of the animal's total length. Their hind limbs are longer than their fore limbs, which makes them highly adapted for jumping through rugged terrain or pouncing on their prey. They have tawny pelage that can be lighter/whitish on their belly and the undersides of their legs and they have areas of white around the muzzle, throat and chest. They have black fur on the backs of their rounded ears, the tip of their tail, and outlining their muzzle. Their eyes are a grayish brown to golden color, and the nose is pink with a black outline.

Adult body size and weight can vary depending on the geographic range (Iriarte et al. 1990). Mountain lions are smaller and weigh less near the equator and are larger and heavier towards the poles, which likely reflects the size of available prey and the presence of sympatric carnivores (Iriarte et al. 1990). Males are typically larger than females. Males generally weigh 55-65kg with a length of 2.2-2.3m from the nose to the tip of the tail, and females generally weigh 35-45kg with a length of 2.0-2.1m (Currier 1983).

Mountain lion kittens are born weighing approximately 400g, and their eyes and ear canals remain closed for one to two weeks after birth (Currier 1983). They have light coats with dark spots and a white muzzle, chest, and belly. Like the adults, they have black fur on the backs of their rounded ears, the tip of their tail, and outlining their muzzle. Their eyes are initially blue, change to mostly brown within four months, and then change to a golden color at around nine months (Currier 1983). The dark spots on their coat start to fade at 12-14 weeks of age, presumably when a kitten starts to accompany its mother on hunts, but the spots are still distinguishable until the animal is about one year old (Currier 1983). Adult weight is typically reached between the second and fourth year.

## 2.2 Taxonomy and Population Genetics

The mountain lion is in the order Carnivora and is a member of the cat family Felidae. Unlike the large, roaring cats of the subfamily Pantherinae (e.g., lions, tigers, and leopards), mountain lions are categorized with small, purring cats in the subfamily Felinae (e.g., bobcats, lynxes, ocelots, cheetahs, and jaguarundi). Their scientific name is *Puma concolor*, formerly called *Felis concolor*. Based on molecular and morphological features, it is thought that mountain lions share a common ancestor with cheetahs (*Acinonyx jubatus*) and jaguarundi (*Puma yaguaroundi*).

Mountain lion fossil records in North America date back 300,000 years (Pierce and Bleich 2003); however, they were likely extirpated during a massive extinction event at the end of the Pleistocene, which eliminated about 80% of large vertebrates in North America (Culver et al. 2000; Caragiulo et al. 2013). Genetic studies suggest that after this extinction event, a small number of Central and South American mountain lions migrated north and repopulated North America (Culver et al. 2000; Caragiulo et al. 2013). As a result, existing North American mountain lions exhibit founder effects and have less genetic diversity compared to mountain lions in Central and South America (Culver et al. 2000; Caragiulo et al. 2013).

There is some debate regarding the number of subspecies of mountain lions. Two subspecies are “tentatively” recognized by the International Union for Conservation of Nature (IUCN) Species Survival Commission (SSC) Cat Specialist Group: *Puma concolor concolor* (Linnaeus, 1771) in South America and *Puma concolor couguar* (Kerr, 1792) in North and Central America and possibly northern South America west of the Andes Mountains (Kitchener et al. 2017). However, there are various studies that suggest the divergence of multiple subspecies of mountain lions. About 30 subspecies of mountain lions throughout the Americas have been referenced in the literature, with about 15 subspecies in North America (Young and Goldman 1946; Currier 1983; Pierce and Bleich 2003).

Based on more recent genetic analyses of mitochondrial DNA (mtDNA) from mountain lions throughout the Americas, Caragiulo et al. (2013) found that the mountain lions they sampled could be separated into three broad groupings: North America, Central America, and South America, with North American mountain lions having the least variation in mtDNA compared to populations in Central and South America. Although that study genotyped 601 specimens, the distribution of sampling within the broad geographic range was limited compared

to a study conducted by Culver et al. (2000), which analyzed mtDNA from 315 mountain lions sampled from more locations throughout the species' geographic distribution. Culver et al. (2000) found six phylogeographic groupings or subspecies throughout the Americas.

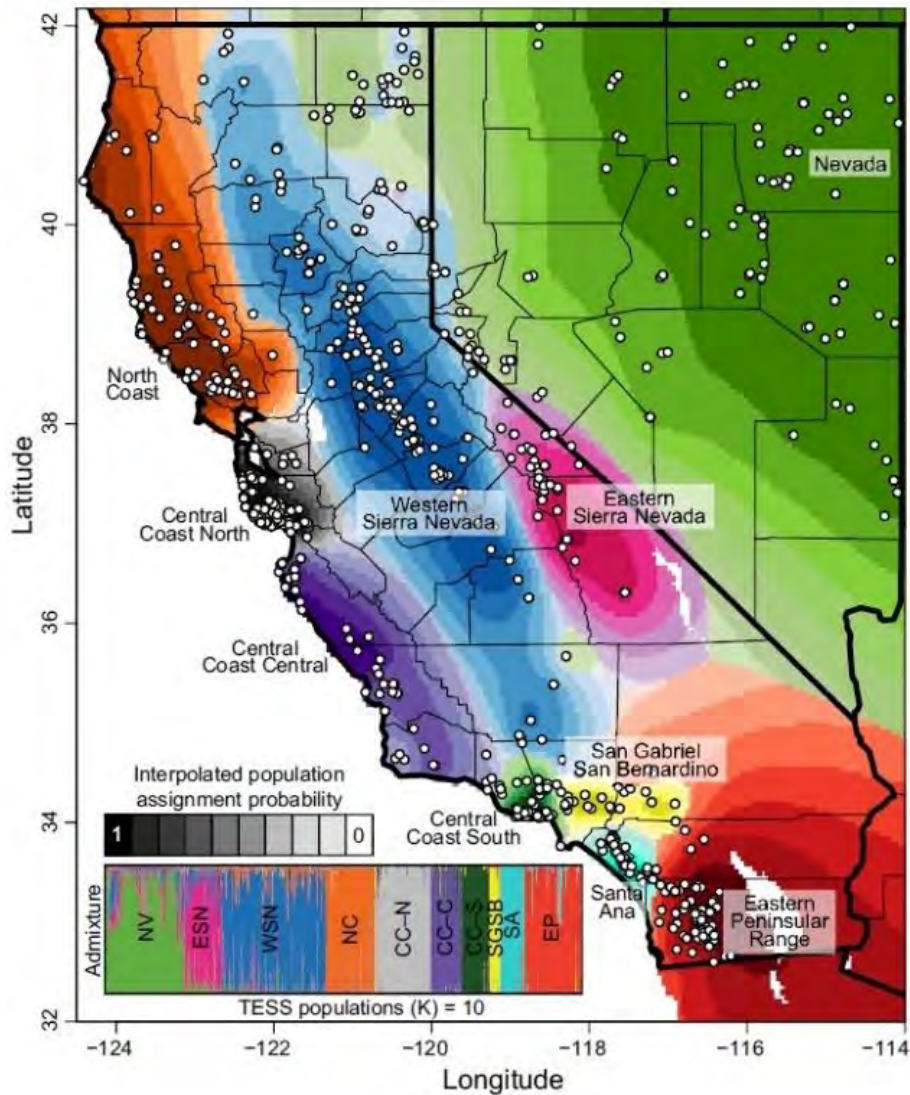

Despite this ongoing debate, the United States Fish and Wildlife Services (USFWS) has long recognized mountain lion subspecies under the federal Endangered Species Act (ESA). Two of these subspecies have been protected under the ESA due to low population sizes: the eastern cougar (*Puma concolor cougar*), which was listed as endangered and is now thought to be extinct, with the last recorded occurrence in 1938 (USFWS 2018), and the endangered Florida panther (*Puma concolor coryi*), which is an isolated population that is now restricted primarily to the cypress swamps of southern Florida. In addition, the California mountain lion (*Puma concolor californica*) was recognized by USFWS in response to a 1994 petition by the Mountain Lion Foundation to list the population of California mountain lions in the Santa Ana Mountains as endangered, as those populations that occur within most of California, southern Oregon, western Nevada, and northern Baja California, Mexico (USFWS 1994). Additionally, the California Department of Fish and Wildlife (CDFW) recognizes the Yuma Puma (*Puma concolor browni*) as a (sub)species of special concern that occurs in the desert plains and low mountains along the Colorado River in southeastern California, southwestern Arizona, northeastern Baja California, Mexico, and northwestern Sonora, Mexico (CDFW 1990).

In California, researchers have recently identified 10 genetically distinct mountain lion populations in California and Nevada, nine of which have core areas in California (Figure 1) (Gustafson et al. 2018). In the study, 992 mountain lions from throughout California and Nevada were genotyped using 42 microsatellite loci to identify regional populations and evaluate functional connectedness between the populations (Gustafson et al. 2018). The divergence of these populations is likely the result of habitat fragmentation caused by roads and development (Ernest et al. 2003; Ernest et al. 2014; Riley et al. 2014; Vickers et al. 2015; Benson et al. 2016a; Gustafson et al. 2017; Gustafson et al. 2018; Benson et al. 2019). According to Gustafson et al. (2018), mountain lions in the North Coast and inland populations (Nevada, Eastern Sierra Nevada, Western Sierra Nevada) appear to be better-connected than those in the south and along the central coast, with relatively larger effective population sizes and higher levels of genetic diversity. The authors suggest that these populations may comprise an evolutionarily significant unit (ESU). Considering the genetic source-sink dynamics among the remaining populations (Gustafson et al. 2018), petitioners demonstrate that the populations in Southern California and along the Central Coast collectively comprise an ESU (referred to as the “Southern California/Central Coast ESU”). See *Section 3.0 Southern California and Central Coast Mountain Lions Comprise and Evolutionarily Significant Unit* for more discussion.

The Southern California/Central Coast ESU is comprised of six genetically distinct mountain lion populations: Central Coast North (CC-N, which includes mountain lions in the Santa Cruz Mountains), Central Coast Central (CC-C), Central Coast South (CC-S, which includes mountain lions in the Santa Monica Mountains), San Gabriel/San Bernardino Mountains (SGSB), Santa Ana Mountains (SAM), and Eastern Peninsular Range (EPR) (Figure 1) (Gustafson et al. 2018). Most of these populations appear to be struggling with low genetic diversity and effective population sizes, which puts them at increased risk of extinction (Ernest et al. 2014; Riley et al. 2014; Vickers et al. 2015; Benson et al. 2016a; Gustafson et al. 2018;

Benson et al. 2019). The populations struggling the most include the SAM, CC-S, SGSB, and CC-N populations. Although the CC-C and EPR have slightly higher levels of genetic diversity and effective population sizes, high rates of development in both areas could lead to a similar fate of isolation, genetic drift, low effective population size, and increased risk of extinction in the foreseeable future.

**Figure 1.** Map of genetically distinct mountain lion populations in California. The Central Coast North (CC-N), Central Coast Central (CC-C), Central Coast South (CC-S), San Gabriel/San Bernardino (SGSB), Santa Ana Mountains (SAM), and Eastern Peninsular Range (EPR) mountain lion populations should be considered an evolutionarily significant unit (ESU). Each color represents a genetically distinct mountain lion population. White dots are individual animals sampled. Source: Gustafson et al. (2018).

Although discrete populations have been identified in Southern California mountain ranges, other mountain lions have been regularly observed outside of the CC-S, SAM, SGSB, and EPR core areas, including transient and resident mountain lions in the Mojave and Colorado deserts and along the Lower Colorado River (*i.e.*, Yuma mountain lion [*Puma concolor browni*], a recognized subspecies of special concern). These populations presumably occur in low

densities due to limited resources, such as lower prey abundance/vulnerability or less suitable habitat. In fact, Kucera (1998) states that habitat within the Yuma mountain lion range is generally considered to be of low or no suitability for mountain lions. Relatively low density populations are inferred by the larger ranges of mountain lions in desert environments; four individual Yuma mountain lions had home ranges of 389km<sup>2</sup> to 1621km<sup>2</sup>, which is much larger than other California mountain lion home ranges (Grigione et al. 2002; Riley et al. 2014; Zeller et al. 2017; see *Section 2.5 Habitat Requirements* for more details) but similar to those estimated for other desert mountain lions (Kucera 1998). This petition considers these low-density transients and resident lions as included within the Southern California/Central Coast ESU.

### 2.2.1 Effective Population Size and Extinction Risk

It has been established that genetic factors play a critical role in extinction risk. Inbreeding depression, loss of genetic diversity, and accumulation of deleterious mutations can lead to elevated extinction risk due to reduced reproductive fitness and evolutionary potential (*i.e.*, the ability to adapt to change) (Spielman et al. 2004; Frankham 2005; Traill et al. 2010). Effective population size ( $N_e$ ) is a key metric used to assess a population's genetic viability and its chances of long-term persistence. Effective population size is an estimate of the size of an idealized population that would lose heterozygosity (*i.e.*, genetic diversity) at the same rate as the observed population; it indicates a population's rates of inbreeding and genetic drift (changes in allele frequencies over generations based purely on chance). A lower effective population size indicates a higher risk of inbreeding depression. Factors that affect effective population size include census population size (*i.e.*, the total number of individuals within a population), breeding sex ratio, variance in reproductive success, and population density. Several characteristics of these mountain lion populations, including small census population size, low density, female-biased sex ratios, and skewed male reproductive success, reduce effective population size, which suggests that these populations have an increased risk of inbreeding depression and extinction (Ernest et al. 2014; Riley et al. 2014; Vickers et al. 2015; Benson et al. 2016a; Gustafson et al. 2018; Benson et al. 2019).

The minimum effective population size for a population to persist has been debated (*e.g.*, Jamieson and Allendorf 2012; Frankham et al. 2014). Although minimum viable effective population size has been found to vary depending on the species (Frankham 1995), general conservation management practice over the past few decades has followed a 50/500 rule, which purports that an effective population size of 50 is sufficient to prevent inbreeding depression in the short term (over the duration of five generations) and an effective population size of 500 is sufficient to retain evolutionary potential in perpetuity (Frankham et al. 2014). In a 2012 review, Jamieson and Allendorf (2012) concluded that the 50/500 rule is a useful guiding principle in conservation management when genetic concerns are likely to affect the short- and long-term viability of populations. However, Frankham et al. (2014) later revised the 50/500 rule and recommended an effective population size of 100 to limit the loss of total fitness to <10% in the short-term and an effective population size of 1,000 to retain evolutionary potential for fitness in perpetuity, while recognizing that fragmented populations should be evaluated on a case-by-case basis.

Whether the 50/500 or 100/1,000 rule is considered, it is clear that Central Coast and Southern California mountain lion populations are genetically imperiled and face extinction in both the short- and long-term. Five of the six populations have effective population sizes well below 50 (from lowest to highest, according to Gustafson et al. 2018: CC-S, SGSB, SAM, CC-N, EPR), and the remaining population (CC-C) is just barely above that threshold at  $N_e = 56.6$  (Table 1) (Ernest et al. 2014; Riley et al. 2014; Benson et al. 2016a; Gustafson et al. 2018; Benson et al. 2019). Although the ratio of effective to total adult population size ( $N_e/N$ ) varies by species, the effective population size is often much lower than the total adult population size (Frankham 1995). Several studies indicate that the  $N_e/N$  in wild vertebrate populations ranges from 0.2 to 0.5 (Ballou et al. 1989; Mace and Lande 1991; Spong et al. 2000; Laundré and Clark 2003). Ballou et al. (1989) estimated the  $N_e/N$  to be 0.25-0.5 in their population viability assessment of the Florida Panther, which aligns with other studies on big cats (Frankham 1995; Spong et al. 2000). This range was used in the USFWS’s Florida Panther Recovery Plan (USFWS 2008), and, if applied to the Central Coast and Southern California mountain lion populations, the total number of mountain lions in the areas combined would be 255 to 510 individuals (Table 1). This is well below the recommended minimum viable population size of at least 5,000 adult individuals for the long-term persistence of a population (Frankham 1995; Reed et al. 2003; Traill et al. 2010).

**Table 1.** Effective population size and estimated total adult population of Central Coast and Southern California Mountain Lion Populations from Gustafson et al. (2018).

<b>Population</b>	<b>Effective Population Size (<math>N_e</math>)</b>	<b>Estimated Total (Adult) Population (N)<sup>1</sup></b>
Central Coast North (CC-N)	16.6	33-66
Central Coast Central (CC-C)	56.6	113-226
Central Coast South (CC-S)	2.7 <sup>2</sup>	5-10
Santa Ana Mountains (SAM)	15.6 <sup>3</sup>	31-62
San Gabriel/ San Bernardino Mountains (SGSB)	5	10-20
Eastern Peninsular Range (EPR)	31.6	63-126
<b>Total</b>		<b>255-510</b>

<sup>1</sup>Calculations are based on the estimated ratio of effective to total adult population size ( $N_e/N$ ) of Florida panthers being 0.25 to 0.5 (Ballou et al. 1989). This ratio was used in the USFWS Florida Panther Recovery Plan (USFWS 2008). Petitioners recognize that these derived population estimates, while informative, are not definitive and will likely be superseded by new population estimates being developed by CDFW.

<sup>2</sup>Benson et al. (2019) calculate an  $N_e$  of 4 for the Santa Monica Mountains population within the CC-S. Applying the Ballou et al. (1989) factors would lead to an estimate of 8-16 mountain lions in this area, which is roughly consistent with current estimates of this well-monitored population.

<sup>3</sup>Several studies provide  $N_e$  calculation for the SAM population. Ernest et al. (2014) calculated an  $N_e$  of 5.1 and Benson et al. (2019) calculated an  $N_e$  of 6. Applying the Ballou et al. (1989) factors to the most recent calculation would lead to an estimate of 12-24 mountain lions in the SAM, which is roughly consistent with current estimates

Habitat loss and fragmentation due to roads and development have led to extreme levels of isolation in these populations, which have lowered their effective population sizes and, ultimately, their ability to survive and reproduce with a diverse gene pool (Ernest et al. 2014; Riley et al. 2014; Benson et al. 2016a; Gustafson et al. 2018; Benson et al. 2019). However, re-establishing gene flow among isolated subpopulations of a species can increase effective population size and reduce extinction risk (Frankham et al. 2014). Thus, the implementation of wildlife crossing infrastructure at existing barriers along with the preservation of intact, heterogeneous habitats would facilitate connectivity among Central Coast and Southern California mountain lion populations and significantly improve their chances of long-term survival.

### 2.2.2 Central Coast North (CC-N) Mountain Lion Population

In a statewide study, Gustafson et al. (2018) found that the CC-N population clustered genetically with the CC-C and CC-S populations. The population exhibited evidence of a previous genetic bottleneck and was found to have low genetic diversity and a low effective population size ( $N_e = 16.6$ ). There is some evidence, though weak, that suggests the CC-N population is a source population, with limited gene flow with the other Central Coast populations and the Western and Eastern Sierra Nevada populations (Gustafson et al. 2018). CDFW has identified that the Santa Cruz Mountains population, which occurs within the CC-N area, is struggling due to fragmentation from roads and development as well as lack of protected habitat (Dellinger 2019). The low genetic diversity and effective population size threaten both the short- and long-term survival of the CC-N population.

### 2.2.3 Central Coast Central (CC-C) Mountain Lion Population

The CC-C mountain lion population has been found to exhibit a previous genetic bottleneck (Gustafson et al. 2018). It has intermediate levels of genetic diversity and the highest effective population size ( $N_e = 56.6$ ) among the Central Coast and Southern California populations (Gustafson et al. 2018). Although this effective population size exceeds the older standard of 50 to prevent in-breeding depression in the short-term, it falls well below the recommended newer standard of 100 and is insufficient for the long-term persistence of the population. This population was found to be clustered genetically with the CC-N and CC-S populations and identified as a source population with limited gene flow with other Central Coast populations, the Western and Eastern Sierra Nevada populations, and the SGSB population (Gustafson et al. 2018). Although the CC-C population appears to be the healthiest population in the Central Coast and Southern California, the lack of sufficient protected lands and high rates of development and habitat fragmentation in the area threaten the persistence of this population (Dellinger 2019).

### 2.2.4 Central Coast South (CC-S) Mountain Lion Population

The CC-S mountain lion population has been found to exhibit a prior genetic bottleneck, with low genetic diversity and an extremely low effective population size ( $N_e = 2.7$  to 4) (Riley et al. 2014; Benson et al. 2016a; Gustafson et al. 2018; Benson et al. 2019). This population was

found to be clustered genetically with the CC-N and CC-C populations and identified as a genetic sink population, with limited gene flow from mountain lions along the Central Coast and in the Sierra Nevada (Gustafson et al. 2018).

A recent population viability analysis focused on the Santa Monica Mountains population, a subpopulation within the CC-S that has been severely isolated due to roads and development, found that if the population remains isolated with little or no immigration (similar to what is currently being observed in the area), the population could experience high levels of genetic erosion, with 40-57% loss of predicted heterozygosity within 50 years (Benson et al. 2016a). When considering just demographic processes with little or no immigration and no inbreeding depression, the population was predicted to have a 15-22% chance of extinction within 50 years (Benson et al. 2016a; Benson et al. 2019). However, if inbreeding depression occurs, which is a strong possibility given the predicted substantial loss of genetic diversity and the documentation of father-daughter, grandfather-granddaughter, and grandmother-grandson inbreeding within the population (*e.g.*, Riley et al. 2014)<sup>3</sup>, population growth will likely decline and chances of extinction within 50 years is predicted to be 99.7%, with a median time to extinction of 15.1 years (Benson et al. 2016a; Benson et al. 2019).

### 2.2.5 Santa Ana Mountains (SAM) Mountain Lion Population

The SAM mountain lion population has been found to have the lowest genetic diversity of all populations in California, with levels nearly as low as the endangered Florida panther (Ernest et al. 2014; Gustafson et al. 2017; Gustafson et al. 2018; Benson et al. 2019). This population is also estimated to have a low effective population size ( $N_e = 5.1$  to 15.6) and high levels of relatedness and inbreeding (Ernest et al. 2014; Gustafson et al. 2018; Benson et al. 2019). The SAM population was found to be a genetic sink population, with limited gene flow with the EPR population (Gustafson et al. 2018). In a 16-year study (2001-2016) seven migrants (out of 146 sampled animals), were detected via genetics and GPS collar tracking to have crossed the I-15 between the EPR and SAM (three males from the EPR to SAM, four males from the SAM to the EPR); only one migrant is known to have reproduced (Gustafson et al. 2017). Low genetic diversity and effective population size in the SAM are indicative of a genetic bottleneck that is estimated to have occurred 40-80 years ago, around the time when urban development and multi-lane highway construction boomed in Southern California (Ernest et al. 2014; Gustafson et al. 2018). This population was also found to be largely disconnected from all the other California populations, along with the EPR population.

A recent population viability analysis found that if the population remains isolated with little or no immigration (similar to what is currently being observed in the area), the population could experience further genetic erosion, with 28-49% loss of predicted heterozygosity within 50 years (Benson et al. 2019). When considering just demographic processes with little or no immigration and no inbreeding depression, the population was predicted to have a 16-21% chance of extinction within 50 years. However, to avoid inbreeding depression in wild populations, loss in heterozygosity should be less than 5-10% over 100-200 years (Soule et al. 1986; Benson et al. 2016a), which suggests that inbreeding depression in the SAM population is

---

<sup>3</sup> Inbreeding has been documented in the SMM population in Riley et al. 2014 and in ongoing studies by the NPS. More information from the NPS is available here: <https://www.nps.gov/samo/learn/nature/puma-profiles.htm>

a strong possibility. In addition, evidence of potential inbreeding depression has been observed in the population (*e.g.*, kinked tails coupled with low genetic diversity, Figure 2, Ernest et al. 2014). When inbreeding depression was considered in the population viability analysis, population growth will likely decline and chances of extinction within 50 years is predicted to be 100%, with a median time to extinction of 11.7 years (Benson et al. 2019).

**Figure 2.** Two SAM mountain lions with a kink at the base of the tail (A) and near the tip of the tail (B). These individuals had among the lowest genetic diversity measured in the study. Source: Ernest et al. 2014.

#### 2.2.6 San Gabriel/San Bernardino Mountains (SGSB) Mountain Lion Population

According to Gustafson et al. (2018), the SGSB mountain lion population exhibits extremely low genetic diversity and effective population size ( $N_e = 5$ ), though the sample size from SGSB was low. They were also found to be a sink population, with limited gene flow with populations in the Western Sierra Nevada, CC-C, and the EPR (Gustafson et al. 2018). Although genetic studies on this population are limited, patterns of isolation, loss of genetic diversity, and low effective population size are similar to those of the SAM and CC-S populations and likely indicate a high risk of extinction. Not only is the population's long-term survival at stake, but the geographic location of the SGSB population is paramount. Despite only limited gene flow between the SGSB population and the Western Sierra Nevada, CC-C, and EPR, this population represents a critical linkage between mountain lion populations in the northern, central coast, and southern mountain ranges of California (Gustafson et al. 2018). Restoration and enhancement of connectivity is key for the continued survival of the SGSB population as well as the Central Coast and Southern California mountain lion populations.

#### 2.2.7 Eastern Peninsular Range (EPR) Mountain Lion Population

Gustafson et al. (2018) found that the EPR population exhibits a prior genetic bottleneck. Although the population was found to have a higher effective population size than the other Southern California mountain lion populations ( $N_e = 31.6$ ), this is still well below the older standard of 50 to prevent in-breeding depression in the short-term and is insufficient for the long-term persistence of the population. In addition, the EPR population was found to be largely disconnected from all the other California populations, with limited gene flow and low connectivity with the SAM and SGSB populations (Gustafson et al. 2018). With continued development in San Diego, Riverside, and Imperial Counties, the EPR population could have a

similar fate of isolation, genetic drift and inbreeding, and risk of extinction as the other Central Coast and Southern California populations.

As mentioned previously, there are records for mountain lions outside of the core mountain ranges in Southern California, which are likely transients or residents of smaller populations. For example, the Yuma mountain lion has been recognized by CDFW as a subspecies of special concern, and likely occurs in low density in the desert plains and low mountains of the Colorado River Valley. Genetic studies on the Yuma mountain lion are limited, and no samples were obtained from that area for the study conducted by Gustafson et al. (2018). However, the low densities of transients and smaller populations in areas where roads and development threaten connectivity make them part of the EPR and larger Southern California population, and as such, they are considered a conservation concern and are included in this petition.

### 2.3 *Reproduction and Growth*

Dens are often in rocky outcrops (left) or in dense vegetation (right). Photos: NPS.

Mountain lions are polygamous breeders, and mates likely locate each other with auditory and olfactory signals (Currier 1983). They may reproduce at any time of year, though seasonal pulses have been documented and the timing of reproduction may be affected by prey abundance or climate (Pierce and Bleich 2003). In North America, kitten births are most common between April and September (Currier 1983; Beier 1995; Pierce and Bleich 2003).

Pairs generally mate for about 2-5 days (Beier et al. 1995), though there are instances in which pairs have been recorded traveling together for up to 16 days (Seidensticker et al. 1973). During this time they vocalize frequently, travel little, will sometimes share a kill, and copulate up to 70 times per day (Seidensticker et al. 1973; Beier et al. 1995; Pierce and Bleich 2003). Female estrous cycles last an estimated 4-12 days, and it is hypothesized that numerous acts of copulation stimulate ovulation and improve chances of successful fertilization (Pierce and Bleich 2003, Kitchener 1991). If the litter is born dead or removed within 24 hours of birth, females will go into estrous within a few weeks (Currier 1983). In addition, competing males have been

known to commit infanticide<sup>4</sup>, presumably to trigger estrous in females, though scientists are still investigating what drives this behavior.

Gestation lasts 82-96 days (Young and Goldman 1946; Currier 1983). Litter size ranges from 1-6, though 2-4 kittens per litter are typical (Pierce and Bleich 2003; Beier et al 2010; Riley et al. 2014). Females average larger litters during their first year of reproduction and tend towards smaller litters when they are older (Pierce and Bleich 2003). The sex ratio of litters has generally been found to be equal (Pierce and Bleich 2003). Females keep their kittens in dens located in rocky terrain or in dense vegetation that provide cover (Young and Goldman 1946), and they may move their young to several different dens until the young are weaned at about 2-3 months old (Pierce and Bleich 2003). Denning mountain lions have been found to avoid roads and stay at a distance from human disturbance four times greater (~600m) than non-reproductive mountain lions (~150m) (Wilmers et al. 2013).

Females care for their young for 1-2 years, at which point the mother comes into estrous and either abandons the cubs or acts aggressively towards them to prevent them from following her, as older males will kill cubs (Young and Goldman 1946; Seidensticker et al. 1973; Currier 1983; Beier 1995; Pierce and Bleich 2003). Newly independent young have been found to stay in the area where the mother leaves them for 2-3 weeks, and then disperse away from the direction their mother left (Beier 1995). Typically 50% of females stay in their natal range and 50% disperse while all males disperse, and siblings sometimes travel for a short time together (Pierce and Bleich 2003; Logan and Sweanor 2010). Subadult mountain lions may disperse up to 500km from their natal home ranges as they explore and establish their own territories (Pierce and Bleich 2003).

Mountain lions reach sexual maturity at 2-4 years of age. Although they are rarely known to mate until they have an established home range, transient males may occasionally breed with resident females (Hornocker 1970; Seidensticker et al. 1973; Currier 1983).

#### 2.4 *Diet and Foraging Ecology*

Mountain lion cub feasting on a deer kill in the Santa Monica Mountains. Photo: NPS.

---

<sup>4</sup> Infanticide has been documented in the Santa Monica Mountains mountain lion population. More information from the NPS is available here: <https://www.nps.gov/samo/learn/nature/puma-profiles.htm>

Large ungulates, especially deer, are the preferred prey of mountain lions, making up about 70% of their diet (Currier 1983; Iriarte et al. 1990). Hornocker (1970) estimated that the average adult mountain lion consumes 860-1,300kg of large prey annually. However, mountain lions are opportunistic predators, and they have been documented eating a wide variety of other large and smaller prey, including moose, elk, wild horses, burros, pronghorn, bighorn sheep, mountain goats, wild hogs, coyotes, bobcats, porcupines, badgers, rabbits, raccoons, rodents, turkeys, and livestock (Currier 1983; Iriarte et al. 1990; Garcelon unpublished data).

Their diet can vary by prey availability, prey vulnerability, the presence of sympatric carnivores, the season, and the age and sex of the mountain lion (Currier 1983; Iriarte et al. 1990; Knopff et al. 2010; Allen et al. 2014a). For example, deer have been found to make up >90% of the diet in mountain lions in the Santa Monica Mountains and in Northern California (Allen et al. 2014a; Riley et al. 2014), while in Florida wild hogs were found to be the most common prey (Maehr et al. 1990), and in northwestern Sonora, Mexico bighorn sheep were found to be the primary prey (Rosas-Rosas et al. 2003). These observed patterns were likely due to the availability of different prey in different geographic regions. A study conducted in Alberta, Canada, Knopff et al. (2010) found that while adult females were more likely to kill small ungulates (*e.g.*, deer), adult males were more likely to kill larger ungulates (*e.g.*, elk), and subadults relied on both small ungulates and nonungulate prey (*e.g.*, beavers, snow hares). A similar pattern was found in a mountain lion population in the Greater Yellowstone Ecosystem, in which older, larger individuals hunted larger prey and younger, smaller individuals hunted smaller prey (Elbroch and Quigley 2019). In addition, mountain lions were found to prey upon female ungulates in the spring before and during the birthing period, and they would more often prey upon male ungulates in the fall during the rut, highlighting that prey vulnerability may play a role in mountain lion predation (Knopff et al. 2010).

Mountain lions roam through expansive home ranges in search of prey, often hunting between dusk and dawn. Although they are generally most active at dusk and dawn, their peak activities have been observed to shift to more nocturnal patterns when they are closer to human

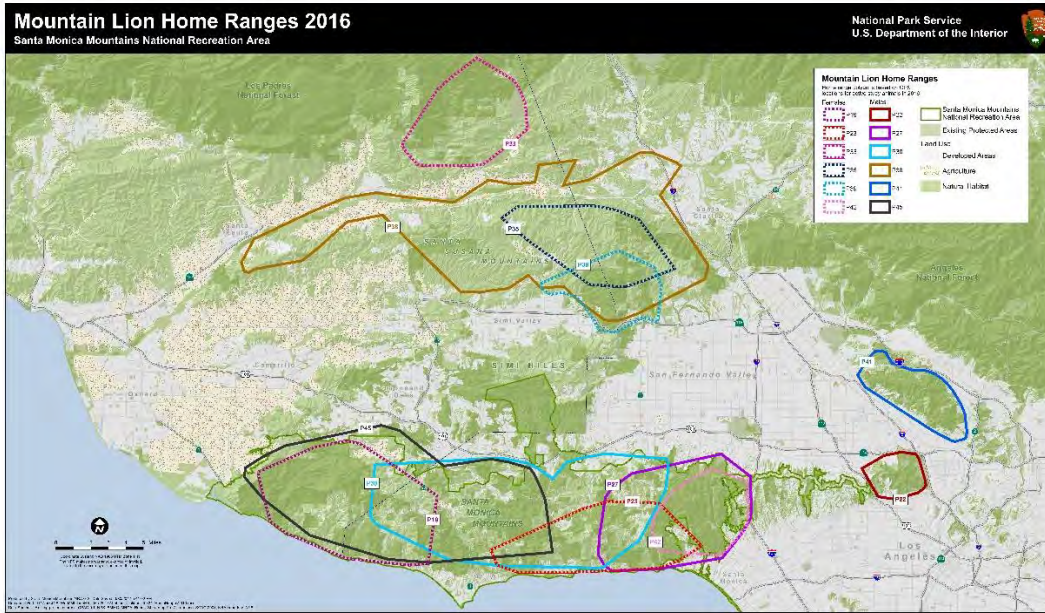

disturbance (Van Dyke et al. 1986). Mountain lions are primarily solitary animals and will repeatedly move and wait as they stalk and ambush their prey (Beier et al. 1995). Once within close proximity, mountain lions will lunge at their prey and kill the animal by crushing the trachea and suffocating it or by breaking its neck at the base of the skull with a bite (Currier 1983; Pierce and Bleich 2003). Instead of eating their kill right away, mountain lions drag their kill to a secluded spot to feed. They cover it with brush and other debris and return to feed at night for up to five days (Currier 1983; Beier et al. 1995). However, the presence or perceived presence of humans has been found to reduce overall feeding time (Smith et al. 2015; Smith et al. 2017).

Deer kill rates vary depending on the sex of the mountain lion, whether or not the female has cubs, and surrounding human land use. Male kill rates have been found to range from 35 to 47 ungulates per year, regardless of housing density (Anderson, Jr. and Lindzey 2003; Cooley et al. 2008; Knopff et al. 2010; Smith et al. 2015). However, kill rates for females differ depending on human disturbance. In lower density housing areas, kill rates of solitary females and females with kittens have been found to be 52-60 and 57-68 ungulates per year, respectively, while females in high density housing areas were found to have a kill rate of 81 ungulates per year (Anderson, Jr. and Lindzey 2003; Cooley et al. 2008; Knopff et al. 2010; Smith et al. 2015). This pattern could be driven by reduced time spent at kill sites in more developed areas, indicating that females are not consuming as much of each carcass and therefore need to kill more prey (Smith et al. 2015). This may reflect a trade-off made by females to choose feeding sites closer to human-disturbed areas and expend more energy killing prey in order to reduce potential encounters with males that pose a threat to themselves or their kittens (Benson et al. 2016b). Another factor that may be contributing to higher kill rates in developed areas is that mountain lions expend more energy traveling faster and farther in human-dominated landscapes and therefore require increased caloric intake compared to mountain lions away from developed areas (Wang et al. 2017).

## 2.5 *Habitat Requirements*

Mountain lions are primarily solitary (except in certain situations, such as when breeding, when females are rearing cubs, or when dispersing with siblings), territorial cats that occur in low density. They require large areas of relatively undisturbed habitats with adequate connectivity to allow for dispersal and gene flow. They have large home ranges that include heterogenous habitats. In the United States these often consist of pine forests, riparian and oak woodlands, streams, chaparral, and grasslands, though they are also known to occur in desert habitats (e.g., Figure 3).

**Figure 3.** Home ranges of mountain lions being actively studied in 2016 by NPS in and near the Santa Monica Mountains. Source: NPS.

Mountain lions have been found to utilize different habitats within a 24-hour period (Dickson and Beier 2002; Dickson et al. 2005; Dickson and Beier 2006; Kertson et al. 2011; Zeller et al. 2017). Riparian habitats were found to be preferred over grasslands and human-disturbed areas during the day, which likely represents the animals resting in areas with understory vegetation for cover (Dickson and Beier 2002; Dickson et al. 2005). However, nocturnal movement patterns showed that mountain lions utilize a broad range of habitats as they travel through their home ranges and hunt (Dickson et al. 2005). Although riparian vegetation was the highest ranked habitat for nocturnal use, usage of riparian areas was not statistically different from the use of scrub, chaparral, grasslands, or woodlands (Dickson et al. 2005).

Nocturnal patterns of movement and stasis suggest that mountain lions generally avoid areas with human disturbance (*i.e.*, residential developments and two-lane paved roads) and use a variety of habitats to stalk and pursue their prey (Dickson and Beier 2002; Dickson et al. 2005). In addition, Dickson and Beier (2006) found that when mountain lions were traveling or hunting, they preferred canyon bottoms and gentle slopes and used steeper slopes and ridgelines to a lesser extent. And Benson et al. (2016b) found that mountain lions tend to choose feeding sites on steeper slopes in habitats with dense understory vegetation, such as chaparral, scrub, and upland forest. Although mountain lions will use moderately disturbed areas as they travel and hunt (Wilmers et al. 2013; Gray et al. 2016), occupancy is lower in developed areas and they are more likely to use developed areas if they border open spaces (Wang et al. 2015). Thus, mountain lions require a habitat mosaic that provides sufficient room to roam away from human-disturbed areas and connected to expansive, intact, heterogeneous habitats (Beier 1995; Dickson and Beier 2002; Dickson et al. 2005; Kertson et al. 2011; Zeller et al. 2017).

Home range size can vary depending on geographic area, season, sex, reproductive status, and prey density (Currier 1983; Grigione et al. 2002; Riley et al. 2014). Males generally have

much larger home ranges than females, and females with cubs tend to have even smaller home ranges (Beier et al. 1995; Grigione et al. 2002). Male home ranges tend to include partially or entirely overlapping female home ranges, and to a limited extent, they may partially overlap with other male home ranges (Figure 3) (Seidensticker et al. 1973; Currier 1983; Pierce and Bleich 2003). Mountain lions mark their home ranges with scrapings in the ground, often containing urine or feces (Seidensticker et al. 1973). Males make scrapings more often than females (Allen et al. 2014b), and females may only make scrapings when they are in estrous (Seidensticker et al. 1973; Currier 1983; Pierce and Bleich 2003).

Seasonal variation in home range size can differ depending on geographic area. Grigione et al. (2002), found strong influences of seasonality in average mountain lion home ranges in the Sierra Nevada mountains, with much larger home ranges in the summer (541km<sup>2</sup> for females, 723km<sup>2</sup> for males) compared to those in the winter (349km<sup>2</sup> for females, 569km<sup>2</sup> for males). These patterns likely reflect the abundance and distribution of deer – during the winter deer would be concentrated at lower elevations, which allowed mountain lions to reduce their home ranges, while in the summer deer could disperse to higher elevations and the mountain lions would expand their ranges accordingly (Grigione et al. 2002). However, seasonal variation was not as pronounced and had the reverse trend in Coastal California mountain ranges, including in the SAM, where the average area of winter home ranges was slightly larger (100km<sup>2</sup> for females, 350km<sup>2</sup> for males) than summer home ranges (90km<sup>2</sup> for females, 300km<sup>2</sup> for males) (Grigione et al. 2002). These differences were not statistically significant, and this pattern is likely due to the moderate year-round climate in the coastal ranges, where prey abundance and distribution does not exhibit as extreme shifts as those in the Sierra Nevada (Grigione et al. 2002). This generally aligns with Zeller et al. (2017), who found that mountain lion home ranges in the SAM and EPR ranged from 41-497 km<sup>2</sup>, with mean home range sizes of 188km<sup>2</sup> for females and 316 km<sup>2</sup> for males. And Riley et al. (2014) found that CC-S mountain lions had home ranges similar in size to the SAM and EPR mountain lions, with female home ranges being 100-200km<sup>2</sup> and male home ranges being 300-500 km<sup>2</sup>. According to the Santa Cruz Puma Project, in the Santa Cruz Mountains female home ranges are on average about 100 km<sup>2</sup> and male home ranges are about 230 km<sup>2</sup> (Santa Cruz Puma Project 2015). Although studies are limited regarding the home range size of the CC-C and SGSB mountain lions, given their close proximity and similar seasonality to other Central Coast and Southern California populations, they are likely similar.

## 2.6 *Survivorship and Mortality*

According to the National Park Service (NPS), mountain lions can live up to 13 years in the wild. As a top carnivore with no natural predators, conspecifics and humans are the main drivers of mountain lion survivorship and mortality. Although studies regarding kitten (<18 months), subadult (18-30 months), and adult (>30 months) survivorship are limited, some long-term studies of radio-collared mountain lions on the CC-S, SAM, and EPR provide valuable insights for these Central Coast and Southern California populations (Beier and Barrett 1993; Riley et al. 2014; Vickers et al. 2015).

In a study conducted in the CC-S area (which encompasses the Santa Monica Mountains, Simi Hills, and Santa Susana Mountains) that included 42 mountain lions from 2002 to 2012, Riley et al. (2014) found an annual adult survival of  $\geq 75\%$ , though Benson et al. (2016a) found

lower subadult survival rates. Although adult survival in the CC-S is similar to previous studies conducted in California and the southwestern US (Beier 1993; Logan and Sweanor 2001), it is higher than what was found in the SAM and EPR populations during the same time period. From following 74 radio-collared mountain lions from 2001 to 2013, Vickers et al. (2015) found an annual survival rate across all age groups of 56.5% and 55.4% in the SAM and EPR, respectively.

In the Santa Monica Mountains: Female mountain lion P-23 hunted down a deer on Mulholland Drive (left). In 2018 she was killed by a vehicle strike on Malibu Canyon Road. An uncollared mountain lion killed by a vehicle strike on Malibu Canyon Road in 2004 (right). Photos: NPS

Vehicle strikes, depredation kills, and intraspecific strife (including male aggression towards conspecifics and infanticide) are the primary causes of mortality in the Central Coast and Southern California populations (Beier 1993; Riley et al. 2014; Vickers et al. 2015). Other known causes of death in California mountain lion populations include rodenticide poisoning, disease, poaching/illegally killing, starvation/abandonment, public safety removal, and human-caused wildfires (Beier 1993; Riley et al. 2014; Vickers et al. 2015). Causes of mortality will be discussed more in depth in *Section 5.0 Abundance and Population Trends* and *Section 6.0 Factors Affecting Ability to Survive and Reproduce*.

### **3 Southern California and Central Coast Mountain Lions Comprise an Evolutionarily Significant Unit**

#### *3.1 CESA Provides for Listing of ESUs*

CESA defines an “endangered species” as a species or subspecies of animal or plant that is in serious danger of becoming extinct through either all or “a significant portion” of its range. (Cal. Fish & Game Code § 2062.) A “threatened species” is likely to become an endangered species in the foreseeable future in the absence of special protection and management efforts. (Cal. Fish & Game Code § 2067.) CDFW has concluded—and appellate courts have upheld—that the term “range” is construed to refer to the range of a species or subspecies *within* California, not the worldwide range of the species or subspecies. (*California Forestry Assn. v. California Fish & Game Com.* (2007) 156 Cal.App.4th 1535, 1550-551.) This means that a species or subspecies which may not be endangered in other states or countries may still be endangered within California. Courts also have confirmed that the phrase “significant portion” of

a range authorizes CDFW to designate certain populations of a species or subspecies as “evolutionarily significant units” or “ESUs” and list such populations as endangered under CESA. (*Id.* at 1549; *Central Coast Forest Assn. v. Fish & Game Com.* (2018) 18 Cal.App.5th 1191, 1236-37 [“CCFA IP”].) In other words, ESUs are a population of a species or subspecies “that is considered distinct for purposes of conservation.” (*Central Coast Forest Assn. v. Fish & Game Com.* (2012) 211 Cal.App.4th 1433, 1439 fn 5 [depublished] [“CCFA P”].)

CDFW has confirmed that the use of ESUs to evaluate the status of species pursuant to CESA is appropriate.<sup>5</sup> In the *Status Review of Fisher*, CDFW designated fishers in northern California and the southern Sierra Nevada as two separate ESUs based upon the reproductive isolation of these fisher populations and the degree of genetic differentiation between them. In designating these ESUs, CDFW highlighted the need to maintain “geographically widespread and genetically diverse” populations of the species.

### 3.2 *Southern California and Central Coast Mountain Lions are Significantly Reproductively Isolated from Other Populations and Form an ESU*

Southern California and Central Coast mountain lion populations could be grouped into one or several potential ESUs. However, petitioners believe that for purposes of listing under CESA, treating the CC-N, CC-C, CC-S, SAM, SGSB, and EPR populations as a single Southern California/Central Coast ESU is both supported by the best available science and makes sense from a management perspective. Gustafson et al. (2018) suggest that the North Coast and inland populations (Nevada, Eastern Sierra Nevada, and Western Sierra Nevada) may form an ESU (hereinafter “North Coast/Inland ESU”) given that they were found to be genetically diverse and well-connected. Due to extreme isolation and high levels of human-caused mortalities, functional connectivity between Southern California and Central Coast mountain lion populations and the healthier North Coast/Inland ESU has become severely impaired (Gustafson et al. 2018, see further discussion in *Section 2.2 Taxonomy and Population Genetics* and *Section 6.0 Factors Affecting Ability to Survive and Reproduce*). There is a tenuous link made up of small mountain ranges (*i.e.*, Tehachapi and Sierra Pelona Mountains) that connect the North Coast/Inland ESU with the proposed Southern California/Central Coast ESU. Thus, although there is some (limited) connectivity between the North Coast/Inland ESU and the proposed ESU, as a practical matter under current management the two ESUs are functionally isolated.

Southern California and Central Coast populations have lower levels of genetic diversity and are relatively disconnected from each other compared to North Coast and inland populations. The Central Coast populations form a genetic cluster while the SAM and EPR populations form a second, less connected genetic cluster (Figure 4) (Gustafson et al. 2018). The SGSB population, though isolated, is most genetically similar to the Western Sierra Nevada, CC-C, and EPR populations, which indicates that it is an important intersection for statewide genetic connectivity (Figure 4) (Gustafson et al. 2018).

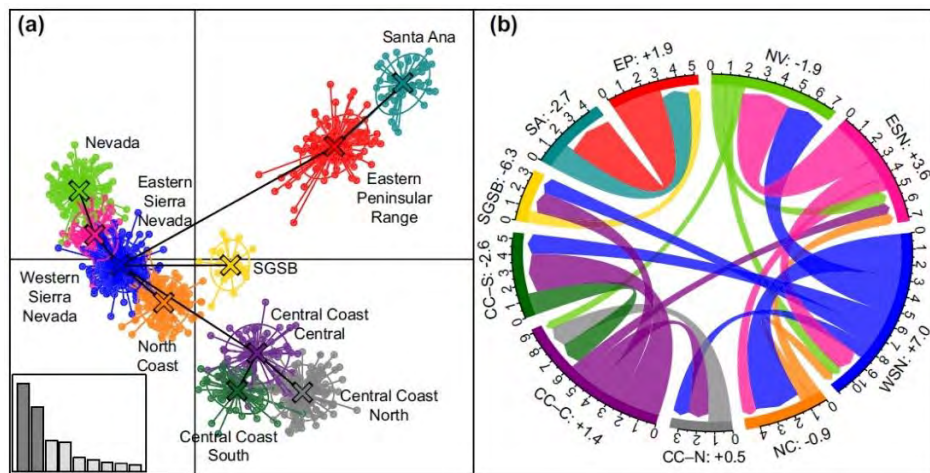

Genetic source-sink dynamics are informative in determining gene flow among the populations and how they are connected. Five genetic source populations were identified: the

---

<sup>5</sup> California Department of Fish and Wildlife, *Status Review of Fisher* (June 10, 2015), available at <https://nrm.dfg.ca.gov/FileHandler.ashx?DocumentID=101470>.

Eastern and Western Sierra Nevada populations, CC-N, CC-C, and EPR (Gustafson et al. 2018). The Sierra Nevada populations were the greatest genetic source populations and the CC-N population had only weak evidence of being a source population (Gustafson et al. 2018). The CC-S, SGSB, and SAM were identified as genetic sink populations with limited connectivity to source populations (Figure 4) (Gustafson et al. 2018). Maintaining and reestablishing genetic connectivity with source populations like the CC-C, EPR, and Western Sierra Nevada populations are important for the long-term viability of Southern California and Central Coast populations (Ernest et al. 2014; Riley et al. 2014; Vickers et al. 2015; Benson et al. 2016a; Gray et al. 2016; Gustafson et al. 2017). This underscores the importance of the Tehachapi and Sierra Pelona Mountains as the key remaining linkage, though tenuous, for statewide genetic connectivity.

**Figure 4.** Functional connectedness of California mountain lion populations. Each color represents a genetically distinct population. In (a), the results of the discriminant analysis of principal components shows connectivity among California mountain lions. The x-axis represents latitude with north to the left and south to the right. The y-axis represents longitude, separating the Central Coast populations from Southern California populations. In (b), estimated migration rates between populations are shown. Source-sink dynamics are indicated by positive (source) or negative (sink) net migration rates. Source: Gustafson et al. (2018).

While genetics as currently understood could support several different ESU formulations, petitioners believe a single Southern California/Central Coast ESU is the most pragmatic from a management perspective, as recovery of the individual subpopulations ultimately depends upon maintaining and/or reestablishing connectivity between them. *See CCFA II*, 18 Cal.App.5th 1191, 1237 (“[T]he nature of the ESU designation is such that genetics alone are not determinative: One must look beyond genetics to questions of policy to determine which populations to include in an ESU.”) (quotations omitted). Designating Southern California and Central Coast mountain lions as an ESU would help ensure “geographically widespread and genetically diverse” populations of mountain lions in California.

While petitioners believe that listing of a single Southern California/Central Coast ESU as threatened is both a permissible and prudent course of action for the Commission, petitioners also request that as additional data become available over the course of CDFW conducting its status review that the agency also assess other possible ESU formulations for Southern California and Central Coast mountain lions. One such formulation would be to group all three Central Coast populations (CC-N, CC-C and CC-S) into one ESU, with the remaining three

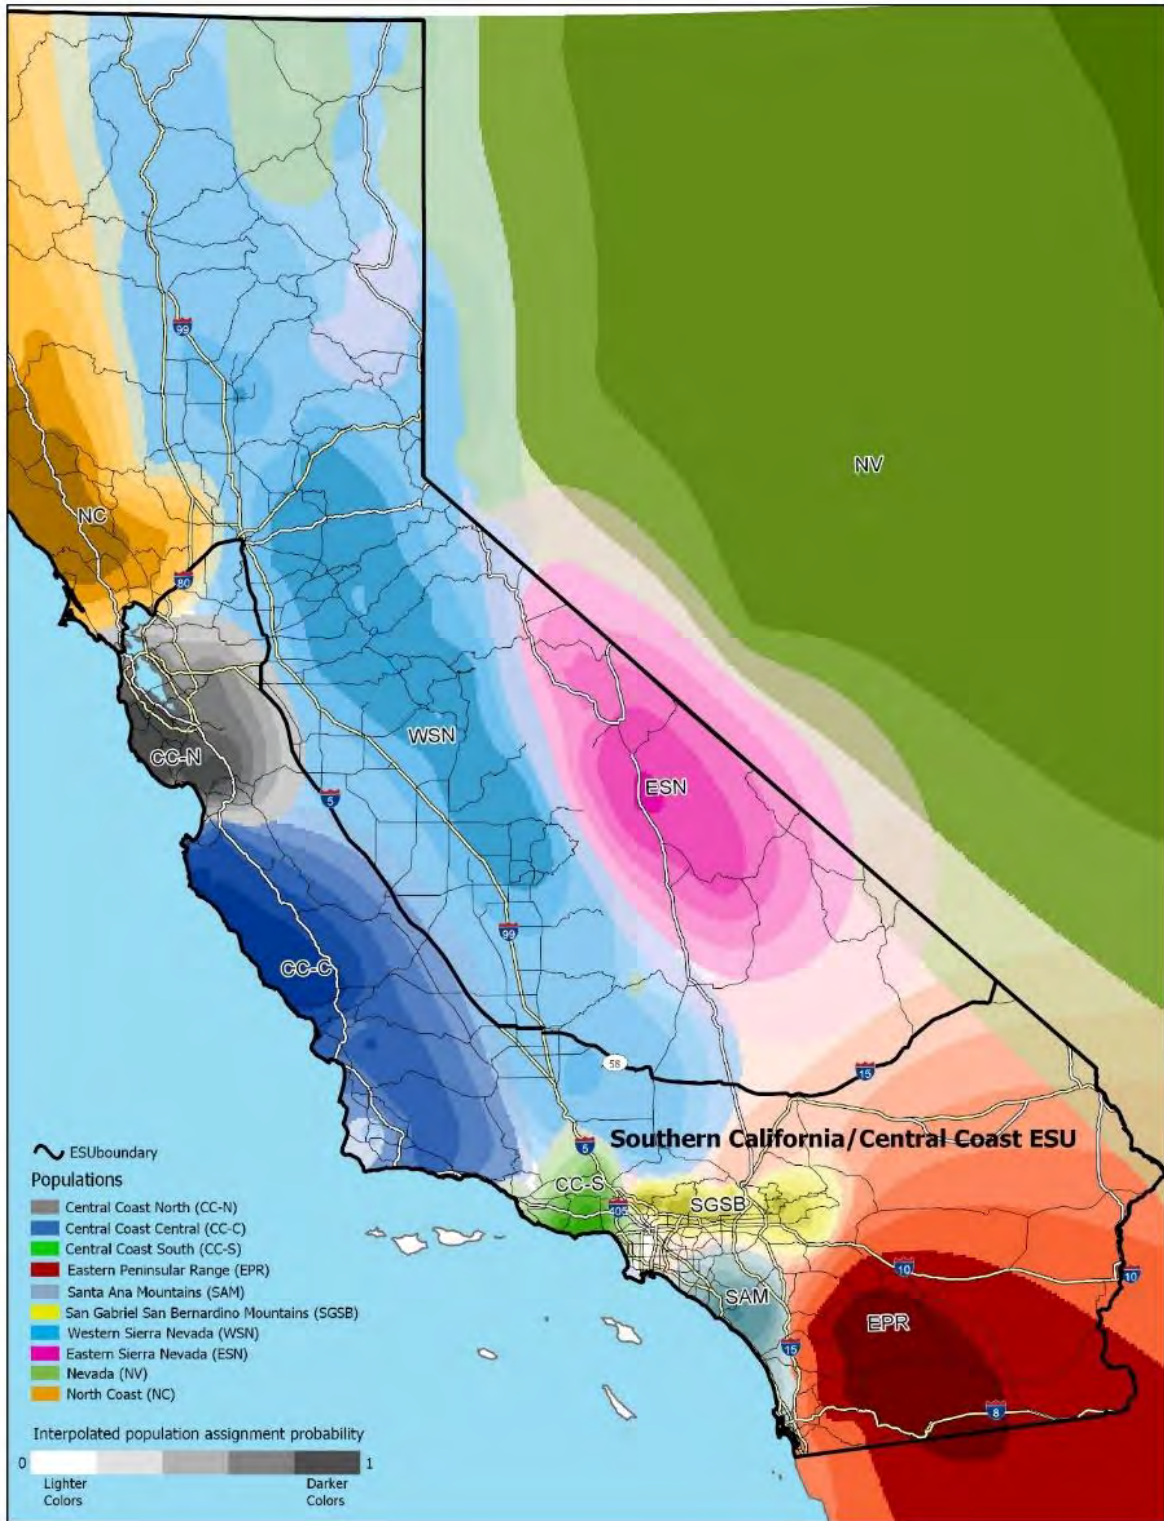

populations placed into a second ESU (SAM, EPR and SGSB). Alternatively, the Central Coast populations could be treated as one ESU, SAM and EPR as a second ESU, and SGSB separately listed as a third ESU. Petitioners believe the genetic data in Gustafson et al. (2018) could support each of these alternative formulations. Lastly, given each of the six populations at issue are themselves already genetically distinguishable and occupy significant portions of the range of mountain lions in California, each could be separately treated as an ESU. Under this formulation, the SAM and CC-S populations would clearly warrant endangered listing, the CC-C and EPR populations would warrant threatened listing, and the CC-N and SGSB populations would warrant at least threatened and likely endangered listing.

### *3.3 Proposed Boundary of the Southern California/Central Coast ESU*

We propose the Southern California/Central Coast ESU to include mountain lions that occur in areas east of the Pacific Ocean, south of the San Francisco Bay Area waters and I-80, west of I-5 to the intersection of I-5 and SR-58 at Bowerbank/Buttonwillow, south of SR-58 to I-15, south of the I-15 from the SR-58 intersection to the California-Nevada border, and, for the purposes of CESA, north of the California-Mexico border (Figure 5). These boundaries are recommended as they include virtually all mountain lions associated with the six populations comprising the ESU and are also unambiguous and readily discernable for purposes of management.<sup>6</sup>

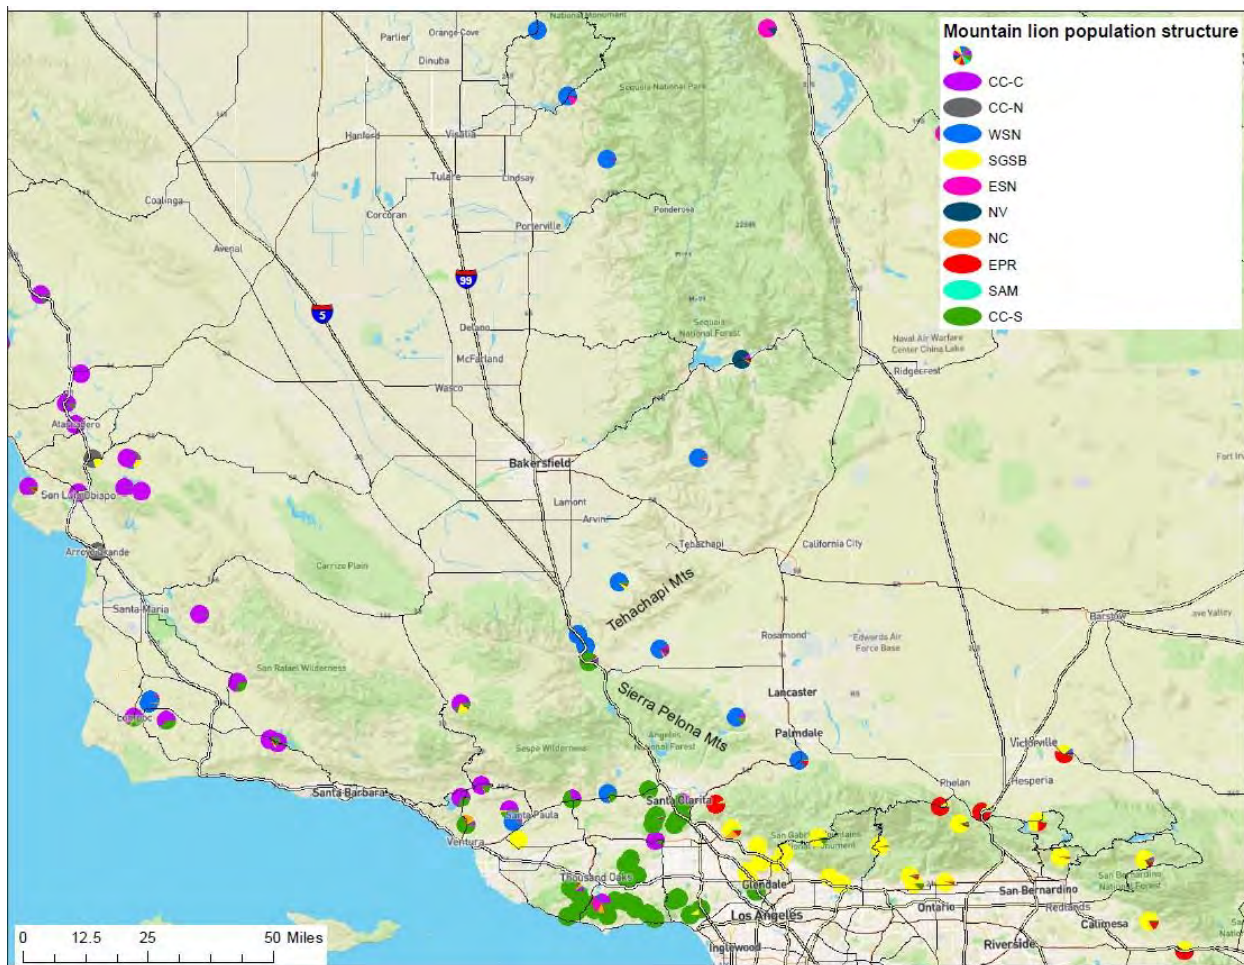

---

<sup>6</sup> In the event the Commission determines that the proposed ESU should instead be treated as separate Southern California (SAM, EPR, SGSB) and Central Coast (CS-N, CS-C, CS-S) ESUs, we propose the boundary between them to be delimited by I-5 and I-710.

**Figure 5.** Map of the Southern California/Central Coast ESU boundary. Derived from Gustafson et al. (2018). Genetics data source: Kyle Gustafson, PhD, Department of Biology and Environmental Health, Missouri Southern State University, and Holly Ernest, DVM, PhD, Department of Veterinary Sciences, Program in Ecology, University of Wyoming, Laramie. Roads data source: ESRI.

We recommend including mountain lions in the Tehachapi and Sierra Pelona Mountains south of SR-58 in the Southern California/Central Coast ESU. While most mountain lions sampled from this region share some genetic affinities with Western Sierra Nevada (WSN) animals, individuals sampled in the Tehachapi Mountains and surrounding areas, including the Sierra Pelona Mountains in the Angeles National Forest and the Los Padres National Forest, had genetic structures made up of multiple genetic populations from the northern, central coastal, and southern populations (Figure 6). This area serves not just as a connecting link between mountain lion populations comprising the Southern California/Central Coast ESU, but also between this ESU and all other California mountain lions. The Tehachapi and Sierra Pelona Mountains are the last remaining linkages for statewide genetic connectivity and are critical for the overall genetic health of Southern California and Central Coast mountain lions. Consequently, mountain lions in these areas should be considered part of the listed entity.

**Figure 6.** Map of mountain lion genetic structure in and surrounding the Tehachapi and Sierra Pelona Mountains, the last remaining linkage between the coastal, southern, and northern populations. Data source: Kyle Gustafson, PhD, Department of Biology and Environmental Health, Missouri Southern State University, and Holly Ernest, DVM, PhD, Department of Veterinary Sciences, Program in Ecology, University of Wyoming, Laramie.

### 3.4 *Southern California and Central Coast Mountains Lions are Essential to the Region's Biodiversity*

Additional support for designation of a Southern California/Central Coast ESU is provided by the fact that mountain lions are a keystone species critical to maintaining biodiversity in coastal California's ecosystems. The loss of these mountain lions—which are the only remaining large predator in the region—would lead to a trophic cascade wherein deer populations would increase and overgraze vegetation due to the lack of predation and lack of risk of predation, causing other repercussions to other species and habitats (Ripple and Beschta 2006; Ripple and Beschta 2008; Ripple et al. 2014). In addition, their kills are an important source of food for multiple terrestrial and avian scavengers (Ruth and Elbroch 2014; Elbroch et al. 2017; Barry et al. 2019).

Ripple and Beschta (2006) highlighted the critical role of mountain lions in western ecosystems by comparing habitat quality and the levels of biodiversity in two separate areas of Zion National Park – Zion Canyon, which mountain lions generally avoid due to high human presence, and North Creek, which mountain lions inhabit due to less human presence. The sustained lack of mountain lions in Zion Canyon has led to an unnaturally high density of deer, which has had profound impacts on Zion Canyon ecosystems. Ripple and Beschta (2006) observed Zion Canyon had low numbers of hydrophytic plants, wildflowers, amphibians, lizards, and butterflies while North Creek had significantly higher numbers in each of these categories.

North Creek riparian areas had well vegetated and stable banks while Zion Canyon lacked bank vegetation and its banks were continuing to erode (Ripple and Beschta 2006). The study noted that such geomorphic transformation of stream channels where mountain lions were absent were caused by plant loss on stream banks, which led to high levels of erosion and sedimentation, less shading and higher water temperatures, a larger width:depth ratio in streams, loss of hydrologic connectivity with historical floodplains, and loss of a wide variety of species, including native plants, benthic invertebrates, butterflies, fish, amphibians, and reptiles (Ripple and Beschta 2006).

The study concluded that removing a large carnivore from an ecosystem “appears to have [] profound effects on lower trophic levels, as well as multiple indicators of ecosystem status and native species abundance.” (Ripple and Beschta 2006.) A similar study found that in Yosemite Valley—where mountain lions are largely absent due to high human presence—deer populations have expanded leading to a lack of oak recruitment and a decrease in biodiversity (Ripple and Beschta 2008). And their kills support disproportionately high levels of mammal, bird, and invertebrate diversity (Ruth and Elbroch 2014; Elbroch et al. 2017; Barry et al. 2019) and may even play a role in tree and other vegetation growth (Ruth and Elbroch 2014). In sum, extinction of Southern California and Central Coast mountain lions would result in degraded habitats and reduced abundance and diversity of other species, likely undermining the biological diversity, ecosystem function, and resilience of California's coastal regions.

### 3.5 *Californians Derive Aesthetic, Recreational, and Economic Value from Southern California and Central Coast Mountain Lions*

The people of California derive aesthetic, recreational, economic, spiritual, scientific, educational, and emotional value from Southern California and Central Coast mountain lions. For instance, the City of Los Angeles has designated October 22 as “P-22 day” to honor a young (and mate-less) male mountain lion that lives in Griffith Park and to acknowledge the importance of Southern California mountain lions to the region. Many people view mountain lions as a symbol of wildness and cherish landscapes that still are home to these predators. People from within and beyond the region choose to recreate, hike, bike, camp, fish, and hunt in California’s wildlands in part because they enjoy exploring and sharing landscapes with mountain lions. And these activities are a significant economic driver for the state: A report commissioned for California State Parks found that direct outdoor recreation expenditures for Los Angeles, Southern California, the Central Coast and the San Francisco Bay Area totaled nearly \$15 billion per year.<sup>7</sup> The Outdoor Industry Association concluded that outdoor recreation in California generates \$92 billion of consumer spending annually and directly employs 691,000 Californians—more jobs than the wine and television industry combined.<sup>8</sup>

Mountain lions also provide an economic and social benefit because, by controlling deer populations, they reduce collisions between deer and automobiles. There are 1.2 million deer-vehicle collisions in the United States per year, incurring an estimated \$1.66 billion in damages, 29,000 injuries, and 200 deaths (Gilbert et al. 2016). Impacts of deer-vehicle collisions are particularly severe in the eastern United States where white-tailed deer are overabundant. Gilbert et al. (2016) determined that if mountain lions recolonized the eastern United States, their presence would result in a 22 percent decline in deer-vehicle collisions over thirty years.

It is estimated that 7,000 to 23,000 wildlife vehicle collisions have occurred annually on California roads (Shilling et al. 2017; Shilling et al. 2018; State Farm Insurance Company 2016, 2018). These crashes result in human loss of life, injuries, emotional trauma, and property damages that can add up to \$300-600 million per year (Shilling et al. 2018). If Southern California and Central Coast mountain lions became extinct, there would likely be a significant increase in deer-vehicle collisions in the region, along with associated human fatalities, injuries, and property damage.

An overabundance of deer in the eastern United States is also linked to an increase in ticks, which has led to increased incidences of Lyme disease among humans (Telford 2017; Côté et al. 2004). Lyme disease is now the most common vector-borne illness in the United States, with over 30,000 cases per year, primarily in the eastern United States.<sup>9</sup> Increases in deer abundance and attendant increases in ticks and tick-borne disease among humans would be

<sup>9</sup> Centers for Disease Control and Prevention, *Lyme Disease Data and Surveillance*, available at [https://www.cdc.gov/lyme/datasurveillance/index.html?CDC\\_AA\\_refVal=https%3A%2F%2Fwww.cdc.gov%2Flyme%2Fstats%2Findex.html](https://www.cdc.gov/lyme/datasurveillance/index.html?CDC_AA_refVal=https%3A%2F%2Fwww.cdc.gov%2Flyme%2Fstats%2Findex.html).

expected if Southern California and Central Coast mountain lions became extinct. Loss of Southern California and Central Coast mountain lions would have far-reaching effects not only on California's ecology, but also on public health and the region's economy.

Protection of Southern California and Central Coast mountain lions under CESA would confirm that this species is a vital member of our ecosystems which is worthy of protection. Conservation of these mountain lions would provide compelling evidence that large carnivores and abundant human populations can co-exist, even in densely populated landscapes (Benson et al. 2019).

#### 4 Historical and Current Distribution

Mountain lions once had the most expansive range of any New World terrestrial mammal (Seidensticker 1991). They roamed most of the Americas (excluding most of Alaska and the northern areas of Canada) from approximately 50° N to 50°S latitude and could be found from sea level to about 4,000m elevation (Young and Goldman 1946, Pierce and Bleich 2003) in habitats varying from dense forests, to dry deserts, savannahs, and swamp lands.

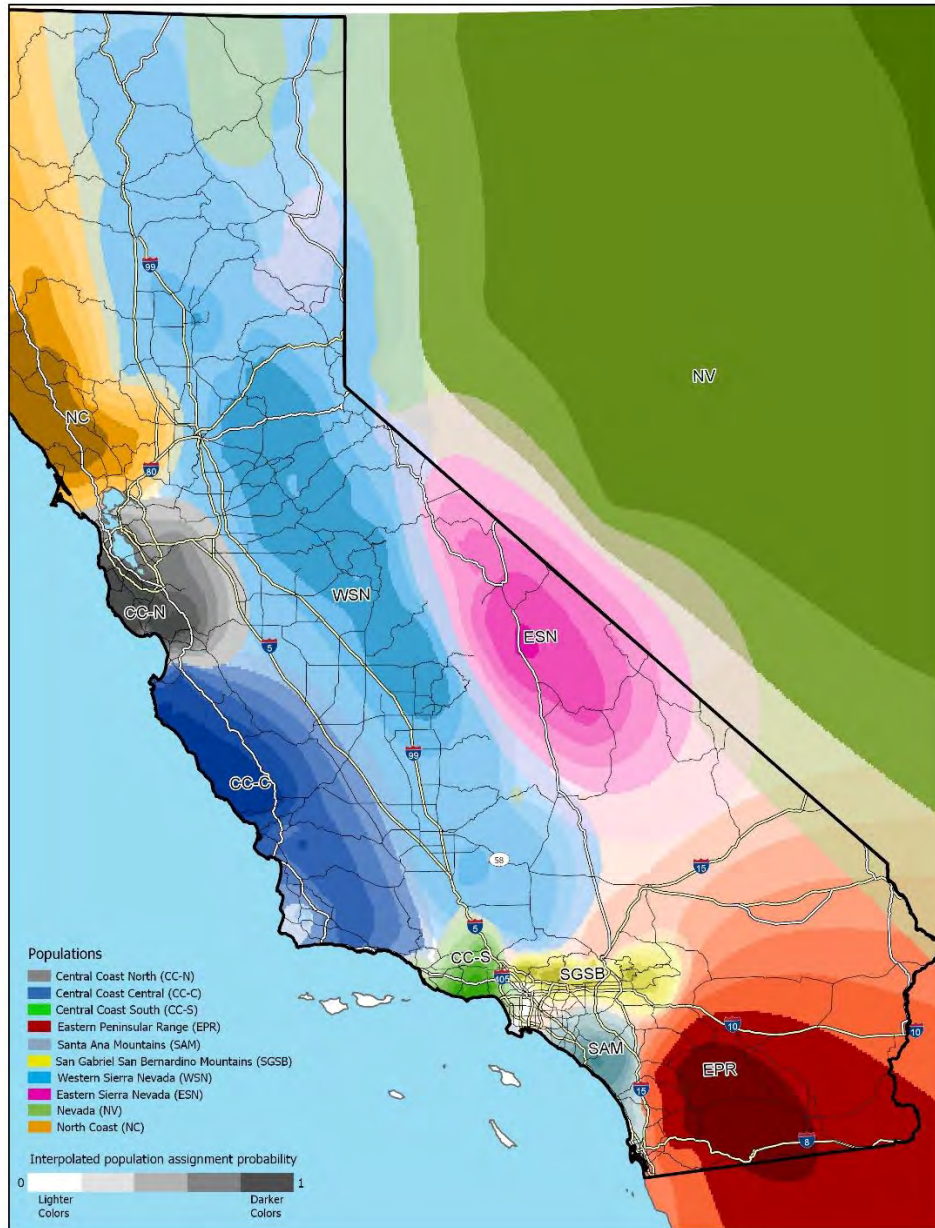

Due to habitat loss and hunting after the arrival of European colonists, the mountain lion's current range has been reduced to one third of its historical range in North America (Figure 7) (Culver et al. 2000; Pierce and Bleich 2003). In the United States, the species' range has been reduced to 15 western states and a small remnant population in Florida (endangered Florida panthers [*Puma concolor coryi*]), with isolated animals occasionally appearing in additional states. Continued hunting pressure and changes in land management practices have pushed most populations into mountainous, relatively unpopulated areas, though isolated populations are known to occur in more urban areas (Currier 1983; Gustafson et al. 2018).

**Figure 7.** Historical and current range of mountain lions. Source: Hansen 1992.

In California, habitat fragmentation from roads and development has led to highly fragmented, divergent populations (Ernest et al. 2003; Ernest et al. 2014; Riley et al. 2014; Vickers et al. 2015; Gustafson et al. 2018). As mentioned in *Section 2.2 Taxonomy and Population Genetics*, nine genetically distinct populations have been identified within California

(Gustafson et al. 2018), with Southern California and Central Coast populations being the most constrained populations, (and a tenth population centered in Nevada but extending slightly into California). Those located in highly urbanized areas of Southern California coastal mountain ranges, including the CC-S, SAM, and SGSB populations are especially restricted (Figure 8) (Vickers et al. 2015; Benson et al. 2016a; Gustafson et al. 2018; Benson et al. 2019).

**Figure 8.** Map of genetically distinct mountain lion populations and major roads in California. The CC-S (which includes the Santa Monica Mountains), SGSB, and SAM populations are exceptionally constrained. The map is based on data collected from 1992-2016 (the division and status of these populations could change over time and with further research. Derived from Gustafson et al. (2018). Genetics data source: Kyle Gustafson, PhD, Department of Biology and Environmental Health, Missouri Southern State University, and Holly Ernest, DVM, PhD, Department of Veterinary Sciences, Program in Ecology, University of Wyoming, Laramie. Roads data source: ESRI.

#### *4.1 Central Coast North (CC-N) Mountain Lion Population*

The CC-N mountain lion population occurs mostly within the counties of Alameda, Contra Costa, San Mateo, Santa Clara, and Santa Cruz (Figure 8). The area is almost divided into two portions: an eastern half and a western half. The Santa Cruz Mountains make up the core area of the CC-N, bound by the Pacific Coast to the west, development lining the San Francisco Bay to the north and north west, and Highway 101 to the south. The eastern portion of the CC-N consists of various open space and nature preserves in the Berkeley Hills and Diablo Range bound by development lining the San Francisco Bay and Highway 101 and associated developments to the west, San Pablo Bay and Suisun Bay and associated developments to the north, I-5 to the east, and State Route 130 (SR-130) to the south. Interestingly, the CC-N seems almost bisected by the San Francisco Bay and Highway 101 and associated developments.

#### *4.2 Central Coast Central (CC-C) Mountain Lion Population*

The CC-C mountain lion population occurs mostly within the counties of Monterey, San Benito, San Luis Obispo, and Santa Barbara. The area encompasses the central and southern portions of the Southern Coast Ranges, including the Santa Lucia Range, Sierra de Salinas, the Temblor Range, and the Sierra Madre Mountains. It is bound by the Pacific Ocean to the west, Highway 101 and SR-156 and associated development to the north, the I-5 and San Joaquin Valley to the east, and SR-126 and associated developments to the south (Figure 8).

#### *4.3 Central Coast South (CC-S) Mountain Lion Population*

The CC-S mountain lion population is limited to the Santa Monica Mountains, Simi Hills, and the Santa Susana Mountains in Ventura and Los Angeles Counties (Figure 8). The Santa Monica Mountains population has the isolated area with about 660 km<sup>2</sup> within the Santa Monica Mountains National Recreation Area (Riley et al. 2014). The Pacific Ocean lies to the south while the cities of Oxnard, Thousand Oaks, San Fernando Valley, Los Angeles, and Santa Monica and major freeways including Highway 101, Interstate 5 (I-5) and Interstate 405 surround the area and create major movement barriers.

The Simi Hills is a smaller area of open space located north of the Santa Monica Mountains; the areas are bisected by Highway 101. This open space is mostly surrounded by development, including Simi Valley to the northwest, Thousand Oaks to the west, Agoura Hills to the southwest, Calabasas to the southeast, and Woodland Hills, Canoga Park, and Chatsworth to the east.

The Santa Susana Mountains are located north of the Santa Monica Mountains and Simi Hills. The area is generally bordered by freeways and the edges of development and agriculture. SR-118 borders the south and southwest, SR-126 borders the north and northwest, and I-5 borders the east.

#### 4.4 *San Gabriel/San Bernardino Mountains (SGSB) Mountain Lion Population*

The SGSB mountain lion population occurs within the Transverse Ranges located northwest of the City of Los Angeles within Los Angeles, Kern, and San Bernardino Counties (Figure 8). The western and southern boundaries of the San Gabriel and San Bernardino Mountains are lined with urban developments and major freeways, including the San Fernando Valley, cities of San Bernardino, Rancho Cucamonga, and West Covina, and the I-5, I-210, and I-10 freeways. The northern and eastern boundaries of the area are abutted by agriculture, suburban development, high desert, and roads.

#### 4.5 *Santa Ana Mountains (SAM) Mountain Lion Population*

The SAM mountain lion population inhabits about 1,533km<sup>2</sup> of undeveloped areas of the SAM within Orange, Riverside, and San Diego Counties (Beier and Barrett 1993; Benson et al. 2019). The area is mostly bound by major freeways and development (Figure 8). SR-241 creates the western boundary, SR-91 borders the northwest boundary, I-5 creates the eastern boundary, and agriculture and development border the southern extent. The closest intact habitat known to be used by other mountain lions is to the east/southeast, in the Peninsular Ranges.

#### 4.6 *Eastern Peninsular Range (EPR) Mountain Lion Population*

The EPR mountain lion population occurs in mountain ranges east of the SAM and south of the San Bernardino Mountains. The EPR is a predominantly north to south range that runs through San Diego, Riverside, and Imperial Counties and the California-Mexico border. They include the San Jacinto, Laguna, and San Ysidro Mountains in California and continue south into the mountain ranges of Baja California, Mexico. The western boundary of the EPR population is lined with roads and urban development, including areas around the cities of Escondido, San Diego, and Chula Vista. Studies regarding the northern, southern, and eastern extent of the population are limited; however, movement patterns documented by Vickers et al. (2015) and Vickers et al. (2017) between 2001 and 2016 suggest that EPR mountain lions generally stay north of the U.S. – Mexico border, along the edges of the desert that borders the east side of the EPR, and south of I-10. Although the EPR population has been found to be largely disconnected from all other California populations, some mountain lion movement was documented traversing between the EPR and SGSB (Vickers et al. 2015), which would have occurred at the northern boundary of the EPR, and there is evidence of limited genetic exchange between the two populations (Gustafson et al. 2018). In addition, one young male mountain lion was documented to the south using the Parque-to-Park Linkage to cross the US-Mexico border several times (where the terrain is too rugged to install a border wall), but he was eventually killed in Mexico in a collision with a vehicle (Vickers et al. 2015; W. Vickers *unpublished data*). Little is known about the mountain lions south of the border, but the movement patterns of EPR mountain lions suggest that they may form a discrete population within the EPR north of the US-Mexico border (Vickers et al. 2015; Vickers et al. 2017).

## 5 Abundance and Population Trends

According to the International Union for Conservation of Nature (IUCN), mountain lion populations are decreasing throughout their remaining range (Nielsen et al. 2015). Mountain lion population densities are generally low, which may be driven by prey density, competition between males for access to females, and mutual avoidance (Pierce and Bleich 2003). In the United States, population densities for mountain lions have been found to range from 0.4 to 4.3 resident adults per 100km<sup>2</sup> and 0.4 to 7.1 total mountain lions per 100km<sup>2</sup>, though it varies by population and the presence of human-induced pressures (*e.g.*, hunting) (Pierce and Bleich 2003). In California, where hunting has been outlawed but other anthropogenic pressures such as roads and development are present, resident adult and total population densities have been found to be 1.1 and 3.6 per 100 km<sup>2</sup>, respectively (Pierce and Bleich 2003). Adult sex ratio has been reported to be about 2-3:1 in favor of females (Hornocker 1970; Seidensticker et al. 1973; Beier 1993; Santa Cruz Puma Project 2015). These low population densities and female-biased sex ratios further highlight the species' need for expansive, connected, heterogeneous habitats to support viable populations.

It has been estimated that 4,000 to 6,000 adult mountain lions roam California (Mansfield and Weaver 1989). However, CDFW acknowledges that this estimate from 1984 is outdated and relied on density estimates from regional studies to derive a statewide abundance. The agency has since declared that the number of mountain lions throughout the state is unknown, and they have embarked on an intensive statewide research project to better understand mountain lion numbers regionally and throughout the state.<sup>10</sup> Working with other agencies, academic institutions, and non-profits, CDFW plans to have statewide and region-specific mountain lion population estimates by 2022 (Vaughan 2018).

As mentioned in *Section 2.2 Taxonomy and Population Genetics*, one way in which the abundance of mountain lions can be estimated is with the ratio of effective to total adult population size ( $N_e/N$ ) of 0.25 to 0.5, as was used by USFWS to generate an abundance estimate for the endangered Florida panther (Ballou et al. 1989; USFWS 2008). Using this method with the estimated effective population sizes of the nine genetically distinct mountain lion populations centered in California from Gustafson et al. (2018) and Benson et al. (2019), the statewide total population would be 818 to 1,634 individuals (255 to 510 in the Central Coast and Southern California populations [Table 1], and 563 to 1,124 in the remaining Eastern Sierra Nevada, Western Sierra Nevada, and North Coast populations), which is much lower than the 4,000 to 6,000 estimate. This is also well below the recommended minimum viable population size of at least 5,000 adult individuals for the long-term persistence of a population (Frankham 1995; Reed et al. 2003; Traill et al. 2010). Petitioners recognize that the  $N_e/N$  methodology has limitations and is but one method of generating an overall abundance estimate. More studies are needed to determine regional and statewide mountain lion abundance, including CDFW's ongoing efforts which should produce a more scientifically robust statewide abundance estimate.

---

<sup>10</sup> CDFW 2018 - Commonly Asked Questions About Mountain Lions. Accessed on 11 April 2019 at: <https://www.wildlife.ca.gov/Conservation/Mammals/Mountain-Lion/FAQ#359951241-how-many-mountain-lions-are-in-california>

Despite unknown statewide population estimates, researchers have been closely tracking several of the Central Coast and Southern California populations. Through their published studies and reports they provide some insights regarding abundance and population trends for these populations.

### 5.1 *Central Coast North (CC-N) Mountain Lion Population*

Studies on the CC-N mountain lion population are limited, and abundance and population trends are unknown. However, with an effective population size of 16.6 (Gustafson et al. 2018), and an  $N_e/N$  of 0.25 to 0.5 (Ballou et al. 1989; USFWS 2008), the estimated total adult population would be 33 to 66 individuals (see Table 1). As mentioned previously in *Section 2.2 Taxonomy and Population Genetics*, these numbers are grossly insufficient to prevent inbreeding depression in the short term or maintain evolutionary potential in the long term (Jamieson and Allendorf 2012; Frankham et al. 2014).

Gustafson et al. (2018) found that this population has low genetic diversity and a low effective population size, which suggests that it is at increased risk of inbreeding depression within five generations and eventual extinction. Ongoing studies in the Santa Cruz Mountains highlight high levels of human-caused mortalities. Depredation kills are the leading cause of death in collared mountain lions in the Santa Cruz Mountains (Wang et al. 2017), and CDFW reported 34 depredation kills between 2010 and 2016 in the CC-N counties of Alameda, Contra Costa, San Mateo, Santa Clara, and Santa Cruz (see Appendix A<sup>11</sup>). In addition, at least six mountain lions have been killed by vehicle strikes on Highway 17 in the Santa Cruz Mountains between 2008 and 2018 (Midpensinsula Regional Open Space 2017; Slade 2018) and news outlets reported at least three mountain lions killed by vehicle strikes on the I-280 in San Mateo County between 2014 and 2016 (Wilmers 2014, CBS SF 2015, Kamala 2016). The poor genetic health of the CC-N population is likely due to habitat fragmentation and isolation caused by roads and development combined with high levels of human-caused mortalities. CDFW has identified the Santa Cruz Mountains population as at risk due to current habitat and genetic concerns, at-risk internal habitat and connectivity, limited external connectivity, and lack of protected habitat (Dellinger 2019). Poor connectivity and continued development in the CC-N will likely lead to further isolation, increased human-caused mortalities, decreased genetic diversity, and increased risk of extinction in the foreseeable future.

### 5.2 *Central Coast Central (CC-C) Mountain Lion Population*

Studies on the CC-C mountain lion population are limited, and abundance and population trends are unknown. However, with an effective population size of 56.6 (Gustafson et al. 2018), and an  $N_e/N$  of 0.25 to 0.5 (Ballou et al. 1989; USFWS 2008), the estimated total adult population would be 113 to 226 individuals (see Table 1).

Although Gustafson et al. (2018) found that this population has intermediate levels of genetic diversity and the highest effective population size among the Central Coast and Southern

---

<sup>11</sup> These data were downloaded from the CDFW website; however, they no longer appear to be available online. These numbers have been shown to be low by a factor of two in some areas, likely due to incomplete reporting, and therefore should be considered absolute minimums (W. Vickers, *pers comm*).

California mountain lion populations, with an effective population size of 56.6, it just barely exceeds the older standard of 50 to prevent inbreeding depression in the short-term (Frankham et al. 2014; Gustafson et al. 2018). In addition, it falls well below the recommended newer standard of 100 and is insufficient for the long-term viability of the population (Frankham et al. 2014). And the lack of sufficient protected lands and high rates of development in the area threaten the persistence of this population (Dellinger 2019). Thus, although the CC-C population appears to be the healthiest population in the Central Coast and Southern California, it is still at increased risk of inbreeding depression and extinction, and connectivity to smaller adjacent areas should be improved (Dellinger 2019).

### 5.3 Central Coast South (CC-S) Mountain Lion Population

The NPS has been studying the CC-S population since 2002, though most studies regarding population dynamics focus on the Santa Monica Mountains mountain lions (Riley et al. 2014; Benson et al. 2019). Since 2002, NPS has collected data from 55 mountain lions within the Santa Monica Mountains and 19 mountain lions from the Simi Hills and Santa Susana Mountains.<sup>12</sup> There are currently 20-25 live mountain lions being tracked in the Santa Monica Mountains, 7-12 of which are adults (born in 2014 or earlier, the status of 5 adults are unknown) and 13 of which are juveniles or subadults (born in 2015 or later).<sup>13</sup> Given that the Santa Monica Mountains area is relatively small, adult survival rate is high ( $\geq 75\%$ ), and juvenile/subadult survival is low due to intraspecific strife and the inability to disperse, the Santa Monica Mountains population is likely space-limited and these numbers may represent the Santa Monica Mountains' carrying capacity (Riley et al. 2014; Benson et al. 2019). As mentioned previously in *Section 2.2 Taxonomy and Population Genetics*, the extremely low effective population size and total adult population size are grossly insufficient to prevent inbreeding depression in the short term or maintain evolutionary potential in the long term (Jamieson and Allendorf 2012; Frankham et al. 2014). And CDFW has identified the CC-S population as at risk due to current habitat and genetic concerns, at-risk internal habitat and connectivity, limited external connectivity, and lack of protected habitat (Dellinger 2019).

The long-term survival of the Santa Monica Mountains population is severely threatened due to extreme habitat fragmentation and isolation caused by surrounding roads and development that impede movement in or out of the area (Riley et al. 2014). Limited space and lack of connectivity with suitable mountain lion habitat inhibit dispersal for subadults and likely drive unusually high levels of intraspecific strife, which is the most common cause of mortalities in the

---

<sup>12</sup> The NPS provides puma profiles (last updated August-November 2018) of the marked animals (*i.e.*, tagged or radio-collared) they have been studying in the CC-S, which includes those studied in Riley et al. (2014). Some data presented in this section take these data into account. Accessed on 3 April 2019 at: <https://www.nps.gov/samo/learn/nature/puma-profiles.htm>.

<sup>13</sup> The adult population in the Santa Monica Mountains is generally consistent with the estimated 0.25 to 0.5  $N_e/N$ ; the Santa Monica Mountains was estimated to have an effective population size of four (Benson et al. 2019), which would suggest a total adult population size of 8 to 16. Interestingly, Gustafson et al. (2018) estimated an effective population size of 2.7 for the greater CC-S population, which would indicate a total adult population of 5 to 10 individuals throughout the Santa Monica Mountains, Simi Hills, and Santa Susana Mountains (see Table 1). There are currently 10 to 17 adult mountain lions being tracked throughout the CC-S area, which would put their  $N_e/N$  ratio at 0.16 to 0.27, which is still within the range of other species'  $N_e/N$  ratios (Frankham et al. 1995; Ballou et al. 1989; Mace and Lande 1991; Spong et al. 2000; Laundré and Clark 2003).

area (Riley et al. 2014). Although intraspecific strife is known to occur among mountain lions, there have been multiple cases of aggressive adult males killing their siblings, female offspring, and previous mates documented in the Santa Monica Mountains population, and researchers noted that “clearly this is rarely a sound evolutionary strategy as the survivorship of offspring or siblings is traded against the probability of future reproduction” (Riley et al. 2014). For 23 radio-collared individuals within the Santa Monica Mountains for which the cause of death is known, nine deaths were the result of intraspecific strife. Eight of the nine deaths (89%) were of animals less than four years old. In addition, three uncollared mountain lions in the Santa Monica Mountains less than four years old were found dead by intraspecific strife, which brings the total to 12 deaths by intraspecific strife documented in the Santa Monica Mountains between 2002 and 2018.

Although all subadult males and half of subadult females typically disperse from their natal areas (Logan and Sweaner 2010), only one subadult successfully dispersed from the Santa Monica Mountains between 2002 to 2012 – P-22, the famous male mountain lion who successfully crossed Highway 101 and I-405 freeways and established his home range in Griffith Park (Riley et al. 2014). Unfortunately, P-22 is extremely isolated with the smallest home range ever reported for an adult male (26km<sup>2</sup>), and he has not had any opportunities to mate (Riley et al. 2014). In addition, vehicle strikes account for 17% (4/23) of known radio-collared mountain lion deaths in the Santa Monica Mountains. According to the NPS, most males in the Santa Monica Mountains do not live past the age of two. Thus, many healthy, young animals are not able to disperse from the Santa Monica Mountains, establish their own home ranges, and successfully reproduce.

Conversely, lack of connectivity also inhibits migrants coming from outside the Santa Monica Mountains and contributing to the population’s gene pool. Only two outside mountain lions have been known to immigrate into the Santa Monica Mountains since 2002: P12 (from Simi Hills, alive as of August 2018, age 12) and P45 (from north of Highway 101, status unknown, age would be 6-7 if alive). While there has been no sign of P-45 since February, 2019 and no offspring from him have been detected, P-12 has been fairly prolific in the Santa Monica Mountains, fathering at least eight litters. Although P-12’s appearance initially improved genetic diversity in the Santa Monica Mountains population, consistent immigration in small populations is needed so that the genetic diversity gains of immigrant mountain lions are not lost (Riley et al. 2014; Benson et al. 2016a; Benson et al. 2019). Subsequent inbreeding by P-12 with his daughters and granddaughters and inbreeding already occurring with other breeding adults in the Santa Monica Mountains have led to dangerously low genetic diversity (Riley et al. 2014; Benson et al. 2016a; Gustafson et al. 2018; Benson et al. 2019). With continued isolation, inbreeding, and loss of genetic diversity, there is increasing risk of inbreeding depression and extinction. With inbreeding depression, the probability of extinction within 50 years is predicted to be 99.7 %, with a median time to extinction of 15.1 years (Benson et al. 2016a; Benson et al. 2019).

#### 5.4 Santa Ana Mountains (SAM) Population

Restricted habitat availability and high mortality rates in the SAM likely limits population size, and Benson et al. (2019) estimated that the SAM population is likely comprised of 16 adults and 13 juveniles (kittens and subadults). These numbers are slightly lower than the 31 to 62 adult mountain lions estimated from the SAM population's effective population size of 15.6 (Gustafson et al. 2018) (see Table 1). According to (Benson et al. 2019), high levels of human-caused adult mortalities may limit growth potential in the SAM, and it is uncertain if the population could be larger without as many anthropogenic pressures. In fact, although hunting is illegal in California, mountain lions in Southern California have a lower annual survival than many hunted populations (Vickers 2014). Interestingly, other studies calculated a much lower effective population size of 5.1 (Ernest et al. 2014) and four (Benson et al. 2019), which would align with the suggested carrying capacity. Regardless of which effective population size is used, they are all well below the frequently-used threshold of 50 and insufficient to prevent inbreeding depression in the short-term.

Although population trends are unclear, two long-term studies on radio-collared mountain lions in the SAM provide some insight (Beier 1993; Vickers et al. 2015). In a study that consisted of 32 radio-collared animals in the SAM from 1988 to 1993, researchers found a 75% adult survival rate (Beier and Barrett 1993), which is similar to adult survival rates in other populations, like the CC-S population (Riley et al. 2014). However, in a second, more recent study conducted in the area consisting of 31 marked mountain lions from 2001 to 2013, researchers found a 56.5% survival rate across all sexes and age groups (Vickers et al. 2015). The marked decrease in adult survival rate between the two studies coincides with an increase in the proportion of mortalities caused by vehicle strikes, with the 1988-1993 and the 2001-2013 studies resulting in 32% (10/31) and 46% (6/13) of deaths caused by vehicle strikes, respectively (Beier 1993; Vickers et al. 2015). It also parallels an upward trend of mountain lion mortalities caused by vehicle strikes throughout Southern California over time (Vickers et al. 2015). Other causes of death in the SAM population included depredation kills, illegal killing, disease, intraspecific strife, and human-caused wildfires (Beier and Barrett 1993; Vickers et al. 2015). Depredation kills were found to be 3.4 times more likely with males compared to females (Vickers et al. 2015).

The SAM mountain lion population's high adult mortality rates combined with isolation, small size, low genetic diversity, low effective population size, and limited immigration of new individuals cause demographic instability and put the population at high risk of extinction (Beier 1993; Beier and Barrett 1993; Ernest et al. 2014; Vickers et al. 2015; Gustafson et al. 2017; Gustafson et al. 2018; Benson et al. 2019). As mentioned previously in *Section 2.2 Taxonomy and Population Genetics*, the extremely low effective population size and total adult population size are insufficient to prevent inbreeding depression in the short term or maintain evolutionary potential in the long term (Jamieson and Allendorf 2012; Frankham et al. 2014). Roads and development prevent dispersal and sustained immigration in the SAM, and lack of consistent gene flow has led to high levels of inter-relatedness and inbreeding (Ernest et al. 2014; Gustafson et al. 2017; Gustafson et al. 2018; Benson et al. 2019). Further genetic erosion is likely without improved connectivity to facilitate immigration (Benson et al. 2019). CDFW has identified the SAM population as at risk due to current habitat and genetic concerns, at-risk internal habitat and

connectivity, limited external connectivity, and lack of protected habitat (Dellinger 2019). If inbreeding depression occurs within this population, population growth will likely decline and the probability of extinction within 50 years is predicted to be 100%, with a median time to extinction of 11.7 years (Benson et al. 2019).

In 13 years, only one radio-collared individual crossed I-15, the major barrier between the SAM and the EPR, and that animal was killed 25 days after his crossing for depredating domestic sheep (Vickers et al. 2015). And although Gustafson et al. (2017) documented three males immigrating into the SAM from the EPR and four males emigrating from the SAM to the EPR over a 15-year period, only one of the males (M86, an immigrant to the SAM) is known to have successfully bred. While M86 improved the SAM population's genetic diversity (Gustafson et al. 2017), high levels of mortalities due to vehicle strikes and depredation/illegal killings likely reduce the number of immigrants that can successfully establish as breeding adults (Vickers et al. 2015). With high levels of adult mortalities due to vehicle strikes, depredation kills affecting 3.4 times more males than females, and a small population with a female-biased adult sex ratio, there is potential for occasional male extinction in the SAM, which could severely limit the short- and long-term viability of the population (Beier and Barrett 1993; Benson et al. 2019).

### 5.5 *San Gabriel/San Bernardino Mountains (SGSB) Population*

Studies on the SGSB mountain lion population are limited, and the abundance and population trends are unknown. However, with an effective population size of 5 (Gustafson et al. 2018), and an  $N_e/N$  of 0.25 to 0.5 (Ballou et al. 1989; USFWS 2008), the estimated total adult population would be 10 to 20 individuals (see Table 1). As mentioned previously in *Section 2.2 Taxonomy and Population Genetics*, these numbers are grossly insufficient to prevent inbreeding depression in the short term or maintain evolutionary potential in the long term (Jamieson and Allendorf 2012; Frankham et al. 2014). And CDFW has identified the SGSB population as at risk due to current habitat and genetic concerns, at-risk internal habitat and connectivity, limited external connectivity, and lack of protected habitat (Dellinger 2019).

Although a population viability study has not been conducted for the SGSB population, given its low genetic diversity, low effective population size, and patterns of isolation due to roads and development creating movement barriers (Gustafson et al. 2018), the SGSB mountain lion population likely has high risk of inbreeding depression and extinction. The loss of this population could undermine genetic connectivity for mountain lions statewide because the SGSB population, along with the Tehachapi and Sierra Pelona Mountains, represents a critical linkage between mountain lion populations in the northern and southern mountain ranges of California (Gustafson et al. 2018). Restoration and enhancement of connectivity in the SGSB and surrounding mountain ranges are key for the continued survival of the SGSB population as well as all of the Central Coast and Southern California mountain lion populations.

### 5.6 *Eastern Peninsular Range (EPR) Population*

Studies on the EPR mountain lion population are limited and the abundance and population trends are unknown. However, with an effective population size of 31.6 (Benson et al. 2019), and an  $N_e/N$  of 0.25 to 0.5 (Ballou et al. 1989; USFWS 2008), the estimated total adult

population would be 63 to 126 individuals (see Table 1). As mentioned previously in *Section 2.2 Taxonomy and Population Genetics*, these numbers are insufficient to prevent inbreeding depression in the short term or maintain evolutionary potential in the long term (Jamieson and Allendorf 2012; Frankham et al. 2014).

Vickers et al. (2015) followed 43 marked mountain lions in the EPR from 2001 to 2013, and their study provides some insight regarding survival rate and causes of mortality. Annual survival rate was found to be 55.4% in the EPR, which is similar to the SAM population (Vickers et al. 2015). The primary causes of death of marked mountain lions were depredation kills (26% [6/23]) and vehicle strikes (17% [4/23]). When assessing mountain lion death data from CDFW from 1981 to 2013, depredation and vehicle strikes accounted for about 70% of mountain lion deaths in the EPR: 40% (62/154) by depredation kills and 30% (46/154) by vehicle strikes (Vickers et al. 2015).

Although the EPR population was found to have the highest genetic diversity and effective population size among the Southern California mountain lion populations (Gustafson et al. 2018), movement and genetic studies have shown that the EPR population is largely disconnected from all other California populations (Ernest et al. 2014; Vickers et al. 2015; Vickers et al. 2017; Gustafson et al. 2018). And CDFW has identified the EPR population as at risk due to current habitat and genetic concerns, at-risk internal habitat and connectivity, limited external connectivity, and lack of protected habitat (Dellinger 2019). Thus, high human-caused mortality rates combined with continued development in San Diego, Riverside, and Imperial Counties could lead to further isolation, decreased genetic diversity, increased inbreeding depression, and increased risk of extinction.

## 6 Factors Affecting Ability to Survive and Reproduce

Female mountain lion, P-23, crossing a road in the Santa Monica Mountains. She was struck by a vehicle and found dead near Malibu Canyon Road in January 2018. Photo: NPS

Most, if not all, factors affecting the ability of the Southern California and Central Coast mountain lion populations to survive and reproduce are caused by humans. Lack of wildlife connectivity is the primary driver of their potential demise. Habitat loss and fragmentation due to roads and development have led to extreme levels of isolation and high mortality rates, which are driving these populations towards extinction. Continued development in current suitable

mountain lion habitat further threatens these populations. With low genetic diversity and high risk of inbreeding depression due to genetic isolation, vehicle strikes on roads, increased conflicts with humans that lead to depredation kills, high levels of intraspecific strife likely due to limited space and lack of connectivity, rodenticide and other environmental toxicant poisoning, and impacts of more frequent wildfires and climate change, Southern California and Central Coast mountain lions will likely not persist unless there is a concerted effort to restore and enhance functional connectivity between populations and large blocks of heterogeneous habitats.

The populations in Southern California are especially vulnerable to extinction, which is reflected in a 2005 review conducted by the US Forest Service regarding Land Management Plans in the National Forests of Southern California that states the “greatest concern for the long-term health of mountain lion populations on the national forests of southern California is loss of landscape connectivity between mountain ranges and large blocks of open space on private land.”<sup>14</sup> The review emphasizes that continued development along with new and wider roads degrade habitat linkages and create movement barriers, and “[w]ithout the national forests and linkages between the mountain ranges and other large habitat preserves, there is not much long term potential for mountain lions in southern California.”

Ultimately, the persistence of mountain lions in the Central Coast and Southern California requires maintenance and restoration of connectivity between subpopulations and adequate habitat. The extreme isolation, dangerously low genetic diversity, high levels of inbreeding, and high rates of human-caused mortalities (e.g., vehicle strikes, depredation kills, intra-specific strife due to limited space, rodenticide poisoning, etc.) underscore the urgent need for proactive measures to enhance connectivity (Ernest et al. 2014; Riley et al. 2014; Vickers et al. 2015; Benson et al. 2016a; Gustafson et al. 2017; Benson et al. 2019).

Male mountain lion M110 in San Diego County was euthanized by a CDFW warden because he was severely injured and for stated public safety concerns (he was found in a neighborhood close to homes). This occurred days after he was illegally shot by a livestock owner (open wound on right flank). Necropsy results indicated he had two broken legs consistent with a vehicle strike and four different compounds of anticoagulant rodenticides in his blood. Had he not been euthanized, he likely would have died from starvation due to his injuries. Source: Vickers (2014).

---

<sup>14</sup> Forest Service, U.S. Department of Agriculture, *Final Environmental Impact Statement, Land Management Plans, Angeles National Forest Cleveland National Forest Los Padres National Forest San Bernardino National Forest* (Sept. 2005), available at [https://www.fs.usda.gov/Internet/FSE\\_DOCUMENTS/stelprdb5166889.pdf](https://www.fs.usda.gov/Internet/FSE_DOCUMENTS/stelprdb5166889.pdf).

Measures to conserve core habitat areas and functional wildlife corridors, like the recently adopted Habitat Connectivity and Wildlife Movement Ordinances in Ventura County,<sup>15</sup> are vital to the preservation of Central Coast and Southern California mountain lion populations, but just protecting land is not enough to ensure their survival. Conserving natural habitats on both sides of freeways and constructing effective crossing infrastructure (*e.g.*, culverts, underpasses, vegetated overpasses, and exclusionary fencing) at existing roads and barriers would facilitate movement and gene flow while reducing mortalities due to vehicle strikes (Riley et al. 2014; Vickers et al. 2015; Benson et al. 2019). Promoting wider implementation of predator-proof enclosures for domestic animals would further reduce human-caused mortalities by limiting opportunities for potential conflict and reducing the use of depredation permits (Vickers et al. 2015). In addition, changes in depredation permit policy could further reduce mortalities. For example, CDFW adopted a new depredation permit policy based on a 2017 bulletin for mountain lions in the CC-S and SAM areas, which requires affirmative non-lethal alternatives and improved husbandry before kill permits are issued when mountain lion depredations occur in those areas (CDFW 2017; see *Section 8.1.1 CDFW Departmental Bulletins*). Expanding these policies in conjunction with enforceable implementation and reporting requirements across the state, or at least into the SGSB, EPR, CC-N, and CC-C, population areas, would reduce mortalities from this source. Prohibiting the use of second-generation anticoagulants, rodenticides, and other environmental toxicants in California (*i.e.*, with AB 1788, sponsored by Assembly Member Richard Bloom in 2019) would even further reduce human-caused mortalities of mountain lions, as toxicants bioaccumulate up the food chain and can kill mountain lions or weaken their immune systems and make them more susceptible to disease or more vulnerable to conspecifics (Riley et al. 2003; Riley et al. 2007; Serieys et al. 2015). A combination of habitat conservation, implementation of effective road/barrier crossing infrastructure, and outreach and education to property owners and owners of domestic animals combined with depredation permit policy change could save these populations from extinction (Vickers et al. 2015).

### 6.1 Low Genetic Diversity and Inbreeding Depression

As detailed in *Section 2.2 Taxonomy and Population Genetics* and *Section 5.0 Abundance and Population Trends*, inbreeding is a serious threat to the persistence of the Central Coast and Southern California mountain lion populations. Inbreeding depression, loss of genetic diversity, and accumulation of deleterious mutations can lead to elevated extinction risk due to reduced reproductive fitness and evolutionary potential (*i.e.*, the ability to adapt to change) (Spielman et al. 2004; Frankham 2005; Traill et al. 2010). Decades of isolation due to roads and development fragmenting habitat and limiting connectivity has led to low genetic diversity and effective population sizes, high levels of inter-relatedness, and dangerous levels of inbreeding, especially in the CC-S, SAM, SGSB, and CC-N populations (Ernest et al. 2014; Riley et al. 2014; Vickers et al. 2015; Benson et al. 2016a; Gustafson et al. 2017; Gustafson et al. 2018; Benson et al. 2019). Although demographic and environmental stochasticity (*e.g.*, a disease outbreak, wildfire, drought or flooding) can increase risk of extinction, especially in small populations, inbreeding has also been shown to be an indicator of extinction risk and may impact how populations are able to respond to stochastic events (Frankham and Ralls 1998). In addition, endangered species

---

<sup>15</sup> More information regarding the Habitat Connectivity and Wildlife Movement Ordinances available at: <https://vcrma.org/habitat-connectivity-and-wildlife-movement-corridors>

tend to have lower genetic diversity than non-endangered species, which suggests that inbreeding and low genetic variation may have an important role in a species' risk of extinction (Frankham and Ralls 1998). Thus, genetic factors should be considered when assessing the status of these populations.

The CC-S, SAM, SGSB, and CC-N populations have been found to have low genetic diversity, with the SAM population's genetic variation nearly as low as the endangered Florida panther's (*Puma concolor coryi*) (Ernest et al. 2014; Riley et al. 2014; Gustafson et al. 2017). And, as mentioned previously in *Section 2.2 Taxonomy and Population Genetics*, the CC-S, SGSB, SAM, CC-N, and EPR populations have effective population sizes well below the older and less conservative threshold of 50, while the CC-C population's effective population size is just barely above that threshold at  $N_e = 56.6$  (Ernest et al. 2014; Riley et al. 2014; Benson et al. 2016a; Gustafson et al. 2018; Benson et al. 2019). These numbers suggest that inbreeding depression could occur within the short-term (over the duration of five generations) and these populations are at increased risk of extinction.

Without improved connectivity, the SAM and Santa Monica Mountains (within the CC-S) populations are predicted to experience continued genetic erosion and losses in heterozygosity of 28-49% and 40-57%, respectively, within 50 years (Benson et al. 2016a; Benson et al. 2019). This could lead to inbreeding depression, which could cause reduced fitness in a variety of ways. In Florida panthers, inbreeding depression led to reproductive issues (e.g., poor sperm quality, low testosterone levels, poor fecundity and recruitment, failure of testes to descend), increased susceptibility to parasites and disease, and physical issues (e.g., atrial septal defect, a deadly congenital heart defect; kinked tails) (Roelke et al. 1993; Johnson et al. 2010). Suffering from shrinking, fragmented habitats, high mortality rates from hunting, and inbreeding depression, the Florida panther population declined to less than 30 individuals, and genetic restoration via the translocation of eight female mountain lions from Texas (*Puma concolor stanleyana*) was needed to prevent their extinction (Johnson et al. 2010).

The SAM and CC-S populations are severely constrained in fragmented habitats with similar numbers as the Florida panther population prior to genetic rescue (Beier and Barrett 1993; Johnson et al. 2010; Riley et al. 2014; Vickers et al. 2015). Although the fragmented populations appear to be stable, high levels of inbreeding have been documented in the Santa Monica Mountains (Riley et al. 2014) and evidence of inbreeding depression (i.e., low genetic diversity and kinked tails) has been observed in the SAM (Ernest et al. 2014). If these populations remain isolated, they will inevitably have the same fate as the Florida panthers. Researchers predict that with inbreeding depression, the SAM and Santa Monica Mountains populations have a 100% and 99.7% chance of becoming extinct within 50 years, with median time to extinction of 11.7 and 15.1 years, respectively (Benson et al. 2019).

The SGSB population was also found to have low genetic diversity and effective population size (Gustafson et al. 2018), which suggests that the population experienced a prior genetic bottleneck and inbreeding is likely. Although genetic studies on this population are limited, it is clear that continued development in and around the SGSB will further isolate the population and lead to more inbreeding and even lower genetic diversity, which will drive the population faster towards extinction. It is important to note that despite only limited gene flow

between the SGSB population and the Western Sierra Nevada, CC-C, and the EPR (Gustafson et al. 2018), this population represents a critical linkage between mountain lion populations in the northern and southern mountain ranges of California. Restoration and enhancement of connectivity is key for the continued survival of the SGSB population as well as all of the other the Central Coast and Southern California mountain lion populations.

Gustafson et al. (2018) found that the EPR population also exhibits a prior genetic bottleneck. The EPR population was found to be largely disconnected from all the other California populations, with limited gene flow and low connectivity with the SAM and SGSB populations (Gustafson et al. 2018). Movement patterns and genetics indicate potential isolation from other populations (Vickers et al. 2015; Gustafson et al. 2017; Gustafson et al. 2018), and continued development in these areas will likely lead to further isolation, genetic drift, and risk of extinction similar to what is being observed in the CC-S, SAM, and SGSB populations.

Although genetic studies are limited for the CC-N population, it was found to have low genetic diversity and low effective population size (Gustafson et al. 2018), which forewarns of inbreeding depression and increased risk of extinction. CDFW has identified the Santa Cruz Mountains mountain lion population, which occurs within the CC-N area, as vulnerable to decline and extinction due to fragmentation from roads and development as well as lack of protected habitat (Dellinger 2019).

Studies suggest that one immigrant every 1-2 years would reduce extinction risk in the SAM and Santa Monica Mountains populations (Beier and Barrett 1993; Gustafson et al. 2017; Benson et al. 2019). This may apply to the other populations with low genetic diversity and effective population size (Gustafson et al. 2018). Increasing connectivity throughout the Central Coast and Southern California would address issues of inbreeding by facilitating movement between populations, increasing effective population size, and reducing high mortality rates driven by vehicle strikes and depredation. Thus, proactive measures to effectively restore and enhance connectivity are needed to minimize risk of inbreeding depression and extinction in Central Coast and Southern California populations.

## 6.2 *Vehicle Strikes*

In California, an estimated 100 mountain lions are killed every year by vehicle strikes (Pollard 2016). In the Central Coast and Southern California, vehicle strikes represent a significant threat to the persistence of mountain lion populations, though Southern California has more documentation regarding this issue. The number of mortalities caused by vehicle strikes has been increasing in Southern California since the 1980s, and vehicle strikes account for a high proportion of deaths in mountain lions in the SAM, CC-S, and EPR (Beier and Barrett 1993; Riley et al. 2014; Vickers et al. 2015; Vickers et al. 2017). From 1981 to 2013 vehicle strikes accounted for 53% (50/94) of mountain lion deaths in the SAM and 30% of mountain lion deaths in the EPR (46/154) (Vickers et al. 2015). Riley reported that 14% (2/14) of collared mountain lion deaths from 2002 to 2012 were due to vehicle strikes, and the NPS reported that 18 mortalities from vehicle strikes occurred between July 2002 and January 2018 in the CC-S (Figure 9). Although the CC-N population is less studied, there is evidence that vehicle strikes are a significant cause of mortalities in this population; at least six mountain lions have been

killed by vehicle strikes on Highway 17 in the Santa Cruz Mountains between 2008 and 2018 (Midpeninsula Regional Open Space 2017; Slade 2018) and news outlets reported at least three vehicle strikes killing mountain lions on the I-280 in San Mateo County between 2014 and 2016 (Wilmers 2014; CBS San Francisco 2015; Kamala 2016). Similarly, in 2018 at least two mountain lions were reported to have been killed by vehicle strikes in San Luis Obispo County in the CC-C (Tanner 2018). Clearly, vehicle strikes are an important cause of mortality for the Central Coast and Southern California mountain lion populations.

**Figure 9.** Locations of 18 mountain lion vehicle strikes in the Santa Monica Mountains and surrounding areas from July 2002 to January 2018. Source: NPS

High adult mortality rates can have severe consequences, particularly for small populations with female-biased adult sex ratios and low effective population sizes (Beier and Barrett 1993; Benson et al. 2019). Vehicle strikes have been found to affect males and females equally, regardless of age, which can result in relatively high adult male mortalities (Vickers et al. 2015). Low male adult survival increases the risk of extinction, as it could result in occasional extinctions of breeding males and therefore reduced reproductivity (Benson et al. 2019), which has been previously observed in the SAM (Beier and Barrett 1993). In the Santa Monica Mountains, where adult survival is high, vehicle strikes (along with intraspecific strife) make it more difficult for subadults to successfully disperse, which limits breeding opportunities for mountain lions born in the Santa Monica Mountains (Riley et al. 2014; Benson et al. 2019). Freeways and vehicle strikes also limit the ability for immigrants to enter the Santa Monica Mountains and contribute to the population’s gene pool (Riley et al. 2014; Benson et al. 2019). These patterns highlight the dire outlook for Central Coast and Southern California mountain lion populations due to lack of connectivity between populations and suitable habitat. The continued construction of roads and development and inaction to enhance connectivity threatens the survival of these struggling populations.

### 6.3 Depredation and Illegal Kills

Mountain lions killed on depredation permits (and one killed by vehicle strike) in San Diego County in 2015. Source: Vickers et al. (2017).

In 1990 California voters passed The California Wildlife Protection Act (Proposition 117), making the mountain lion a “specially protected species” and outlawing mountain lion sport-hunting in California. However, the law requires CDFW to issue depredation permits that allow people to “take” mountain lions when a mountain lion kills or injures domestic animals such as livestock or pets or damages property. The legal definition of “take” is to “hunt, pursue, catch, capture, or kill, or attempt to hunt, pursue, catch, capture, or kill” (Cal Fish & Game Code, §86), and the vast majority of permits to take in the three decades since the passage of Proposition 117 have authorized killing one or more mountain lions. The number of depredation permits issued and the number of reported kills has varied over time, and on average over 40% of permits result in reported kills. Since 1990 there has been an average of 97 reported depredation kills every year; however, these estimates are likely low due to underreporting and incomplete records (W. Vickers, *pers comm*). Depredation kills (along with vehicle strikes) account for the majority of mountain lion mortalities in the SAM and EPR (Vickers et al. 2015; Vickers et al. 2017). Although less is known about depredation kill impacts in the CC-N and CC-C, there is evidence that suggests depredation kills could be a significant source of mortality in these populations. In the Santa Cruz Mountains in the CC-N, depredation kills are the leading cause of death in collared mountain lions (Wang et al. 2017), and CDFW reported 34 depredation kills between 2010 and 2016 in the CC-N counties of Alameda, Contra Costa, San Mateo, Santa Clara, and Santa Cruz (see Appendix A<sup>16</sup>). Although population dynamics are even less studied in the CC-C, between 2010 and 2016 there were 46 reported depredation kills in the counties of Monterey, San Benito, San Luis Obispo, and Santa Barbara (See Appendix A<sup>1d</sup>).

---

<sup>16</sup> These data were downloaded from the CDFW website; however, they no longer appear to be available online. These numbers have been shown to be low by a factor of two in some areas, likely due to incomplete reporting, and therefore should be considered absolute minimums (W. Vickers, *pers comm*).

An illegally killed mountain lion in San Mateo County. Photo: Tiffany Yap

Depredation kills result in more deaths in male mountain lions compared to female mountain lions. Statewide, of mountain lions killed for depredation in 2017, 68% were males (CDFW 2018), and from 1981 to 2013, there were 3.4 times more male than female mountain lions killed for depredating in the SAM and EPR (Vickers et al. 2015). The majority of lions reported killed for depredating were of subadult (1-2 years old) and adult mountain lions (>2 years old) (CDFW 2018), many of which were likely dispersers that may have not yet established home ranges. Dispersing lions often come up against roads and development as they search to establish home ranges (Beier 1995, Vickers 2015, Riley 2014). This suggests that even if individuals are able to navigate across roads and freeways without being struck by vehicles, they often come into conflict with humans, which threatens their survival. This was reflected in the EPR, when the only GPS collared immigrant to have crossed I-15 from 2001 to 2013 arrived from the SAM only to be killed on a depredation permit 25 days after his arrival for depredating a sheep (Vickers et al. 2015). Not only do lions killed for depredating diminish the total abundance of these populations, but because males are predominantly killed, the number of animals that are the primary gene dispersers are also greatly reduced, which further inhibits adequate genetic connectivity (Vickers et al. 2017).

Reported depredation kills do not include mountain lions that are illegally poached or killed, many of which likely go undocumented (Beier and Barrett 1993; Vickers et al. 2015). Illegal kills have been observed in the CC-S, SAM, and EPR (Beier and Barrett 1993; Riley et al. 2014; Vickers et al. 2015) as well as in the CC-N (Yap 2018 *pers observation*), and although 80 mountain lions were reported as being killed under depredation permits in 2017, 89 deaths were being investigated (CDFW 2018).

As mentioned in *Section 6.2 Vehicle Strikes*, high levels of mortalities among male breeders or potential male breeders (*i.e.*, dispersers) can have severe impacts on small, isolated mountain lion populations with female-biased adult sex ratios and low effective population sizes (Beier and Barrett 1993; Benson et al. 2019). Low survival of breeding males increases extinction risk, as occasional breeding male extinctions can occur and therefore reduce reproductivity throughout the population (Beier and Barrett 1993; Benson et al. 2019). And low survival of subadults and adults may limit both dispersers and immigrants from successfully

breeding and increasing genetic diversity (Vickers et al. 2015; Benson et al. 2019). Thus, depredation and illegal kills in conjunction with lack of connectivity between populations and suitable habitat in the Central Coast and Southern California severely limit the potential for these populations to survive and reproduce. Continued development and lack of connectivity will likely push mountain lions into more conflicts with humans, which could increase depredation and retributory kills and further drive these populations towards extinction.

#### 6.4 *Intraspecific Strife*

Intraspecific strife: a female mountain lion, P-7, was killed by her father, P-1. Photo: NPS

As detailed in *Section 5 Abundance and Population Trends*, intraspecific strife is the leading cause of mortality in the Santa Monica Mountains (Riley et al. 2014). Although intraspecific strife is a common source of mortality in mountain lion populations, (Beier and Barrett 1993; Logan and Sweaner 2001; Allen 2014), unusually high levels of intraspecific strife have been observed in this population (Riley et al. 2014). About 41% (9/22) of deaths in radio-collared mountain lions being tracked from 2002 to 2018 were from intraspecific strife,<sup>17</sup> with multiple cases of aggressive adult males killing their siblings, offspring (male and female), and previous mates (Riley et al. 2014). While males are likely to have larger home ranges to protect food resources and access to females, killing offspring or potential mates has no apparent evolutionary benefit, as it reduces chances of future reproduction (Riley et al. 2014). In addition, infanticide has been documented in the Santa Monica Mountains (Riley et al. 2014), perhaps to trigger the female to come into estrous. These high levels of intraspecific strife are likely due to limited space in the Santa Monica Mountains caused by dispersal barriers (Riley et al. 2014; Benson et al. 2019). As roads and development further encroach on Central Coast and Southern California mountain lion populations, intraspecific strife could become more common; this was

---

<sup>17</sup> The NPS provides puma profiles (last updated August-November 2018) of the marked animals (*i.e.*, tagged or radio-collared) they have been studying in the CC-S, which includes those studied in Riley et al. (2014). Some data presented in this section take these data into account. Accessed on 3 April 2019 at: <https://www.nps.gov/samo/learn/nature/puma-profiles.htm>.

documented in the SAM on two occasions (one GPS-collared, one previously GPS-collared) since the publication of Vickers et al. (2015) (W. Vickers *unpublished data*). Enhanced connectivity between populations and suitable habitat would facilitate dispersal, which would reduce and/or prevent high levels of intraspecific strife (Riley et al. 2014; Benson et al. 2019) and improve the survival and reproduction rates, especially for the most struggling populations.

### 6.5 Abandonment

Santa Monica Mountains mountain lion kittens P-57 and P-58 were abandoned by their mother, P-42, a first-time mother who left with male P-27 and never returned. Photo: NPS

Abandonment of kittens is fairly common in the Santa Monica Mountains and accounts for about 23% (5/22) of the known causes of death for marked/collared animals.<sup>18</sup> Although this likely occurs in other mountain lion populations, the causes of abandonment are unclear. There are various reasons why females might abandon their cubs. The cubs could be sick, the female may not be able to take care of them, or perhaps the female was initially protecting them from a mature male. Unfortunately, there is a lack of data regarding why and how often cubs get abandoned. Yet this is one of the main causes of death for mountain lions in the Santa Monica Mountains, which likely affects this already-small population.

Mountain lion cubs can also become orphaned if the mother is killed before they have dispersed. If they are too young to fend for themselves, they likely starve to death or are preyed upon by other predators. If the young are more mobile, they may come up against areas where they are more likely to encounter humans as they search for food. This was seen in November 2017, when a mother mountain lion was killed by a vehicle strike in the SAM and two of her cubs were found roaming near human establishments – one in a backyard and the other along a road (Veklerov 2018). Both were too young to survive on their own and were placed in the Oakland Zoo.

## 6.6 Poisoning from Rodenticides and Other Environmental Toxicants

The famous mountain lion of Griffith Park, P-22, suffering from notoedric mange, a parasitic skin disease that has been linked with the ingestion of rodenticide poisoning (left) and mountain lion P-34 found dead on a trail due to rodenticide poisoning (right). Photos: NPS

Although mountain lions are not the primary target of environmental toxicants, such as rodenticides and other pesticides and herbicides, secondary poisoning has been documented in many non-target animals, especially predators (e.g., coyotes (Riley et al. 2003), bobcats (Riley et al. 2007; Serieys et al. 2015), San Joaquin kit fox (McMillin et al. 2008), California fishers (Gabriel et al. 2012), raptors (Lima and Salmon 2010), and many more). Data regarding pesticide poisoning in mountain lions are limited; however, there is evidence that these big cats are likely vulnerable to similar negative impacts that other predators experience, including direct death, weakened immune systems, and vulnerability to predators or conspecifics (Riley et al. 2003; Riley et al. 2007; Serieys et al. 2015; Rudd et al. 2019).

While poisoning can sometimes lead to direct death, rodenticide exposure has also been associated with notoedric mange, a parasitic skin disease that has led to high levels of mortalities, population declines, and even local extirpations in Southern California bobcats (Riley et al. 2007; Serieys et al. 2015). Although the link between rodenticide poisoning and mange is not as clear in mountain lions, since 2002 five mountain lions in the CC-S have been found suffering from mange, and researchers suspect that rodenticide poisoning may have played a role (Reyes-Velarde 2019a). In addition, of four dead mountain lions in the Santa Monica Mountains that were found to have rodenticides in their systems, two died from poisoning and two died from intraspecific strife, and it is possible that indirect effects of poisoning may have prevented the mountain lions from escaping conflict or fighting back (Riley et al. 2007). And rodenticide poisoning is suspected to be the cause of death in mountain lion P-47, who was recently found dead in Santa Monica Mountains (Reyes-Velarde 2019b), and CC-N mountain lion 36m, who was found dead in the Santa Cruz Mountains in 2015 (Wilmers 2015).

The Department of Pesticide Regulation (DPR) analyzed data provided by CDFW and found that 92% (59/64) of tested mountain lions from throughout the state had detectable levels of anticoagulant rodenticides, which indicates alarmingly high exposure rates (DPR 2018). This has been found to be true in the CC-S as well, where researchers have found that 94% (17/18) of mountain lions tested had traces of rodenticides in their systems (Reyes-Velarde 2019a).

Rodenticides have been implicated in mountain lion mortalities in the CC-S, and in the SAM anticoagulant rodenticide residues were detected in the livers of 100% of deceased animals tested, with up to five different compounds being detected in some animals (Riley et al. 2007; Riley et al. 2014; W. Vickers, *pers comm*). And a study conducted by CDFW and the Integral Ecology Research Center (IERC) has found that mountain lions are being exposed to dangerously high levels of illegal pesticides, such as carbofuran, being used on illegal marijuana grow sites, which can also bioaccumulate and cause health issues (Rudd et al. 2019). Furthermore, it is possible that herbicide exposure from deer could be detrimental to mountain lions as well. Although poisoning from environmental toxicants may not constitute a large proportion of direct deaths (that we are aware of), it is possible that high exposure levels influence other causes of mortalities. Any additional mortalities in the small, isolated Central Coast and Southern California populations suffering from other anthropogenic pressures could impact the short- and long-term survival of these mountain lions.

### 6.7 Wildfires

After the Woolsey Fire, the body of mountain lion P-64, known to use culverts to cross the Hwy-101 and SR-118 freeways a total of 41 times, was found dead with severely burned paws. Photos: NPS

Although fire is a natural disturbance in California ecosystems, sprawl development with low/intermediate densities extending into habitats that are prone to fire have led to more frequent wildfires that burn larger areas (Syphard et al. 2007; Syphard et al. 2009). Most wildfires in California are caused by human ignitions, like power lines, arson, improperly disposed cigarette butts, debris burning, fireworks, campfires, or sparks from cars or equipment (Keeley and Fotheringham 2003; Syphard et al. 2007; Syphard et al. 2012; Bistinas et al. 2013; Balch et al. 2017; Radeloff et al. 2018; Syphard et al. 2019). In fact, human-caused fires account for 95-97% of all fires in California's Mediterranean habitats (Syphard et al. 2007, Balch et al. 2017). In addition, climate change is leading to hotter, drier conditions that make fires more likely to burn. At least 29 fires throughout California in the last two years were caused by electric power and distribution lines, and transmission lines are suspected to be the cause of last year's Camp Fire and Woolsey Fire (Atkinson 2018; Chandler 2019).

Increased frequency of wildfires poses a threat to the survival of Central Coast and Southern California mountain lions. Although mountain lions are highly mobile and generally able to move away from wildfires, in severe weather conditions wind-driven fires can spread quickly – they can cover 10,000 hectares in one to two days, as embers are blown ahead of the

fires and towards adjacent fuels (*e.g.*, flammable vegetation, structures) (Syphard et al. 2011). If their movement is constrained by roads and development and they are unable to access escape routes, then their chances of surviving wildfires are greatly reduced. Vickers et al. (2015) documented one death of a collared mountain lion in the SAM and one in the EPR due to human-caused wildfires, and the deaths of two collared mountain lions in the CC-S in 2018 have been attributed to the Woolsey Fire.<sup>19</sup> Environmentally stochastic events (*e.g.*, wildfires, flooding) could destabilize small mountain lion populations and make them vulnerable to extinction (Benson et al. 2016a; Benson et al. 2019). In addition, increased frequency of fire ignitions can cause shifts in natural fire regimes, which can lead to large-scale landscape changes, such as vegetation-type conversion or habitat fragmentation, which can impact wide-ranging species like the mountain lion (Jennings 2018).

Increasing landscape connectivity (*e.g.*, by designing corridors, removing barriers, and preserving habitats that are close to each other) is important for resilience to environmentally stochastic events and climate change adaptation (Heller and Zavaleta 2009). Enhanced connectivity that incorporates corridor redundancy (*i.e.* the availability of alternative pathways for movement) would allow for improved functional connectivity and resilience. Compared to a single pathway, multiple connections between habitat patches increase the probability of movement across landscapes by a wider variety of species, and they provide more habitat for low-mobility species while still allowing for their dispersal (Mcrae et al., 2012; Olson & Burnett, 2008; Pinto & Keitt, 2008). In addition, corridor redundancy provides resilience to uncertainty, impacts of climate change, and extreme events, including wildfires, by providing alternate escape routes or refugia for animals seeking safety (Cushman et al., 2013; Mcrae et al., 2008; Mcrae et al., 2012; Olson & Burnett, 2008; Pinto & Keitt, 2008).

## 6.8 Climate Change

A strong, international scientific consensus has established that human-caused climate change is causing widespread harms to human society and natural systems, and climate change threats are becoming increasingly dangerous. In a 2018 *Special Report on Global Warming of 1.5°C* from the Intergovernmental Panel on Climate Change (IPCC), the leading international scientific body for the assessment of climate change describes the devastating harms that would occur at 2°C warming, highlighting the necessity of limiting warming to 1.5°C to avoid catastrophic impacts to people and life on Earth (IPCC 2018). In addition to warming, many other aspects of global climate are changing. Thousands of studies conducted by researchers around the world have documented changes in surface, atmospheric, and oceanic temperatures; melting glaciers; diminishing snow cover; shrinking sea ice; rising sea levels; ocean acidification; and increasing atmospheric water vapor (USGCRP, 2017).

Climate change is increasing stress on species and ecosystems, causing changes in distribution, phenology, physiology, vital rates, genetics, ecosystem structure and processes, and increasing species extinction risk (Warren et al., 2011). A 2016 analysis found that climate-related local extinctions are already widespread and have occurred in hundreds of species, including almost half of the 976 species surveyed (Wiens 2016). A separate study estimated that nearly half of terrestrial non-flying threatened mammals and nearly one-quarter of threatened

---

<sup>19</sup> Id.

birds may have already been negatively impacted by climate change in at least part of their distribution (Pacifi et al. 2017). A 2016 meta-analysis reported that climate change is already impacting 82% of key ecological processes that form the foundation of healthy ecosystems and on which humans depend for basic needs (Scheffers et al. 2016). Genes are changing, species' physiology and physical features such as body size are changing, species are moving to try to keep pace with suitable climate space, species are shifting their timing of breeding and migration, and entire ecosystems are under stress (Cahill et al., 2012; Chen et al., 2011; Maclean & Wilson, 2011; Parmesan, 2006; Parmesan & Yohe, 2003; Root et al., 2003; Warren et al., 2011).

Improving landscape connectivity is a key factor for climate change resilience and adaptation (Heller and Zavaleta 2009). Without functional connectivity that provides multiple pathways for mountain lion movement, isolated Central Coast and Southern California mountain lion populations and the prey they depend on may not be able to shift their ranges as available resources shift. Enhanced connectivity that provides redundant corridors for safe passage between suitable habitats would improve chances of survival and reproduction in the face of climate change by increasing the probability of movement across landscapes by a wider variety of species and providing alternate escape routes or refugia for animals seeking safety (Mcrae et al. 2008; Pinto and Keitt 2008; Mcrae et al. 2012; Cushman et al. 2013; Olson and Burnett 2013).

## **7 Degree and Immediacy of Threat**

As demonstrated in the previous sections, Central Coast and Southern California mountain lions are at risk of extirpation under current conditions. Roads and development have fractured connectivity, which has led to the separation of at least six isolated, genetically distinct populations in the CC-N, CC-C, CC-S, SAM, SGSB, and EPR (Ernest et al. 2014; Riley et al. 2014; Vickers et al. 2015; Benson et al. 2016a; Benson et al. 2019). Due to extreme isolation and high levels of human-caused mortalities, the SAM and CC-S mountain lions have low genetic diversity, low effective population sizes, and high levels of inbreeding (Ernest et al. 2014; Riley et al. 2014; Vickers et al. 2015; Benson et al. 2016a; Benson et al. 2019). Benson et al. (2019) predicted high losses of heterozygosity in the SAM and Santa Monica Mountains populations, which suggests that inbreeding depression is imminent. If inbreeding depression occurs, the SAM and Santa Monica Mountains/CC-S populations will likely go extinct within 50 years, with median times to extinction of 11.7 years and 15.1 years, respectively (Benson et al. 2019). With similarly low genetic diversity and effective population size, the SGSB and CC-N populations likely have a similar fate. And although the CC-C and EPR populations appear to be slightly healthier with more genetic diversity and a higher effective population size, these populations have effective population sizes that are still well below the most recent recommended threshold to prevent inbreeding depression in the short-term (Frankham et al. 2014; Gustafson et al. 2018); continued development in these areas could propel these populations towards extinction more quickly. Clearly, Central Coast and Southern California mountain lion populations are succumbing to anthropogenic pressures, and without immediate action to restore and enhance connectivity between the populations and suitable habitat, they will be lost, potentially within our lifetimes.

Immediate action is critical for the long-term persistence of Central Coast and Southern California mountain lions and the health of Central Coast and Southern California ecosystems. Connectivity between the populations and suitable habitat must be restored and enhanced to facilitate movement and gene flow while reducing human-caused mortalities. Anthropogenic pressures, especially vehicle strikes and depredation kills, should be minimized to help the recovery of these populations. Although translocation of outbred animals has been shown to be effective to increase genetic diversity (Johnson et al. 2010), this would only be a short-term, unsustainable solution given the current level of isolation of these populations (Ernest et al. 2014; Riley et al. 2014; Vickers et al. 2015; Benson et al. 2016a; Benson et al. 2019). Strategically-placed road/barrier crossing infrastructure that allows for dispersal and gene flow and reduces mortalities would be a more comprehensive, long-term solution to save these populations in perpetuity. And the preservation of intact linkages, especially the Tehachapi and Sierra Pelona Mountains, is essential to maintain statewide genetic connectivity. Immediate regulatory action under the CESA is needed to enhance connectivity among Central Coast and Southern California mountain lion populations and suitable habitat to ensure the conservation of these iconic big cats.

## **8 Inadequacy of Existing Regulatory Mechanisms**

### *8.1 State Regulatory Mechanisms*

#### Proposition 117

The California Wildlife Protection Act of 1990 (Proposition 117) declared that the mountain lion is a “specially protected mammal under the laws of this state.” (Cal. Fish & Game Code § 4800(a).) Proposition 117 acknowledged that mountain lion habitat in the Santa Monica Mountains, Santa Ana Mountains, Santa Susana Mountains, and Simi Hills is disappearing rapidly and that “[s]mall and often isolated wildlife populations are forced to depend upon these shrinking habitat areas within the heavily urbanizing areas of this state.” (Cal. Fish & Game Code § 2780(d).) Proposition 117 further found that “[c]orridors of natural habitat must be preserved to maintain the genetic integrity of California’s wildlife.” (*Id.*)

In order to preserve mountain lion populations in California, Proposition 117 mandated that mountain lions are not to be considered a “game mammal,” such that hunting is generally prohibited. (Cal. Fish & Game Code § 3950.1(a).) Subject to certain exceptions, Proposition 117 makes it unlawful to take, injure, possess, transport, import, or sell a mountain lion. (Cal. Fish & Game Code § 4800(b).) Nonetheless, a mountain lion may still be removed or killed if it is “perceived to be an imminent threat to public health or safety” or is perceived by CDFW to be “an imminent threat to the survival of any threatened, endangered, candidate, or fully protected sheep species.” (Cal. Fish & Game Code § 4801.) Mountain lions that have not been designated an “imminent threat to public health or safety” may still be removed via nonlethal means. (Cal. Fish & Game Code § 4801.5(a).)

A person whose livestock or other property has been damaged or destroyed by a mountain lion may request a permit to “take” the mountain lion. (Cal. Fish & Game Code § 4802.) CDFW is required to immediately take action to confirm that there has been a

depredation. (Cal. Fish & Game Code § 4803.) If CDFW is satisfied that there has been a depredation, CDFW “shall promptly issue a permit to take the depredating mountain lion.” (*Id.*) There is no limit to the number of depredation permits a property owner can request from CDFW. In addition, mountain lions that are encountered while pursuing or inflicting injury on livestock or domestic animals may be taken immediately without the need for a permit. (Cal. Fish & Game Code § 4807.)

While Proposition 117 prohibits all hunting of mountain lions as well as the purposeful killing of mountain lions in most circumstances, it does not contain provisions to ensure that connectivity between core habitats for the Southern California or Central Coast mountain lions will be protected. As discussed above in *Section 6.0 Factors Affecting the Ability to Survive and Reproduce*, the primary threat to Southern California and Central Coast mountain lions is not hunting—it is habitat fragmentation and the lack of crossing infrastructure, which has led to major declines in genetic diversity, high levels of inbreeding, and high levels of human-caused mortalities via vehicle strikes, depredation kills, and intraspecific strife due to limited space and the inability for young mountain lions to disperse.

### 8.1.1 CDFW Departmental Bulletins

CDFW has issued “Departmental Bulletins” relating to mountain lions. The most recent bulletin was issued in December 2017 and applied specifically to the Santa Monica Mountains and SAM mountain lion populations (the “2017 Bulletin”) (CDFW 2017).<sup>20</sup> The 2017 Bulletin acknowledged (1) the lack of genetic diversity in the Santa Monica Mountains and SAM mountain lion populations and (2) that human population growth and anthropogenic barriers are restricting connectivity with other mountain lion populations. In order to reduce unnecessary killings of mountain lions in the Santa Monica Mountains and SAM populations, the 2017 Bulletin provides that any person reporting a depredation (a “reporting party”) may be issued a first permit to employ non-lethal measures to deter mountain lions from further depredation, and a second permit to “haze” a depredating mountain lion. In the first instance, the reporting party would institute economically feasible measures designed to reduce the potential for attracting mountain lions such as removing the carcasses of depredated animals, installing or repairing and consistently using enclosures to exclude mountain lions, or employing guardian animals in the immediate vicinity of livestock or other domestic animals. The 2017 Bulletin provides that CDFW would not be required to issue a lethal depredation permit until (1) a third depredation event has occurred, and (2) CDFW has confirmed that the reporting party has already implemented all reasonable preventative measures.

In January of 2018, CDFW adopted the 2017 Bulletin’s new depredation permit policy. Although this provides some additional protections and will likely reduce lethal take of mountain lions in the Santa Monica Mountains and the SAM, researchers have documented instances wherein domestic animal owners killed mountain lions in these areas without complying with CDFW instructions under the new policy (W. Vickers, *pers comm*). The 2017 Bulletin does not apply to other vulnerable populations, like the SGSB, EPR, CC-N, and CC-C mountain lions. In

---

<sup>20</sup> California Department of Fish and Wildlife, *Human/Wildlife Interactions in California: Mountain Lion Depredation, Public Safety, and Animal Welfare – Amendment to Department Bulletin 2013-02* (Dec. 15, 2017), available at <https://nrm.dfg.ca.gov/FileHandler.ashx?DocumentID=153021>.

addition, the new policy is not designed to ensure protection of habitat or connectivity necessary for the continued survival of the Santa Monica Mountains and SAM mountain lion populations and is insufficient to ameliorate the anthropogenic mortalities related to potential extirpation.

### 8.1.2 California Environmental Quality Act

The California Environmental Quality Act (“CEQA”) is California’s landmark environmental law and establishes a state policy to prevent the “elimination of fish or wildlife species due to man’s activities, ensure that fish and wildlife populations do not drop below self-perpetuating levels, and preserve for future generations representations of all plant and animal communities....” (Cal. Pub. Res. Code § 21001(c)). Towards this end, state and local agencies are required to analyze and disclose the impacts of any discretionary decision or activity. CEQA contains a substantive mandate that agencies should not approve projects as proposed if there are feasible alternatives or mitigation measures which would substantially lessen the significant environmental effects of such projects. (Cal. Pub. Res. Code § 21002.)

CEQA requires a “mandatory finding of significance” if a project may “substantially reduce the number or restrict the range of an endangered, rare or threatened species.” (Cal. Code Regs., tit. 14, § 15065(a)(1).) CDFW has interpreted this provision to apply to species of special concern, which are species that are “experiencing, or formerly experienced, serious (noncyclical) population declines or range retractions (not reversed) that, if continued or resumed, could qualify it for State threatened or endangered status.”<sup>21</sup> CDFW further provides that species of special concern “should be considered during the environmental review process.” (*Id.*; Cal. Code Regs., tit. 14, § 15380.) Thus, a potentially substantial impact on a species of special concern, threatened species, or endangered species could be construed as “per se” significant under CEQA. (*Vineyard Area Citizens for Responsible Growth, Inc. v. City of Rancho Cordova* (2007) 40 Cal.4th 412, 449.) And under CEQA, when an effect is “significant,” the lead agency approving the project must make a finding that changes or alterations have been incorporated into the project to avoid or mitigate its significant impacts, or that such changes are within the responsibility of another agency, or that mitigation is infeasible. (Cal. Pub. Res. Code § 21081(a).) These provisions therefore provide some protections to species that are listed as species of special concern, threatened, or endangered.

However, Southern California and Central Coast mountain lions are not listed as a species of special concern or as threatened or endangered, such that a project that has the potential to significantly impact one of these populations would not necessarily qualify as a “significant effect” under a lead agency’s interpretation of CEQA. In such case, CEQA’s substantive mandate to adopt all feasible alternatives or mitigation measures might not be triggered.

CEQA also requires a “mandatory finding of significance” if a project may “substantially reduce the habitat of a fish or wildlife species; cause a fish or wildlife population to drop below self-sustaining levels; threaten to eliminate a plant or animal community.” (Cal. Code Regs., tit. 14, § 15065.) Moreover, CEQA’s “Environmental Checklist” in Appendix G of the CEQA

---

<sup>21</sup> California Department of Fish and Wildlife, *Species of Special Concern*, available at <https://www.wildlife.ca.gov/Conservation/SSC>.

Guidelines characterizes a project's effects as "significant" if the project would "interfere substantially with the movement of any native [] wildlife species or with established native resident or migratory wildlife corridors...."

While these provisions might theoretically offer some protection for Southern California or Central Coast mountain lions, in practice they have not provided sufficient protection. Under CEQA, lead agencies have discretion to develop their own thresholds of significance. (*East Sacramento Partnerships for a Livable City v. City of Sacramento* (2016) 5 Cal.App.5th 281, 300; Cal. Code Regs., tit. 14, § 15064(d)). This allows local agencies—who are often under pressure from developers to approve projects—to make significance determinations that are inconsistent with independent scientific analysis, including CDFW's analysis. For instance, in December 2017, the City of Temecula approved a 200-acre mixed use project called the Altair Specific Plan that would allow development in the last remaining viable linkage for the SAM mountain lion population between the Santa Ana Mountains and Peninsular Ranges. The City determined that impacts to mountain lions were not significant despite strong disagreement by CDFW, USFWS, and independent mountain lion experts.<sup>22</sup> CDFW warned the City of Temecula that the SAM population has "extremely low genetic diversity which is attributed to low gene flow between the small Santa Ana Mountains population and the larger population in the Peninsular Ranges" and that development is contributing to this genetic decay. (*Id.*) CDFW concluded that "increased human activity associated with the proposed Civic Site at this sensitive location would [] be detrimental to facilitating the movement of mountain lions across Interstate Highway 15 (I-15) to the Peninsular Range." (*Id.*)

Even when a lead agency acknowledges that an effect is "significant," CEQA allows a lead agency to adopt a "statement of overriding considerations" and approve a project if the agency finds that other factors outweigh the environmental costs of the project or that further mitigation is infeasible. (Cal. Code Regs., tit. 14, § 15093(b); Cal. Pub. Res. Code § 21081.) This means that even if a project may have a significant effect on a "wildlife population" like the CC-S, SAM, SGSB, or EPR mountain lions, an agency could interpret CEQA as still allowing approval of the project. CEQA in practice is therefore inadequate to protect the Southern California and Central Coast mountain lions.

Finally, as noted above, the lack of adequate wildlife connectivity and wildlife crossings is the primary factor driving Southern California and Central Coast mountain lions closer to extinction. Yet, agencies have not interpreted CEQA (or the National Environmental Policy Act, discussed further below) as including a clear legal mechanism for mitigation for impacts on wildlife connectivity. For example, in the Final Environmental Impact Report/Final Environmental Impact Statement for the Northwest 138 Corridor Improvement Project (the "Northwest 138 EIR"), Caltrans and the Los Angeles County Metropolitan Transportation Authority wrote: "The proposed project has the potential to directly or indirectly impact wildlife movement throughout the project limits. However, with the inclusion of the proposed avoidance and minimization measures, impact levels are expected to be relatively low. Exact acres of impacts to wildlife corridors are unable to be quantified, and currently there is no real

---

<sup>22</sup> City of Temecula, *Altair Specific Plan Final Environmental Impact Report* (Oct. 2017), available at <https://temeculaca.gov/DocumentCenter/View/4513/Altair-Specific-Plan-Final-Environmental-Impact-Report-FEIR>.

mechanism for compensatory mitigation for these types of impacts.”<sup>23</sup> The Northwest 138 EIR also contained no analysis of the highway’s impacts on mountain lions, given that they are not presently listed as threatened or endangered.

Indeed, CDFW has urged lead agencies to consider wildlife connectivity in CEQA planning documents, without success. For instance, the Los Angeles County General Plan Draft EIR concluded that the buildout of the General Plan “will impact regional wildlife linkages” and have a “significant adverse effect on wildlife movement.”<sup>24</sup> The Draft EIR concluded that policies proposed in the General Plan “do not provide for mitigation for loss of wildlife movement opportunities. If development impacts regional wildlife linkages and impedes wildlife movement, connectivity will be lost on a regional scale in these vital landscape corridors and linkages. Thus impacts to wildlife movement remain significant at the General Plan level.” (*Id.*) In commenting on the Draft EIR, CDFW specifically objected to this conclusion:

The Department does not concur with the conclusion in the DPEIR that unavoidable loss of wildlife movement opportunities or nursery sites within or outside of an SEA does not warrant mitigation. Without mitigation, the Project and subsequent projects would result in direct and cumulative loss of biological diversity. Mitigation opportunities for wildlife corridors and nursery sites are best established during large scale planning efforts such as this General Plan. Wildlife corridor areas can be delineated and set aside in the General Plan for current and future conservation efforts. An assessment could be placed on development within the Project area to secure the acquisition of these critical linkages and sites, therefore reducing impacts to wildlife corridors and nursery sites and ensuring biological diversity.<sup>25</sup>

In responding to this comment, Los Angeles County refused to implement CDFW’s recommendations, claiming “it cannot be assumed that wildlife corridor areas for future conservation that can be set aside because those properties may not become publicly owned.” (*Id.*) Los Angeles County’s responses to CDFW’s recommendations underscore that lead agencies have not interpreted CEQA to include a clear legal mechanism for mitigation for impacts on wildlife connectivity, even though such connectivity is critical to the survival of Southern California and Central Coast mountain lions.

### 8.1.3 Significant Natural Areas Program

The Significant Natural Areas Program (“SNAP”) requires CDFW to develop and maintain a spatial data system that identifies those areas in the state that are most essential for maintaining habitat connectivity, including wildlife corridors and habitat linkages. (Cal. Fish & Game Code § 1932(b).) SNAP also requires CDFW to consult with other government agencies and stakeholders to identify natural areas deemed to be most significant. (Cal. Fish & Game

<sup>23</sup> State of California Department of Transportation, *Northwest State Route 138 Corridor Improvement Project Final Environmental Impact Report / Environmental Impact State and Section 4(f) Evaluation* (June 2017), available at <https://www.metro.net/projects/nw138/nw138-FEIR-FEIS/>.

<sup>24</sup> County of Los Angeles, *Los Angeles County General Plan Update Draft Environmental Impact Report* (June 2014), available at [http://planning.lacounty.gov/assets/upl/project/gp\\_2035\\_deir.pdf](http://planning.lacounty.gov/assets/upl/project/gp_2035_deir.pdf).

<sup>25</sup> County of Los Angeles, *Los Angeles County General Plan Update Final Environmental Impact Report* (March 2015), available at [http://planning.lacounty.gov/assets/upl/project/gp\\_2035\\_lac-gpu-final-eir-final.pdf](http://planning.lacounty.gov/assets/upl/project/gp_2035_lac-gpu-final-eir-final.pdf).

Code § 1932(f.) SNAP further requires CDFW to seek maintenance and perpetuation of the state’s most significant natural areas for present and future generations in the most feasible manner. (Cal. Fish & Game Code § 1932(g).)

However, SNAP does not require or authorize any particular land use action or decision. (Cal. Fish & Game Code § 1932.5.) Likewise, SNAP does not change or prevent the change of use of any area identified pursuant to the program. (Cal. Fish & Game Code § 1933.) It therefore does not *require* any particular natural areas to be conserved. Because of this, it is insufficient to protection wildlife connectivity essential to the survival of Southern California and Central Coast mountain lions.

#### 8.1.4 Natural Community Conservation Planning Act

The Natural Community Conservation Planning Act is a voluntary conservation planning mechanism for proposed development projects within a planning area to avoid or minimize impacts to wildlife. (Cal. Fish & Game Code § 2801(f).) The NCCP Act is designed to promote coordination among agencies and landowners to conserve unfragmented habitat areas and multihabitat management. (Cal. Fish & Game Code § 2801(d).)<sup>26</sup>

There are no Natural Community Conservation Plans (“NCCPs”) that cover the Santa Monica Mountains or San Gabriel Mountains. There are a few NCCPs that cover portions of the Santa Ana Mountains and Eastern Peninsular Ranges, some of which also act as “habitat conservation plans” or “HCPs” pursuant to the Federal Endangered Species Act (16 U.S.C. § 1539). These include the County of Orange (Central Coastal) NCCP/HCP, the Orange County Transportation Authority NCCP/HCP, Western Riverside County Multiple Species HCP, San Diego Multiple Habitat Conservation Program, San Diego Multiple Species Conservation Program, and the San Diego North County Multiple Species Conservation Plan. There also is an NCCP that covers the Coachella Valley and portions of the San Bernardino Mountains called the Coachella Valley NCCP/HCP.

Of these NCCPs, only four “cover” portions of the Southern California mountain lion populations: (1) Western Riverside County Multiple Species HCP; (2) San Diego Multiple Habitat Conservation Program; (3) San Diego County Multiple Species Conservation Program; and (4) San Diego North County Multiple Species Conservation Plan.<sup>27</sup> Below is a discussion of each as they relate to mountain lions:

- (1) The Western Riverside County Multiple Species HCP acknowledges that the SAM mountain lion population is at high risk of extirpation due to demographical instability unless there is a “movement connection between the Santa Ana Mountains

---

<sup>26</sup> The NCCP Act also is described on CDFW’s website at <https://www.wildlife.ca.gov/conservation/planning/NCCP>.

<sup>27</sup> California Department of Fish and Wildlife, *Conservation Plans By Species*, available at <https://nrm.dfg.ca.gov/FileHandler.ashx?DocumentID=108719&inline>. Both San Diego Gas & Electric and San Diego County Water Authority are permittees of HCPs/NCCPs covering mountain lions, but these only apply to activities undertaken by these entities.

and the Palomar Mountains.”<sup>28</sup> However, mountain lions are considered to be “adequately conserved.”<sup>29</sup> As such, the Western Riverside County Multiple Species HCP offers little protection for the SAM mountain lion population. While this HCP does identify linkages designed to ensure connectivity for mountain lions, the Western Riverside County Regional Conservation Authority has failed to enforce the HCP to protect such linkages when permittees such as the City of Temecula approve development that would severely constrict or impair such linkages.

- (2) The San Diego Multiple Habitat Conservation Program is an NCCP and HCP that purportedly covers mountain lions, but the program readily concedes that mountain lions (as well as deer) “were not a major consideration in linkage design.”<sup>30</sup> In addition, the EIR/EIS states that “[d]ue to the limited availability of habitat in the study area, implementation of the MHCP is not expected to substantially increase or decrease the population viability of the mountain lion.”<sup>31</sup> The EIR/EIS likewise concludes there are no major populations or critical locations for the mountain lion within the plan area, and concludes it is “adequately conserved” under the plan. (*Id.*)
- (3) The San Diego Multiple Species Conservation Program is an NCCP and HCP that covers 900 square miles in the southwestern portion of the San Diego. The Program lists mountain lions as “conserved” and states that mountain lions “will be covered by the MSCP because 81% of the core areas (105,000± acres) that support its habitat will be conserved.”<sup>32</sup> While the Program generally notes that linkage areas were designed to accommodate “large animal movement,” the Program does not identify any linkages designed for mountain lions or any specific measures designed to protect them. Likewise, while the Program states that “[s]pecific design criteria for linkages and road crossings/undercrossings are included in subarea plans,” not all subarea plans are complete.

<sup>32</sup> County of San Diego, *Final Multiple Species Conservation Program* (Aug. 1998), available at <https://www.sandiegocounty.gov/content/dam/sdc/pds/mscp/docs/SCMSCP/FinalMSCPPProgramPlan.pdf>.

- (4) The San Diego North County Multiple Species Conservation Plan is one of the “subarea” plans anticipated by San Diego Multiple Species Conservation Program. However, it has not been completed and is still “in development.”<sup>33</sup>
- (5) The Orange County Transportation Authority NCCP/HCP (“OCTA Plan”) lists the mountain lion as a covered species for purposes of the federal HCP, but not for purposes of the NCCP permit. The OCTA Plan acknowledges that despite protection from hunting, annual survival for radio-collared lions is “surprisingly low” at 55.8 percent and that vehicle collisions and depredation permits are primary sources of mortality. The OCTA Plan states that targeted investment in habitat protection is “especially urgent to maintain viability of the Santa Ana Mountains populations.”<sup>34</sup> The OCTA Plan does contain four “Species Goals” for mountain lions, including (1) acquiring 1,013 acres of suitable habitat; (2) fencing realignment near the Highway 241 toll road; (3) funding of the North Coal Canyon Restoration Project; and (4) a “wildlife crossing policy” requiring pre-construction surveys to ensure existing crossings “maintain or improve functionality” if modified by new freeway projects. However, despite allowing the expansion of two highways in lion habitat (Projects G and J), the OCTA Plan does not require the construction of any specific wildlife crossings. The OCTA Plan nonetheless claims that impacts on the mountain lion will be offset through these “Species Goals.”

There are no NCCPs that cover the Central Coast. In addition, there are no NCCPs that cover portions of the Santa Cruz Mountains except the Santa Clara Valley Habitat Plan. However, this Plan does not cover mountain lions.

## 8.2 Federal Regulatory Mechanisms

### 8.2.1 National Environmental Policy Act

The National Environmental Policy Act (“NEPA”) is the nation’s charter for protection of the environment. (40 C.F.R. § 1500.1(a).) NEPA is designed to ensure that environmental information is available to the public *before* decisions are made or actions taken and to help public officials make decisions based on an understanding of the environmental consequences. (40 C.F.R. § 1500.1(b)-(c).) Federal agencies must prepare an environmental impact statement (“EIS”) if it is known that an action will significantly affect the environment, or an environmental assessment (“EA”) if the extent of effects are unknown. (42 U.S.C§ 4332; 40 C.F.R. §§ 1502.3 & 1508.9.) NEPA further requires federal agencies to analyze reasonable alternatives to the proposed project. (40 C.F.R. § 1502.14(a)-(c).) NEPA requires the federal agency to consider the degree of adverse effect on a species or its critical habitat designated pursuant to the Federal Endangered Species Act. (*Conservation Cong. v. United States Forest Serv.* (E.D.Cal. 2017) 235 F.Supp.3d 1189, 1207.)

---

<sup>33</sup> County of San Diego, *Multiple Species Conservation Program*, available at <https://www.sandiegocounty.gov/pds/mscp/>.

<sup>34</sup> Orange County Transportation Authority, *Natural Community Conservation Plan/Habitat Conservation Plan* (Nov. 2016), available at <https://www.octa.net/pdf/NCCP%20HCP%20FINAL.pdf>.

However, agencies have not interpreted NEPA as requiring analysis of impacts to populations that are not currently listed as threatened or endangered, such as the Southern California or Central Coast mountain lions. For instance, Caltrans prepared an Initial Study with Proposed Mitigated Negative Declaration/Environmental Assessment for the State Route 118 Widening Project (the “State Route 118 EA”) in October 2017 pursuant to NEPA and CEQA. The State Route 118 EA contains no analysis of whether adding more traffic lanes to State Route 118 will impact mountain lions or degrade wildlife connectivity even though multiple mountain lions have died recently attempting to cross State Route 118.<sup>35</sup>

NEPA also is insufficient to protect Southern California and Central Coast mountain lions because courts have interpreted NEPA as primarily a “procedural” statute. While NEPA does require federal agencies to consider detailed information regarding a project’s environmental effects, “NEPA itself does not mandate particular results.” (*Winter v. NRDC, Inc.* (2008) 555 U.S. 7, 23.)

### 8.3 Regional and Local Plans and Policies

#### 8.3.1 Santa Monica Mountains National Recreation Area General Management Plan

The Santa Monica Mountains National Recreation Area General Management Plan (“GMP”) was prepared pursuant to NEPA and provides a framework for the management of the Santa Monica Mountains National Recreation Area (“SMMNRA”), which is administered by the National Park Service, California State Parks, and the Santa Monica Mountains Conservancy. The GMP recognizes that the Santa Monica Mountains mountain lion population’s ability to survive in the face of large-scale habitat fragmentation and destruction is uncertain.<sup>36</sup> (GMP at 154.) The GMP states that “it is likely that their persistence [] would depend upon their capability of dispersing to and from other habitat areas beyond the Santa Monica Mountains.” (GMP at 154; see also GMP at 157.) The GMP identifies the “greatest threat” to natural resource preservation in the SMMNRA as “loss of habitat connectivity from increased development and urban encroachment.” (*Id.* at 157.) The GMP concedes that “the situation is especially serious for mountain lions” and lists mountain lions as a “park species of concern.” (*Id.* at 157 & 161.) The GMP agrees that improvements to facilitate wildlife movement across freeways or through developments may be necessary, but does not propose or require any specific actions to improve wildlife movement across freeways or through development.

The preferred alternative in the GMP provides for enhancing connectivity of undisturbed habitats in the SMMNRA by creating large expanses of open space. (*Id.* at 292.) In addition, the Las Virgenes Canyon and Liberty Canyon areas are included within the SMMNRA boundary to help provide wildlife connectivity for mountain lions and other large species. (*Id.* at 293.) Even though the GMP recognizes the threats facing the Santa Monica Mountains mountain lion

---

<sup>35</sup> National Parks Traveler, *Another Mountain Lion Killed Near Santa Monica Mountains National Recreation Area* (Jan. 27, 2017), available at <https://www.nationalparkstraveler.org/2017/01/another-mountain-lion-killed-near-santa-monica-mountains-national-recreation-area>.

<sup>36</sup> National Park Service, U.S. Department of Interior, *Santa Monica Mountains National Recreation Area General Management Plan Environmental Impact Statement* (July 2002), available at <https://www.nps.gov/samo/learn/management/loader.cfm?csModule=security/getfile&PageID=383979>.

population and takes steps to protect this population, the GMP does not apply to lands outside of the SMMNRA and thus is insufficient to address the regional connectivity issues facing the population. Nor does the GMP apply to roads and highways under Caltrans' jurisdiction.

### 8.3.2 Ventura County Wildlife Connectivity Ordinance

The Ventura County Board of Supervisors adopted an ordinance on March 12, 2019 (the "Connectivity Ordinance") to help facilitate wildlife connectivity and minimize habitat fragmentation for mountain lions, mule deer, California gnatcatchers, bobcats, least bell's vireos, California red-legged frogs, and other species. The Connectivity Ordinance establishes overlay zones called "habitat connectivity and wildlife corridors" ("HCWCs") and "critical wildlife passage areas" ("CWPAAs") in which development standards and permitting requirements apply. Development standards include 200-foot setbacks from surface water features such as streams and wetlands, limits on certain wildlife impermeable fencing, encouraging compact siting of development, and prohibiting non-commercial planting of invasive plants. Two of the linkages targeted in the Connectivity Ordinance are the Santa Monica Mountains – Sierra Madre Mountains connection and the Sierra Madre Mountains – Castaic Connection, which connect wildlife habitat in the Santa Monica Mountains, Santa Susana Mountains, Simi Hills, and Los Padres National Forest.

While the Connectivity Ordinance should help allow wildlife to move more easily through private lands between core habitat areas, it would do little to ensure connectivity across major roads and highways because Ventura County does not have jurisdiction over these areas. The ordinance would, however, establish 200-foot setbacks from the exit and entry points of 25 existing road crossings in order to facilitate wildlife movement through the crossings. Caltrans and its road maintenance and improvement activities are not regulated by the Connectivity Ordinance. The Connectivity Ordinance is therefore a step in the right direction but insufficient on its own to address the threats facing the CC-S mountain lion population.

### 8.3.3 Los Angeles County Significant Ecological Areas Program

Los Angeles County is currently in the process of updating the Significant Ecological Areas ("SEAs") Ordinance. The draft ordinance is intended to protect biodiversity in SEAs from incompatible development and ensure that projects reduce habitat fragmentation and edge effects by providing technical review of impacts and requiring mitigation.<sup>37</sup> Like the Ventura County ordinance, the SEAs designations can lead to compact development and allow wildlife to more easily move across private lands between core habitat areas. However, the SEA ordinance is not specifically designed to protect mountain lions and would not regulate Caltrans and its road maintenance and expansion activities.

---

<sup>37</sup> Los Angeles County Department of Regional Planning, *Significant Ecological Areas Ordinance Update, Public Hearing Draft* (Feb. 14, 2019), available at <http://planning.lacounty.gov/site/sea/wp-content/uploads/2019/02/EX-C-SEA-Ordinance-Public-hearing-Draft-2-14-2019.pdf>

#### 8.4 *Future Development Will Further Threaten the Survival of Southern California Mountain Lions*

Continued development in Southern California is expected to further impair connectivity between core habitat areas, leading to further decreases in genetic diversity for Southern California mountain lions. In the environmental review for Southern California national forest land management plans, the U.S. Forest Service found that impaired connectivity poses a serious threat to Southern California mountain lions: the “greatest concern for the long-term health of mountain lion populations on the national forests of southern California is loss of landscape connectivity between mountain ranges and large blocks of open space on private land.”<sup>38</sup> The review warned that private land development in Southern California is “steadily reducing the habitat linkages that wildlife species need to connect large blocks of national forest land with other public and private natural spaces and habitat reserves.” The review observed that the “widening of the existing highway system and new highways” are a threat to mountain lions because they create barriers to movement. The review concluded that “[w]ithout the national forests and linkages between the mountain ranges and other large habitat preserves, *there is not much long term potential for mountain lions in southern California.*” The review noted that maintenance and restoration of corridors between large wildlands is essential to conserving mountain lions in Southern California

As anticipated by the U.S. Forest Service’s environmental review, private land development is currently being approved on linkage areas without sufficient mitigation for Southern California mountain lions or wildlife connectivity. For instance, the 1,000-acre Northlake Specific Plan (“Northlake”) was approved by the Los Angeles County Board of Supervisors on April 2, 2019. The Santa Monica Mountains Conservancy (“SMMC”) formally objected to the Board’s approval of Northlake, noting that the development would degrade a known wildlife linkage between the Angeles National Forest and Los Padres National Forest.<sup>39</sup> CDFW raised similar concerns about the development because it would impair a linkage that is “highly suitable for regional wildlife movement and connectivity” for mountain lions and other species.<sup>40</sup> The Board of Supervisors approved Northlake notwithstanding the objections and concerns of SMMC and CDFW.

Likewise, the Los Angeles County Board of Supervisors approved the 12,000-acre Centennial Specific Plan (“Centennial”) on April 30, 2019, despite SMMC warning the Board that Centennial “would sever the most optimal five-mile-wide habitat linkage across Highway 138 between I-5 and State Route 14.”<sup>41</sup>

<sup>41</sup> Santa Monica Mountains Conservancy, *Centennial Project Draft Environmental Impact Report Comments County Project No. 02-232*, July 17, 2017.

In the SAM, key linkage and habitat areas remain unprotected and subject to potential or actual development. The Altair Specific Plan discussed in *Section 8 Inadequacy of Existing Regulatory Mechanisms* exemplifies this trend. Other lands in the Santa Ana-Palomar Mountain linkage have been subject to development proposals such as the Temecula Creek Inn (Vickers 2015). The Orange County Board of Supervisors also approved a 6,000-acre development in the Santa Ana Mountains in the “center of puma habitat” (Vickers 2015).<sup>42</sup>

Development in wildlands and linkages will intensify as Southern California’s population increases. The Southern California Association of Governments (“SCAG”) Program EIR estimates that between 2016 and 2040 the Southern California region will grow by 3.8 million residents and 1.5 million households.<sup>43</sup> The SCAG Program EIR concludes that transportation projects within the SCAG region such as “mixed flow lane projects” and “grade separation projects” may result in significant impacts on wildlife movement, including direct habitat removal and fragmentation that would disrupt corridor functionality. The SCAG Program EIR also acknowledges that “an increase in wildlife-roadway interactions as a result of the development of new transportation projects may increase wildlife injury and fatalities.”

The SCAG Program EIR recognizes that “[b]arriers to wildlife movement exist throughout the SCAG region, including large areas of urban development and multilane freeways that cut off regional movement corridors for large migratory species such as mountain lions (*Puma concolor*).” SCAG Program EIR further notes that “wildlife crossings serve to alleviate these barriers and facilitate wildlife movement through the region” and references the planned Liberty Canyon Crossing. However, the Program EIR does not identify any other planned crossings or identify funding for the Liberty Canyon Crossing.

The SCAG Program EIR also confirms that only portions of the lands in the Santa Monica Mountains, SAM, SGSB, and EPR are designated as “open space and recreation” or “undevelopable and protected.” Indeed, much of these lands are designated for single family residential or mixed residential. At this time, there are also “vast areas” in Southern California that are undeveloped but are not designated as open space or are otherwise protected, according to SCAG. In addition, agricultural lands are rapidly being converted to urban development throughout Southern California with an estimated 230,000 acres converted between 1996 and 2004 and up to 700,000 acres may be converted by 2030. In short, SCAG recognizes that wildlife connectivity will become even more impaired in the Southern California region due to anticipated growth, but SCAG does not offer any solutions to address the effects of this impaired connectivity on Southern California mountain lions.

Other studies confirm that much of the remaining mountain lion habitat in Southern California is on unprotected lands and at risk of development. According to Burdett et al. (2010), almost half of suitable mountain lion habitat in Southern California (since 1970) is on private lands, of which 35% will be developed by 2030, and other currently contiguous habitat will

---

<sup>42</sup> See also Chris Boucly, “New community coming to South County,” *The Orange County Register* (Mar. 24, 2012), available at <https://www.ocregister.com/2012/03/24/new-community-coming-to-south-county/>

<sup>43</sup> Southern California Association of Governments, *Draft Program Environmental Impact Report* (Dec. 2015), available at [http://scagrtpscs.net/Documents/2016/peir/draft/2016dPEIR\\_Complete.pdf](http://scagrtpscs.net/Documents/2016/peir/draft/2016dPEIR_Complete.pdf).

become fragmented. Hunter et al. (2003) similarly found that 30% of high suitability mountain lion habitat and 76% of medium suitability mountain lion habitat in Southern California is not protected from development. In addition, Zeller et al. (2017) found that only 35% of resource-use patches and 47% of corridors identified in their study area, which encompassed much of the SAM and EPR, were fully protected. Given the extreme isolation, low genetic diversity, and high adult mortality rates from vehicle strikes and depredation kills, increased efforts to protect the species and their habitat are warranted.

Within Riverside County, which covers a significant portion of the Santa Ana Mountains, population growth is expected to be especially high; the Riverside County General Plan predicts that the County's population and housing stock will increase to 3.6 million people and 1.3 million dwelling units by 2035, which constitutes a 65 percent increase.<sup>44</sup> Within San Bernardino County, which encompasses portions of the San Bernardino and San Gabriel Mountains, more than 630,000 people will be added to the County along with 230,000 homes.<sup>45</sup> As urban development overtakes mountain lion habitat and linkage areas throughout the region, conflict with mountain lions, and consequent killing of lions under depredation permits will likely increase. Similarly, use of anticoagulant rodenticides and other environmental toxicants in these areas will likely increase, leading to increased illness and fatalities to "non-target organisms" such as Southern California mountain lions.

Caltrans and local transportation agencies are expected to continue building and expanding roads and highways in Southern California to accommodate actual and anticipated vehicles and development. Caltrans' 2018 State Transportation Improvement Program ("STIP") lists many large-scale road and highway projects planned for Southern California.<sup>46</sup> These include converting SR-71 to a four- and six-lane freeway as well as adding more lanes to the I-15 Freeway adjacent to the SAM,<sup>47</sup> which already acts as a nearly impenetrable barrier to the SAM and EPR mountain lion populations. As noted in *Section 8 Inadequacy of Existing Regulatory Mechanisms*, Caltrans has certified an EIR/EIS to convert the existing two-lane SR-138 into a four or six-lane highway, which will create major barrier between the Tehachapi Mountains and Angeles National Forest. Caltrans also intends to widen SR-118, which will further impair connectivity between the Santa Monica Mountains and Santa Susana Mountains to the detriment of the Santa Monica Mountains mountain lions. There are numerous other road and highway projects planned for Southern California in the next few years.<sup>48</sup> These projects will be funded in part by SB 1, which will raise approximately \$52 billion over 10 years.

Along with this expansion in roads and highways will come an increase in automobile use: SCAG predicts that the number of vehicle miles travelled (“VMT”) in the region is expected to increase 13.3 percent by 2040 (from 448 million VMT per day to 504 million VMT per day). This significant increase in automobile use will further impair connectivity and lead to more collisions between automobiles and lions.

### 8.5 *Future Development Will Further Threaten the Survival of Central Coast Mountain Lions*

Future development and highway expansion in the San Francisco Bay Area and Central Coast is anticipated to further fragment habitat for Central Coast mountain lion populations and will increase threats to their survival.

The Association of Bay Area Governments’ Plan Bay Area projects that the population of the San Francisco Bay Area is expected to increase from 7.2 million to 9.3 million by 2040—a 30 percent increase.<sup>49</sup> This includes a 26 percent increase in San Mateo County and a 36 percent increase in Santa Clara County, both of which encompass significant portions of the Santa Cruz Mountains. The Plan Bay Area also envisions a 25 percent increase in housing units in San Mateo County, and a 31 percent increase in Santa Clara County.

The Greenbelt Alliance’s “At Risk” Report (“Greenbelt Report”) estimates that 22,700 acres in San Mateo County are at medium or high risk for development, significant portions of which are in the Santa Cruz Mountains.<sup>50</sup> The Greenbelt Report shows that only 113,000 acres of the Santa Cruz Mountains are permanently protected and warns that San Mateo County has planned to develop housing in remote areas on the eastern slope of the Santa Cruz Mountains. The Greenbelt Report estimates that Santa Clara County has 54,100 acres at high or medium risk of development, significant portions of which are in the Santa Cruz Mountains and eastern foothills. The Greenbelt Report further shows that while large swaths of the eastern Santa Cruz Mountains are currently at “low risk” for development, only fragmented portions enjoy permanent protection.

Similarly, the EIR for the Plan Bay Area 2040 notes that land use growth footprints overlap with approximately 1,040 acres of “Essential Connectivity Areas” or “ECAs.”<sup>51</sup> The EIR claims these growth footprints are in already urbanized corridors that are degraded so that their function as linkages is limited. The EIR acknowledges that development projects may directly encroach on wildlife corridors, but does not provide any plan to address the effects of

such encroachment. In addition, Caltrans has a number of highway improvement projects planned in Santa Clara and San Mateo counties.<sup>52</sup>

There also is development pressure on the Pajaro Hills linkage, which is important to the Central Coast North mountain lion population and connects the Santa Cruz Mountains and Gabilan Range.<sup>53</sup> The Land Trust of Santa Cruz County notes that while a few large ranches cover most of the Pajaro Hills, many of the properties are parcelized, creating the potential for development which would fragment the landscape. Only 8 percent of the Pajaro Hills is permanently protected.

Growth is expected to increase in the Monterey Bay Area, leading to further fragmentation of natural habitats by urban or exurban development. The Association of Monterey Bay Area Governments predicts that the population in the Monterey Bay Area will rise from 755,403 in 2015 to 883,300 in 2040.<sup>54</sup> The Land Trust of Santa Cruz County notes that while high rates of conversion of forests, rangeland and farmland has largely been prevented in Santa Cruz County, exurban development, roads and mining are fragmenting wildlife habitat. Vineyard conversion adjacent to Zayante, Beer Creek, and Summit roads is causing habitat fragmentation in one of the largest intact habitat patches connecting Santa Cruz and Santa Clara counties. The Land Trust of Santa Cruz County estimates that only 44 percent of the large patches of intact habitat are protected. The Conservation Lands Network likewise confirms that much of the Santa Cruz Mountains do not currently qualify as protected areas.<sup>55</sup>

In San Luis Obispo County, the population is expected to increase by 41,650 between 2015 and 2045.<sup>56</sup> The sparsely populated North Coast region of San Luis Obispo County is currently characterized by ranchlands, rural development, and open space. However, the San Luis Obispo Council of Governments (“SLOCOG”) predicts more population growth in this region as compared to other regions. SLOCOG also predicts significant increases in traffic volumes on Highway 101 throughout San Luis Obispo County. The US 101 Corridor Mobility Master Plan also contains various proposals to expand the Interstate 101 freeway in San Luis Obispo County, including adding more lanes to the freeway.<sup>57</sup> There are also proposals to widen portions of State Route 46, the western portions of which bisect mountain lion habitat. The Caltrans State Route 46 Corridor System Management Plan concedes that widening segments 2 and 3 of State Route 46 “could present additional barriers to animal movements by further

dividing large, contiguous wildlife habitat areas.”<sup>58</sup> There are numerous other road and highway expansion projects planned for Santa Cruz, Monterey, San Luis Obispo, and Santa Barbara counties.<sup>59</sup> The expansion of existing roads and highways along with increased numbers of automobiles will further impair connectivity in the Central Coast region.

## **9 CESA Listing for Southern California and Central Coast Mountain Lions Would Supplement Proposition 117’s Protections.**

### *9.1 CESA Listing is Consistent with Proposition 117.*

CESA protections for Southern California and Central Coast mountain lions are consistent with and supplemental to those established by Proposition 117. Both CESA and Proposition 117 include “take prohibitions”—CESA makes it unlawful for any person or agency to import, export, take, possess, or purchase a listed species. (Cal. Fish & Game Code § 2080.) By the same token, Proposition 117 makes it unlawful to take, injure, possess, transport, import, or sell a mountain lion. (Cal. Fish & Game Code § 4800(b).)

Both CESA and Proposition 117’s take prohibitions are subject to certain exceptions. Under CESA, CDFW may authorize that a person, agency, or institution take a listed species “for scientific, educational, or management purposes.” (Cal. Fish & Game Code § 2081(a).) CESA defines scientific resources management activities to include “research, census, law enforcement, habitat acquisition, restoration and maintenance, propagation, live trapping, and, transplantation, and, in the extraordinary case where population pressures within a given ecosystem cannot be otherwise relieved, [] regulated taking.” (*San Bernardino Valley Audubon Society v. City of Moreno Valley* (1996) 44 Cal.App.4th 593, 604, quoting Cal. Fish & Game Code § 2061.) The regulations implementing CESA also allow for the take of a listed species for management or law enforcement purposes: “Department wildlife management activities. The possession or take of endangered, threatened, or candidate species by employees and agents of the Department for scientific, educational and management purposes, and for law enforcement purposes, is not prohibited.” (Cal. Code Regs., tit. 14, § 783.1(c).) As discussed above in *Section 8 Inadequacy of Existing Regulatory Mechanisms*, Proposition 117 also contains exceptions which allow for the take of mountain lions in certain circumstances. These exceptions are sufficiently similar that in most cases take of mountain lions properly authorized by Proposition 117 could be consistent with CESA’s exceptions for wildlife management activities or law enforcement purposes. (Cal. Code Regs., tit. 14, § 783.1(c).)

### *9.2 CESA Listing Would Further the Goals of Proposition 117.*

CESA listing would further Proposition 117’s goals of protecting and restoring wildlife habitat as human populations increase. (Cal. Fish & Game Code § 2780(a).) CESA listing would also help preserve “corridors of natural habitat [] to maintain the genetic integrity” of mountain lions in the Santa Monica Mountains, Santa Ana Mountains, Santa Susana Mountains, Simi Hills, and Coast Range. (Cal. Fish & Game Code § 2780(a).)

---

<sup>58</sup> Caltrans, *State Route 46 Corridor System Management Plan* (June 2009), available at [http://www.dot.ca.gov/hq/tpp/corridor-mobility/CSMPs/d5\\_CSMPs/SR%2046/SR-46%20CSMPo100.pdf](http://www.dot.ca.gov/hq/tpp/corridor-mobility/CSMPs/d5_CSMPs/SR%2046/SR-46%20CSMPo100.pdf).

<sup>59</sup> Caltrans District 5, *Projects By County*, available at <http://www.dot.ca.gov/d5/>.

Likewise, CESA requires that “reasonable and prudent alternatives” that will not jeopardize the existence of a listed species be developed in coordination with the project proponent and state lead agency consistent with conserving the listed species and maintaining the project purpose to the greatest extent feasible. (Cal. Fish & Game Code § 2053(b).) In the event that such alternatives are infeasible, individual projects may still be approved if appropriate mitigation measures are implemented. (Cal. Fish & Game Code § 2054.) CESA envisions these mandates will be incorporated into the CEQA process. (Cal. Fish & Game Code §§ 2064-2065; Cal. Code Regs., tit. 14, §§ 783.3 & 783.5.)

Consistent with Proposition 117, CESA further provides that it is the policy of the state to conserve and protect listed species and their habitat, including through acquiring lands for habitat. (Cal. Fish & Game Code § 2052.) Towards this end, CESA directs state agencies to utilize their authority to conserve listed species. (Cal. Fish & Game Code § 2055.) If the Southern California and Central Coast mountain lions were listed under CESA, this mandate would apply to, for example, Caltrans, which currently lacks a clear mandate to conserve these lions or habitat connectivity necessary for their continued survival.

CESA authorizes CDFW to develop and implement “nonregulatory recovery plans” for listed species with priority given to species that are or may be “significantly affected by anticipated land use changes, climate change, or changes in aquatic conditions.” (Cal. Fish & Game Code §§ 2079.1(a) & (b).) Given the strong evidence that land use changes will significantly affect (and have already significantly affected) Southern California and Central Coast mountain lions, CDFW could develop and implement a recovery plan for these lions pursuant to this provision.

In sum, CESA listing would build upon the protections in Proposition 117 by establishing an affirmative duty to ensure the survival and recovery of the Southern California and Central Coast mountain lions by, *inter alia*, (1) prohibiting the approval of projects that could jeopardize their continued existence or result in destruction of essential habitat (Cal. Fish & Game Code § 2053(a)); (2) requiring state agencies such as Caltrans to utilize their authority to conserve listed species (Cal. Fish & Game Code § 2055); and (3) requiring appropriate mitigation measures be implemented for projects that could destroy mountain lion habitat or impair connectivity (Cal. Fish & Game Code § 2054).

To the extent there is any tension between the provisions in Proposition 117 and CESA, Proposition 117 is to be “liberally construed to further its purposes.” (Prop. 117 § 9.) Because Proposition 117 and CESA both have similar purposes, Proposition 117 should be construed to be consistent with CESA.

## **10 Recommended Management and Recovery Actions**

Recommendations for the management and recovery of Southern California and Central Coast mountain lion populations are as follows:

1. Design and build crossing infrastructure in strategic locations to improve wildlife connectivity and permeability at existing roads and highways. Crossing infrastructure should include but is not limited to overcrossings, underpasses, culverts, and exclusionary fencing that guides animals to safer crossing areas. The following crossing locations have been identified by mountain lion experts and should be prioritized for the implementation of crossing infrastructure: 1) I-15 Freeway at Temecula Creek Bridge to enhance the Palomar Linkage and connect the Santa Ana and Eastern Peninsular Mountain Ranges (Gustafson et al. 2017; Zeller et al. 2017; Ernest et al. 2014; Riley et al. 2018); 2) I-15 Freeway at “Site 5” as described in Riley et al. (2018); 3) Hwy-101 at West Liberty Canyon. (Riley et al. 2018.)
2. Improve or add large culverts to existing freeways in areas suitable for mountain lion crossing. (Vickers 2015).
3. Dedicate sufficient Wildlife Conservation Board, Habitat Conservation Fund and other state funding sources towards acquiring key mountain lion habitat and for establishment of highway crossing infrastructure.
4. Ensure that suitable habitat exists (through preservation or restoration/enhancement) on both sides of crossing structures and culverts (South Coast Wildlands 2008). Restrict human activity near crossing structures and relocate foot trails away from these structures (South Coast Wildlands 2008).
5. Fully protect mountain lion habitat, including resource-use patches and corridors (Zeller et al. 2017; Vickers et al. 2015). Prohibit large-scale development in primary travel corridors and habitat linkages, such as in and around the last remaining linkage for statewide genetic connectivity in the Tehachapi and Sierra Pelona Mountains (Gustafson et al. 2018) and in corridor areas between the SAM and EPR (Gustafson et al. 2017).
6. Require analysis of region-wide wildlife connectivity in all new development proposals (Gustafson et al. 2018).
7. Reduce depredation conflicts that precipitate mountain lion deaths (Vickers et al. 2015). Develop and implement outreach and education activities to promote use of predator-proof enclosures for domestic animals. (Vickers et al. 2015.) Expand CDFW’s new three-step depredation permit policy in the CC-S and SAM areas to include all mountain lions across the state, or at a minimum, within the SGSB, EPR, CC-N, and CC-C population areas. Enhance the policy with enforceable implementation of non-lethal protective measures and reporting requirements.
8. Prohibit the use of second-generation anticoagulant rodenticides (“SGARs”), such as brodifacoum, bromadiolone, difenacoum, and difethialone in Southern California and Central Coast mountain lions’ core habitat areas and linkages. Limit the use of other pesticides and herbicides that may have negative effects on mountain lion populations in Southern California and the Central Coast.

9. Identify “priority areas” for establishing wildlife passage features for the Southern California and Central Coast mountain lions using the best available science, including data collected by various agencies, academic institutions, and organizations, including but not limited to the National Park Service, the Karen C. Drayer Wildlife Health Center at UC Davis, the Road Ecology Center at UC Davis, and the Santa Cruz Puma Project at UC Santa Cruz.
  
10. Require Caltrans to analyze how projects in the State Highway Operation Protection Program and State Transportation Improvement Program can be designed to facilitate wildlife connectivity through wildlife passage features such as culverts, undercrossings, overcrossings, bridges, directional fencing, scuppers, barrier breaks, roadside animal detection systems, etc. Require Caltrans to collect and analyze roadkill data to identify hotspots where mountain lions are killed. Require Caltrans to implement wildlife passage features to the greatest extent feasible and as expeditiously as possible.
